Since the late 1990s, NASA's Earth Observing System constellation of satellites has provided continuous, long-term observations of atmospheric and surface processes on Earth including surface albedo and Bidirectional Reflectance Distribution Function (BRDF) that are generated as an operational product using cloud-cleared, multi-angle surface reflectances over the course of several days. The BRDF is central to imagery-based cloud and aerosol retrievals, while the surface albedo is a fundamental Earth energy budget parameter. Yet, this product is currently unavailable at higher latitudes where (1) the low contrast between clouds and sea ice/snow poses a challenge for cloud clearing, and (2) drifting ice floes are not accounted for, resulting in a significant gap in our understanding of the Arctic radiation budget.

To address this gap, we propose the development of a BRDF/albedo product for moving sea ice floes and snow called the Sea Ice Floe and Snow Albedo Tracker (SIF-SAT). By leveraging multi-overpass, multi-angular satellite data, SIF-SAT will retrieve BRDF and albedo under low contrast and moving surface conditions. We combine existing cloud masks with machine learning (ML) models to produce cloud-cleared scenes in the Arctic. These scenes are then fed to a segmentation algorithm to identify individual sea ice floes and their reflectances are tracked

over time to obtain BRDF and albedo. This presentation will primarily focus on the cloud-clearing model which has implications for radiation science in polar regions. SIF-SAT will enhance our capabilities in the Arctic and enable more accurate estimates of the cloud-radiative effect and ice-albedo feedback.

Starting from April 2002, Gravity Recovery and Climate Experiment (GRACE) and, its successor mission GRACE-FO (FollowOn) have provided irreplaceable data for monitoring mass variations within the hydrosphere, cryosphere, and oceans, and with unprecedented accuracy and resolution for over two decades. However, the long-term products of mass variations prior to GRACE-era may allow for a better understanding of spatiotemporal changes in climate-induced geophysical phenomena, including terrestrial water cycle, ice sheet and glacier mass balance, sea level change and ocean bottom pressure. In this study, total water storage anomalies (TWSA) are simulated/reconstructed globally at 1.0°x1.0° spatial and monthly temporal resolutions from January 1994 to December 2020 with an in-house developed hybrid Deep Learning (DL) architecture using GRACE/-FO mascon and SLR gravimetry, ECMWF Reanalysis-5 (ERA5) data. We validated our simulated mass change data products both over land and ocean, not only through mathematical performance metrics (internal validations) such as RMSE or NSE along with comparisons to previous studies, but also external validations with non-GRACE datasets such as El-Nino and La-Nina patterns, barystatic global mean sea level change, degree (d) 2 order (o) 1 spherical harmonic coefficients (C21, S21) retrieved from Earth orientation parameters, Greenland Ice sheet mass balance and in-situ Ocean Bottom Pressure measurements were carried out. The overall validations show that the proposed DL paradigm can efficiently simulate high-resolution monthly global gravity field both in GRACE/GRACE-FO and pre-GRACE era. The resulting simulated data products are available as monthly mass change grids as well as spherical harmonic models up to d/o 180.

Regional ZTD Modeling by Using Multi-Source Data Based on Machine Learning: A Case Study of Severe Weather Event in Turkey

DOI: 10.57757/IUGG23-4023 - LINK

Selma Zengin Kazanci[1], *Bahadır Çelik*[1]
[1]*Osmaniye Korkut Ata University, Geomatics Engineering, Osmaniye, Turkey*

Zenith tropospheric delay (ZTD) is critical information for global navigation satellite systems (GNSS) meteorology. ZTD is estimated from GNSS stations, radiosonde stations, meteorological stations, meteorological reanalysis data, global pressure and temperature 3 model (GPT3), etc. Extreme weather events can detect from ZTD values. In this situation, the importance of obtaining reliable ZTD data increases. With the development of machine learning, its usability has also been raised in ZTD estimation. In this study, we have developed three ZTD models based on the support vector machine model (SVM) using radiosonde ZTD data, the International GNSS Service (IGS)-ZTD products, ZTD estimated by European Centre for Medium-Range Weather Forecasts Reanalysis 5 (ERA5) data throughout July 2017. The reason for choosing the year 2017 is the extreme weather events as severe precipitation and hail events that took place in Istanbul (IGS-ISTA) on July 18-27, 2017. In order to investigate which ZTD model gives better results, Root Mean Square Errors (RMSE), and bias were adopted for our comparisons in extreme weather events and normal weather conditions.

The huge volume of infrasound detections asks for machine learning techniques for the automatic classification of signals. Our objective was to assess machine learning algorithms in identifying signals. Since 2017, the Hungarian infrasound array has collected approximately one million detections, processed with the Progressive Multi Channel Correlation method. Of these, we categorised some 14,000 detections from quarry blasts, storms and a power plant. These detections constitute the dataset for machine learning training, validation and testing. After pre-processing, features were extracted from the waveforms both in the time and frequency domain, to characterize the physical properties of the signals. We also defined PMCC related features to measure the similarity between the detections. For training, two classifiers were selected, Random Forests and Support Vector Machines. Hyperparameter tuning was performed with three-fold cross-validation using grid search. As a metric, f1 score was selected, and the confusion matrices were analysed. The goal was to separate the detections labelled as quarry blasts from the storm and power plant classes. The results reach 0.88 f1 scores, and high true positive rate for the quarry blasts, which show promising step in the direction of infrasound signal classification via machine learning.

The Global Navigation Satellite System (GNSS) is widely acknowledged for its ability to monitor ground deformation and provide guidance to assess associated hazards. However, noise in GNSS time-series can hide or even mask the actual ground deformation signals. Various denoising techniques have been developed to improve the signal-to-noise ratio and detect low amplitude signals. The Discrete Wavelet Transform (DWT) has proven to be one of the most effective techniques. However, the DWT requires extensive time-series data and it is therefore computationally expensive, making it unsuitable for real-time monitoring.

In this research, we first assess the feasibility of using deep learning (DL) to perform the equivalent of wavelet analysis on GNSS data. Secondly, we explore the possibility of using DL to predict the future values of a wavelet-denoised GNSS time-series. The proposed method can be described as follows: i) wavelet analysis is applied to GNSS time-series coming from different sites in a permanent network; ii) a DL model is trained using the original time-series as input and the "Wavelet processed" series as target; iii) the trained model is used to perform real-time denoising on newly recorded GNSS data; iv) a separate model is trained to predict future values of the so-denoised GNSS data.

We tested our approach on GNSS data collected in the Campi Flegrei area (Naples, Italy), an active volcanic caldera well-known for its ongoing deformation. The preliminary results are promising, as the models show good accuracy in both tasks: simulating past denoised signals and predicting future ones.

Modeling of Nitric Oxide infrared radiative flux in lower thermosphere: A machine learning perspective

DOI: 10.57757/IUGG23-0791 - LINK

Dayakrishna Nailwal[1], *Sunil Krishna Mallepula Venkata*[1], *Alok Ranjan*[1]
[1]*Indian Institute of Technology Roorkee, Department of Physics, Roorkee, India*

Nitric oxide (NO) plays a crucial role in the energy budget and chemistry of the mesosphere and lower thermosphere (MLT). During geomagnetic storms, a massive amount of energy is deposited in the thermosphere. To balance this sudden increase of energy deposition, enhanced emission from NO has been observed in the thermosphere. So, an accurate prediction of Nitric Oxide radiative flux becomes vital to understanding the thermospheric behavior, especially during extreme space weather events. Due to the advancement in computation techniques, machine learning (ML) has become a valuable tool in space weather forecasting. The SABER (Sounding of the Atmosphere using Broadband Emission Radiometry) instrument on board the TIMED satellite provides continuous measurements of the radiated energy at 5.3 μm by NO since 2002. The availability of SABER data enables us to use machine learning for developing a data-driven machine learning model for Nitric Oxide Infrared Radiative Flux (NOIRF). Using machine learning, a predictive model (NOEMLM) is developed. The model is able to extract the underlying relationships between the input features and effectively predict the NOIRF. The model NOEMLM has outstanding performance for both the datasets training as well as testing. The model predictions have been verified by using the actual measurements of SABER. The NOEMLM predictions have good agreements with SABER observation during the geomagnetic storms and quiet time, which shows that the model can predict NOIRF during extreme space weather conditions with good accuracy.

Testing a "fully – automated" clustering algorithm for stress inversions (CluStress)

DOI: 10.57757/IUGG23-4514 - LINK

Lili Czirok[1,2], Lukács Kuslits[2], Katalin Gribovszki[2], István Bozsó[2]
[1]Quantectum AG, -, Pfäffikon, Switzerland
[2]Eötvös Loránd Research Network ELKH, Institute of Earth Physics and Space Science EPSS, Sopron, Hungary

The goal of this contribution is to present the "fully-automated" clustering algorithm developed by the authors. This is augmented by a case study where the authors carried out various cluster analyses of the focal mechanism solutions (FMS) estimated from local and teleseismic measurements and then performed stress inversions using the resulting clusters. This algorithm does not call for the setting of hyper-parameters by the users, thus greatly reducing the level of subjectivity introduced by user choice; the time required to finish the clustering can also be decreased. There is, however, an optional hyper-parameter which can be used for outlier detection, i.e. identify the data points considered to be noise in the input dataset, increasing the performance of the stress estimations.

For probing the efficiency of their algorithm, systematic series of tests were executed on synthetic FMS data featuring clusters of various characteristics. During these tests, CluStress has been compared to other established clustering methods, namely, hierarchical density-based clustering for applications with noise (HDBSCAN) and agglomerative hierarchical analysis. Quantitative metrics, mainly the characteristic curves produced using the so-called silhouette-coefficient indicate that CluStress generates the most robust clusters for the stress inversions on synthetic data.

A similar conclusion could be drawn from the same test performed using real FMS data of the investigated study area. As for this latter case, the resulting stress tensors show good agreement with the earlier published results with the notable exception of traces of extension, identified in some parts of the region after FMS clustering.

GNSS Reflectometry (GNSS-R), referring to exploiting the GNSS signal of opportunity reflected off the Earth surface, has emerged as a novel remote sensing technique for monitoring geophysical parameters. The Cyclone GNSS (CYGNSS), launched on December 15th, 2016, is a constellation of eight microsatellites with cost-effected receivers, fully dedicated to the GNSS-R applications, and can track reflected signals from multiple GNSS satellites. Compared with traditional optical and radar remote sensing, GNSS-R can provide massive datasets with global coverage and improved temporal resolution, which offers unique potential for characterizing the complex Earth system.

With the increase of GNSS-R observation data volume, deep learning techniques show their strong capability in retrieving ocean surface wind speed by extracting features from the Delay-Doppler Maps (DDMs). Furthermore, it is shown that deep learning models significantly improve the quality of existing GNSS-R wind speed products. The model achieves an overall RMSE of 1.31 m/s compared with the ERA5 reanalysis data and leads to an improvement of 28% in comparison to the operational retrieval algorithm based on the empirical geophysical model functions (GMFs).

However, some known geophysical parameters, such as precipitation, are theorized to be impacting the reflected signals, altering the pattern of the DDMs, and consequently biasing the retrievals. The correction of such bias is not trivial because of its nonlinear dependency on various environmental and technical parameters. Therefore, we explore how deep learning-based fusion on additional precipitation data can correct the bias and further investigate the potential of deep learning models to retrieve precipitation.

The Earth's gravity field varies temporally due to a multitude of geophysical processes involving mass displacements. These include processes in the areas of continental hydrology, glaciology, oceanography, atmosphere and solid Earth science. As a variation in the gravity field can be represented as the integral over all mass changes on Earth, temporal gravity measurements include the cumulative effect of the above-mentioned mass displacement processes. Interpreting the individual signal components included in such data and further using them, e.g. in order to constrain data-driven process models, requires a method to extract the signal of interest from the spatio-temporal gravity data.

The signal components to be separated differ by their spatial and temporal characteristics, which are in principle known from models or other measurements. We are aiming to exploit these different characteristics for extracting the individual signal components out of the full signal.

As neural networks are known to be powerful in pattern recognition tasks using image data, we transfer our signal separation task to an image-to-image translation task. A neural network is trained based on known signal patterns with the aim to extract individual signal components from their sum.

Although we use the updated ESA Earth System Model for gravity simulations for our method development, the results could be beneficial not only for signal separation in satellite gravity data but also for similar tasks in other geospatial datasets representing the sum of multiple signal components.

Severe Space Weather (SW) activity produced by geomagnetic solar storms gives rise to harmful geomagnetically induced currents (GICs) flowing on technological systems, thus potentially threatening the critical infrastructures on Earth. The first step in developing an alarm system against GICs is to forecast them. This is a challenging task, though, given the highly non-linear dependencies of the response of the magnetosphere to the SW. In the last few years, modern machine-learning (ML) models have shown to be appropriate and very good at predicting magnetic activity indices as the SYM-H. However, such complex models are on the one hand difficult to tune, and on the other hand they are known to induce potentially large prediction uncertainties which are generally difficult to estimate. In this work we aim at predicting the SYM-H index characterising geomagnetic storms one hour in advance, using public interplanetary magnetic field data from the L1 Lagrange point and SYM-H. We implement a type of ML model called long short-term memory (LSTM) networks. Our scope is to estimate -for the first time up to our knowledge- the prediction uncertainties coming from a deep-learning model in the context of SW. The resulting uncertainties turn out to be sizeable at the critical stages of the solar storms. Our methodology also includes an efficient optimisation of important hyper-parameters of the LSTM and robustness tests. This model represents the starting point towards our ultimate goal of providing a real-time prediction model of the GICs from extreme geomagnetic storms on the Spanish critical infrastructures.

Research on modeling and predicting of GNSS satellite clock bias using the LSTM neural network model

DOI: 10.57757/IUGG23-3724 - LINK

Jiulong Liu[1]*, Shaofeng He*[1]*, Xiangwei Zhu*[1]
[1]*Sun Yat-sen University, School of Electrical and Communication Engineering, Guangzhou, China*

In the Global Navigation Satellite System (GNSS), the satellite clock bias (SCB) is one of the sources of ranging error, and the prediction capability directly affects the users navigation and positioning accuracy. The establishment of a reliable SCB predicting model is important for real-time precise point positioning, precise orbit determination and optimization of navigation message parameters. In this report, we apply a Long Short-Term Memory (LSTM) model for predicting BDS-3 SCB, which uses a multiple single-step predicting method to avoid error accumulation in the process. Short- (0 to 6 hours), medium- (6 hours to 3 days) and long-term (3 days to 7 days) predicting is performed, and the results are compared with those of two traditional models to verify the reliability and accuracy of the LSTM method. In the long-term prediction of BDS-3 SCB, LSTM improves the accuracy about 70% and 60% compared to the autoregressive integrated moving average (ARIMA) and quadratic polynomial (QP) model, respectively. This report also presents the results of predicting GPS and Galileo SCB using the LSTM method.

In the Global Navigation Satellite System (GNSS), the satellite clock bias (SCB) is one of the sources of ranging error, and the prediction capability directly affects the users navigation and positioning accuracy. The establishment of a reliable SCB predicting model is important for real-time precise point positioning, precise orbit determination and optimization of navigation message parameters. In this report, we apply a Long Short-Term Memory (LSTM) model for predicting BDS-3 SCB, which uses a multiple single-step predicting method to avoid error accumulation in the process. Short- (0 to 6 hours), medium- (6 hours to 3 days) and long-term (3 days to 7 days) predicting is performed, and the results are compared with those of two traditional models to verify the reliability and accuracy of the LSTM method. In the long-term prediction of BDS-3 SCB, LSTM improves the accuracy about 70% and 60% compared to the autoregressive integrated moving average (ARIMA) and quadratic polynomial (QP) model, respectively. This report also presents the results of predicting GPS and Galileo SCB using the LSTM method.

We present and discuss the outcomes of an investigation into the sporadic meteor radiant distribution using the High-Power Large Aperture Arecibo 430 MHz Incoherent Scatter Radar (ISR) located in Puerto Rico. There has been substantial meteor research using the Arecibo ISR, however, the sporadic meteor radiant distribution has remained elusive due to the radar's inability to estimate the vector velocity. In this work, a machine learning algorithm was specifically developed to determine the radiant density and speed distributions of the sporadic meteoroids observed at Arecibo. This algorithm incorporates a wide range of techniques, including stochastic gradient descent, and draws upon numerical modeling results and observational data to produce its results. The algorithm was trained using over 250,000 meteor observations carried out by the Arecibo radar between the years 2009 and 2017. Our results show that five of the six recognized sporadic meteor sources can be clearly identified, but no clear identification of the South Apex source emerged in the results. Instead, there is a broad distribution centered around the North Apex direction, with the peak density between +/-30° ecliptic latitude. Our analysis reveals that the Arecibo radar is most sensitive to meteors with an arrival angle between 30° and 60° but the radar cannot probe meteors that are moving straight into or perpendicular to the boresight of the antenna's radar. We show that 75% of the meteoroids sensed with the Arecibo radar usually travel in prograde orbits while most of the retrograde meteoroids typically move in inclined, low-eccentricity orbits.

One of the main sources of solar wind disturbances are coronal holes which can be identified in extreme ultra-violet (EUV) images of the Sun. Previous research has shown the connection between coronal holes and an increase of the solar wind speed at Earth. In this study, we propose a new machine learning model predicting the solar wind speed originating from coronal holes. We detect coronal holes by applying a recently introduced segmentation algorithm to solar EUV images. Based on that, we derive time series of coronal hole characteristics, which are used as input to the model to predict the solar wind speed. Since coronal holes are structures that change over time, we also process their temporal evolution. We put a special focus on learning the geoeffective coronal hole areas, by splitting up the solar surface into multiple sectors of different latitudes and longitudes. This approach enables to predict the disturbances up to approximately 5 days in advance. We show that our model can accurately predict the solar wind speed with a temporal resolution of one hour during time periods when the solar wind is dominated by coronal hole activity. Moreover, we apply it to 10 years of data and compare our results to other state-of-the-art models.

Plasma-sheet bubble identification using multivariate time series classification

DOI: 10.57757/IUGG23-1050 - LINK

Xuedong Feng[1], *Jian Yang*[1]
[1]*Southern University of Science and Technology, Department of Earth and Space Sciences, Shenzhen, China*

Plasma-sheet bubbles play a major role in the earthward transport of magnetotail particles. The most remarkable feature of bubbles is their fast bulk flow velocities, along with reduced plasma density and pressure accompanied by magnetic field dipolarization. These bubbles can be identified based on in-situ observations, but subjective ambiguity necessitates human verification, due to confusion with other phenomena mostly associated with magnetic reconnection and plasma waves. In this study, we aim to employ machine learning techniques to detect bubbles automatically and without prior subject expertise. To identify bubbles, we combine three distinct techniques: MINImally RandOm Convolutional KErnel Transform (MINIROCKET), 1D convolution neural network (CNN), and Residual Network (ResNet). The imbalanced training dataset consists of bubble and non-bubble events with a ratio of 1:40 from 2007 to 2020. The results indicate that the accuracy of the all three models is approximately 99%, and their precision, recall, and score are all above 80% for both the validation and test datasets. The three methods are combined with the intersection set as the minimum set of predictions and the union set as the maximum set. The union set can accurately identify 66.7% of plasma bubbles. The methods simultaneously reduce the number of false positives significantly. In the prediction of bubbles in observations made in year 2021 using union set, the bubbles obtained by the model are comparable to those discovered using traditional criteria and manual inspections.

Earthquake source is among the key element within the framework of seismic hazard. However, Seismic waves can be of natural origin or from anthropogenic sources such as mining-related events. Hence, without a proper approach for source discrimination, an earthquake catalog for hazard assessment can be contaminated. In this study, we propose a Convolutional Neural Network based on spectrograms to perform the waveform classification. It is targeted to applications in Madagascar.
The approach consists of three main steps: (1) generation of the time–frequency representation of ground-motion recordings (spectrogram); (2) training and validation of the model using spectrograms of ground shaking; (3) testing and prediction. To measure the compatibility between output predictions and given ground truth labels, we adopt the commonly used loss function and accuracy measure. Given that the spatial distribution of the seismic data in Madagascar is non-uniform, we perform two-step analyses. First, we adopt a supervised approach for 6051 known events in the central part of Madagascar. Then, we use the outcome for the second step training and perform the prediction for non-categorized events throughout the country.
The results show that our model has the potential to separate earthquakes from mining-related events. For the supervised approach, among the 20% used for testing, 97.48% and 2.52% of the events give correct and incorrect labels, respectively. These pre-trained data are subsequently used to perform predictions for unlabeled events throughout Madagascar. Our results show that the model could learn the features of the classes even for data coming from different parts of Madagascar.

Extended range probabilistic forecasts of water temperatures at rivers and lakes in Switzerland using Machine Learning

DOI: 10.57757/IUGG23-1791 - LINK

Konrad Bogner[1], *Massimiliano Zappa*[1]
[1]*Swiss Federal Research Institute WSL, Hydrological Forecast, Birmensdorf, Switzerland*

The increased frequency of the occurrence of drought in combination with heat waves in the recent years raises the need for forecasts of water temperatures to take timely measures to limit damages to aquatic ecosystems and mitigate losses. Furthermore, forecasts could allow identifying possible limitation of water use for cooling purposes by industry when water temperature are too high. Nonetheless, the usage of hydro-meteorological extended range forecasts with lead-times of several weeks is limited by now. Statistical models based on Machine Learning (ML) methods, have gained importance in recent years and show very promising results. However, there are several drawbacks of ML methods, like the lack of interpretability and the incorporation of uncertainty. We tested different ML methods at 60 stations, ranging from high alpine with glacier dominance to lowland, representing the diversity of Swiss runoff regimes. The aim is to analyse these methods in more detail with respect to the importance of the hydro-meteorological input variables used, the necessity of pre- and post-processing steps and the estimation of predictive uncertainties. A recently developed ML method for probabilistic forecasts, called Temporal Fusion Transformer, shows the best results and allows a detailed interpretation of the model results. The results for the period 2012 to 2022 highlight the importance of considering temporal and spatial aggregation of input data (e.g. applying wavelet transformations) as a pre-processing step and using post-processing methods, such as Nonhomogeneous Gaussian Regression, to improve the skill of the probabilistic forecast system.

Generic seismic mass-movement detection leveraging unsupervised statistical learning methods

DOI: 10.57757/IUGG23-0742 - LINK

Patrick Paitz[1], Małgorzata Chmiel[1], Lena Husmann[1], Michele Volpi[2], Francois Kamper[2], Fabian Walter[1]
[1]Swiss Federal Institute for Forest- Snow and Landscape Research WSL, Mountain Hydrology and Mass Movements, Birmensdorf, Switzerland
[2]Swiss Data Science Center, sdsc, Zurich, Switzerland

With global warming potentially increasing the severity and frequency of hazardous mass-movements, monitoring such hazards is crucial to the population and critical infrastructure – especially in alpine areas. Monitoring and early-warning systems have the potential to improve the resilience of mountain communities to catastrophic events. Increasing the spatial coverage of seismic monitoring networks enables new warning perspectives if efficient algorithms screening the seismic data streams for hazardous mass-movements in real-time are available.

We propose to combine physical and statistical features of seismic ground velocity recordings from ground motion sensors such as seismometers. These features are then fed to an unsupervised workflow for mass movement detection. We evaluate the performance, consistency, and generalizability of unsupervised learning approaches by comparing a large number of fitted models obtained from various unsupervised methodologies. Focusing on debris-flow records at the Illgraben torrent in Switzerland, we present a mass-movement detector with high accuracy and early-warning capability that combines multiple statistical learning models into an ensemble classifier. Furthermore, our goal is to generalize this detector to measurements from other sites and thus to maximize its transferability.

Since our results aim to enable mass-movement monitoring and early-warning worldwide, Open Research Data principles like Findability, Accessibility, Interoperability and Reusability (FAIR) are of high importance for this project. We discuss how using the Renku platform (renkulab.io) of the Swiss Data Science Center ensures FAIR data science principles in our investigation. This is a key step towards our goal to enable seismology-based early warning of mass-movements wherever it may be required.

Application of a neural network operator to fill long-term gaps of coastal sea-level data

DOI: 10.57757/IUGG23-1402 - LINK

Eun-Joo Lee[1], *Jae-Hun Park*[1]
[1]*INHA university, Department of Ocean Sciences, Incheon, Korea Republic of*

Sporadic misses in the tide gauge records occur frequently for a number of reasons, which hinders understanding of ocean physics in coastal regions. In other words, general-purpose time-series analysis and prediction methods require continuity of the data. To fill the sea-level data gaps, scientists have been working hard, but the existing reconstruction techniques have a disadvantage when missed sea-level records are longer than the timescales of coastal processes. To solve this problem, artificial neural network model is also being used to fill the gaps, but this method has a chronic problem that the shape of the target is fixed. To overcome this obstacle, we designed a model, named one-step prediction operator, which predicts the sea level after a unit of time. A data assimilation technique is additionally applied to merge seamlessly the model-predicted sea level with observed one. The recursivity of this model makes it possible to reconstruct missing data even longer than 72 hours successfully. The reconstructability of sea level records at 16 tide gauge stations around the Korean peninsula confirms that it can successfully reconstruct missing values with root-mean-squared errors of 0.5–1.3 cm on average.

Understanding the dynamics of energetic electrons in the radiation belts is key to protect space borne equipment and astronauts on-board spacecraft missions. Therefore, global reconstruction of the near-Earth radiation environment should be available at all times and locations. Low Earth Orbit (LEO) satellites provide large data sets of the radiation belt region over a wide range of magnetic local times. However, the use of these data is complicated due to contamination of electron fluxes by protons and precipitating particles, leading to high variability of electron measurements, considerable instrumental errors and the need for background correction. In this study, we present a new intercalibration method for satellite measurements of energetic electrons in the radiation belts using data assimilation. We intercalibrate electron flux measurements of POES satellites against RBSP observations. For this, we use a reanalysis of the radiation belt region, obtained by assimilating RBSP and GOES electron data into 3-D Versatile Electron Radiation Belt (VERB-3D) code simulations via a standard Kalman filter. Since the reanalysis provides global reconstruction of the system, we can compare the POES data with our reanalysis and estimate the flux ratios at each time, location and energy. These ratios are averaged over time and space to obtain energy dependent recalibration coefficients. To validate our results, we perform a traditional conjunction study between POES and Van Allen probes. The conjunction coefficients and the DA estimated coefficients show very good agreement. The use of a data assimilative reanalysis significantly improves statistics and less data is necessary for the intercalibration.

Interpretable machine learning procedure unravels hidden interplanetary drivers of the low latitude dayside magnetopause

DOI: 10.57757/IUGG23-4270 - LINK

Sheng Li[1], Yang-Yi Sun[1], Chieh-Hung Chen[1]
[1]China University of Geosciences, School of Geophysics and Geomatics, Wuhan, China

Interplanetary parameters, such as solar wind and interplanetary magnetic fields (IMF), drive the shape and size of the magnetopause jointly, which has complex relationships. In this study, we proposed an interpretable machine learning procedure to disentangle the influences of interplanetary parameters on the magnetopause standoff distance (MSD) and sort their importance in the MSD simulation. The magnetopause crossings of the THEMIS mission and interplanetary parameters of OMNI during the period of 2007-2016 are utilized to construct machine learning magnetopause models. SHapley Additive exPlanations (SHAP) is the foundation for an interpretable procedure, which introduces interpretability and makes the machine learning magnetopause model to be a “white box”. The solar wind dynamic pressure and IMF B_Z are widely considered the top two important parameters driving the MSD. However, the interpretable procedure suggests that the IMF magnitude (i.e. strength of the IMF) leads B_Z as the second most important interplanetary driver. This ranking result is unexpected, and it implies that the role of IMF magnitude is underestimated although magnetic pressure, which is a function of the IMF magnitude was considered in previous studies. The examination of disentangled effects of interplanetary parameters reveals that the combined influence of the IMF magnitude and B_Z can cause an MSD sag near B_Z = 5 nT. This is for the first time we conduct the interpretable concept into the machine learning model in the study of the magnetosphere.

The magnetosphere undergoes global dynamical reconfigurations termed storms and substorms in response to solar wind driving. Understanding how the 3D magnetic field and associated current systems evolve in time during these events is critical to characterizing the magnetosphere system. However, modeling storms and substorms using first-principles approaches is complicated because non-ideal magnetohydrodynamical processes, such as the formation of the storm-time ring current, thin current sheets, and magnetic reconnection, are key to their description. As such, several unanswered questions persist regarding the global morphology of these events and on their driving mechanisms. Here, we address these questions by empirically reconstructing the global 3D magnetic field and electric currents from decades of spacecraft magnetometer observations. For a given time of interest, the archive of observations is mined to form a subset of data from other times when the magnetosphere was in a similar storm and/or substorm state. This subset of data is used to fit an empirical model of the magnetic field that analytically describes the key magnetospheric current systems. This process is then repeated for each snapshot during an event, allowing for a quantitative dynamical picture to be reconstructed from the magnetometer data. We demonstrate that this data-mining based empirical approach reconstructs the primary features of substorms, including the thinning and stretching of the magnetotail followed by its rapid dipolarization, as well as the build-up of the storm-time ring current and pressure. This approach also locates the site of magnetotail reconnection during these events as confirmed by comparison with in-situ observations.

The magnetosphere undergoes global dynamical reconfigurations termed storms and substorms in response to solar wind driving. Understanding how the 3D magnetic field and associated current systems evolve in time during these events is critical to characterizing the magnetosphere system. However, modeling storms and substorms using first-principles approaches is complicated because non-ideal magnetohydrodynamical processes, such as the formation of the storm-time ring current, thin current sheets, and magnetic reconnection, are key to their description. As such, several unanswered questions persist regarding the global morphology of these events and on their driving mechanisms. Here, we address these questions by empirically reconstructing the global 3D magnetic field and electric currents from decades of spacecraft magnetometer observations. For a given time of interest, the archive of

observations is mined to form a subset of data from other times when the magnetosphere was in a similar storm and/or substorm state. This subset of data is used to fit an empirical model of the magnetic field that analytically describes the key magnetospheric current systems. This process is then repeated for each snapshot during an event, allowing for a quantitative dynamical picture to be reconstructed from the magnetometer data. We demonstrate that this data-mining based empirical approach reconstructs the primary features of substorms, including the thinning and stretching of the magnetotail followed by its rapid dipolarization, as well as the build-up of the storm-time ring current and pressure. This approach also locates the site of magnetotail reconnection during these events as confirmed by comparison with in-situ observations.

Data assimilation into a machine learning-based emulator of global MHD simulation for analysis of the polar ionosphere

DOI: 10.57757/IUGG23-0339 - LINK

The electric field in the polar ionosphere is imposed as a result of physical processes in the magnetosphere. The modeling of the magnetospheric processes is thus essential to reproduce physical phenomena in the polar ionosphere. Nowadays, magneto-hydrodynamic (MHD) models of the magnetosphere produce a realistic ionospheric potential pattern. Therefore, data assimilation into an MHD model would be a promising approach to reproduce ionospheric phenomena with high accuracy. However, the realistic MHD model is too computationally expensive to apply data assimilation. To overcome the problem of the computational cost, we employ a machine learning-based emulator of the global MHD model. The emulator is based on an echo state network model and efficiently mimics the MHD model to reproduce an ionospheric potential pattern under a give solar wind condition. As a pilot study, we assimilate the SuperDARN data into this emulator and obtain the global potential map. We will demonstrate the electric potential maps as a result of data assimilation into the emulator.

Up to 50% of the signal delays of L-band signals used in the Global Navigation Satellite System comes from the topside ionosphere and plasmasphere. In this study, we apply an Ensemble Kalman Filter (EnKF) approach to estimate the 4D electron density of the topside ionosphere and plasmasphere based on space-based STEC data. NeQuick model is used as background. The STEC measurements of eleven LEO satellites are used for the reconstructions. The majority of the approaches, working with EnKF, uses physics-based models for the propagation step. In our work, we investigate the question how the propagation step can be realized, in the case that a physical propagation model is not available or discarded due to computational burden. We explore different propagation models and compare them with the iterative reconstruction technique SMART+ for two periods of the year 2015 covering quiet to perturbed ionospheric conditions. We check the capability of the estimations to reproduce assimilated STEC as well as to reconstruct independent STEC measurements. The comparison with the assimilated STEC shows that during both periods all methods reduce the statistics (Median, SD, RMS) of the STEC residuals in comparison to the background model by up to 86%. In summary, the results indicate that the methods EnKF with exponential decay as propagation model (EnKFexp) and SMART+ perform best, reducing the independent STEC residuals by up to 64%, compared to the NeQuick model.

Big data assimilation revolutionizing numerical weather prediction using Fugaku

DOI: 10.57757/IUGG23-1285 - LINK

Takemasa Miyoshi[1]
[1]*RIKEN, Center for Computational Science, Kobe, Japan*

At RIKEN, we have been exploring a fusion of big data and big computation in numerical weather prediction (NWP), and now with AI and machine learning (ML). Our group in RIKEN has been pushing the limits of NWP through two orders of magnitude bigger computations using the previous Japan’s flagship “K computer”. The efforts include 100-m mesh, 30-second update “Big Data Assimilation” (BDA) fully exploiting the big data from a novel Phased Array Weather Radar. With the new Fugaku, we achieved a real-time BDA application to predict sudden downpours up to 30 minutes in advance during Tokyo Olympics and Paralympics. Moreover, Fugaku is designed to be efficient for both double-precision big simulations and reduced-precision ML applications, aiming to play a pivotal role in creating super-smart “Society 5.0.” We have been exploring ideas for improving the predicting capabilities by fusing BDA and AI. The data produced by NWP models become bigger and moving the data to other computers for ML or even simply saving them may not be feasible. A next-generation computer like Fugaku may bring a breakthrough toward creating a new methodology of fusing data-driven (inductive) and process-driven (deductive) approaches in meteorology. This presentation will introduce the most recent results from BDA experiments, followed by perspectives toward DA-AI fusion and expanding new applications beyond meteorology.

Assimilation of near bound variables

DOI: 10.57757/IUGG23-4915 - LINK

Craig Bishop[1], *Diego Carrio-Carrio*[2], *Dillon Sherlock*[3]
[1]*University of Melbourne, School of Geography Earth and Atmospheric Sciences, Carlton, Australia*

The largest errors in weather and climate predictions are generally associated with near bound variables such as aerosols, clouds and precipitation. These variables are "near-bound" in the sense that they are non-negative (bounded at zero) and that the error standard deviation of their observations and forecasts is not that different from the distance of their true value from the bound. Typically, the observation error standard deviation decreases as the true value of the variable approaches the bound and is typically specified by a relative standard deviation rather than an absolute standard deviation. The associated uncertainty distributions for both forecasts and observations of these variables are typically highly skewed and non-Gaussian. Sometimes the observed variables are non-linear functions of the underlying model variables. In this paper, we will show how well-known data assimilation frameworks such as Serial Ensemble Kalman Filters that assimilate observations in batches, Ensemble Kalman Filters that assimilate observations all at the same time (e.g. ETKF), and variational schemes such as 3DVar and 4DVar, can all be adjusted to greatly improve their ability to accommodate these bounded variables. The new theory will be explained and illustrated with simple examples in which the new method profoundly outperforms methods that attempt to treat these variables in the same way as other (Gaussian) variables.

The GRACE and GRACE-FO satellite missions provide mass variations as a fundamentally new observation type for a broad spectrum of novel applications in Earth science, including oceanography, geophysics, hydrology, and hydrometeorology. Despite all the key findings in hydrology, the utility of GRACE-derived Terrestrial Water Storage Anomaly and its time derivative Terrestrial Water Storage Flux (TWSF) have mainly been limited to large catchments due to their coarse spatial resolution. Here, we propose a method to downscale TWSF by incorporating available finer resolution data. We determine the downscaled TWSF and its uncertainty within a proposed Bayesian framework by incorporating the fine-scale data of TWSF and Soil Moisture Change (SMC) from different available sources. For the Bayesian ingredients, we rely on GRACE data to obtain the prior and rely on copula models to obtain nonparametric likelihood functions based on the statistical relationship between GRACE TWSF with fine-scale data. We apply our method to the Amazon Basin and assess the performances of our products from various fine-scale input datasets. Given the lack of large-scale ground truth for TWSF, we validate our results against space-based Surface Water Storage Change in the Amazon river system and also against the Vertical Crustal Displacements Change observed by the Global Positioning System. Overall, the results show that the proposed method is able to estimate a downscaled TWSF, which is informed by GRACE and fine-scale data. The proposed methodology can be extended to other coarse scale datasets, which are crucial for hydrological application at regional and local scales.

Using FY-4A water vapor data to augment the NWP model forecasting performance over the South China

DOI: 10.57757/IUGG23-2169 - LINK

Zhizhao George Liu[1], Yangzhao Gong[1], Pak Wai Chan[2], Kai Kwong Hon[2]

[2]Hong Kong Observatory, 134A Nathan Road- Tsim Sha Tsui, Kowloon, Hong Kong

Fengyun-4A (FY-4A) is the first satellite in the second generation of China's geostationary meteorological satellite series. The Advanced Geostationary Radiation Imager (AGRI) onboard FY-4A satellite can measure water vapor data at infrared band. In this study, to investigate the benefits of assimilating FY-4A water vapor data to weather forecasting performance over the South China region, we have performed the data assimilation experiments in the Weather Research and Forecasting (WRF) model for two periods with different water vapor conditions, i.e., February 2020 (dry period) and July 2020 (wet period). Two WRF schemes, i.e., WRF no data assimilation scheme (denoted as "WRF_NoDA") and WRF with assimilation of FY-4A Precipitable Water Vapor (PWV) scheme (denoted as "WRF+FY-4A"), have been implemented. The PWV and rainfall forecasting results of the two WRF schemes are validated by Global Navigation Satellite System (GNSS) PWV and the rainfall observations of the surface meteorological stations, respectively. The evaluation results show that, compared with WRF_NoDA scheme, WRF+FY-4A indicates a better performance in both PWV and rainfall forecasting. Specifically, with the assimilation of FY-4A PWV, the average root mean squares error of WRF PWV forecasting results for the first 12 h after data assimilation is reduced from 2.34 kg/m^2 to 2.25 kg/m^2 over the February period and from 4.39 kg/m^2 to 4.35 kg/m^2 over the July period. Additionally, after assimilating FY-4A PWV, the equitable threat score of accumulated rainfall for the first 12 h after data assimilation increases from 0.217 to 0.237 when using 10 mm/12 h as rainfall detection threshold.

Localization and inflation in geomagnetic data assimilation: estimating the dynamic state of the Earth's outer core

DOI: 10.57757/IUGG23-0963 - LINK

Kyle Gwirtz[1], *Weijia Kuang*[1], *Ce Yi*[1], *Andrew Tangborn*[2]
[1]*NASA, Geodesy and Geophysics Laboratory, Greenbelt, USA*
[2]*UMBC, Joint Center for Earth Systems Technology, Baltimore, USA*

The core magnetic field of the Earth is generated by turbulent convection in the planet's electrically-conducting fluid outer core (geodynamo). While the outer core cannot be directly observed, measurements of the magnetic field at and above the Earth's surface provide clues to the state of the geodynamo (e.g., fluid flow and magnetic field in the unobserved deep interior).

In recent years, there has been growing interest in using data assimilation (DA) with 3-D numerical geodynamo models to better understand the Earth's outer core and forecast changes in the magnetic field. There remain however, significant challenges to overcome if such geomagnetic data assimilation (GDA) systems are to make optimal use of available models and data.

We present a set of numerical experiments with NASA's Geomagnetic Ensemble Modeling System (GEMS)—an ensemble Kalman filter (EnKF) based GDA system. The experiments focus on the development of "localization" and "inflation" techniques in GDA. While localization and inflation are common and often critical elements of DA systems in other applications (e.g. numerical weather prediction), localization has only recently begun to be systematically explored in GDA (Sanchez et al. 2019, 2020) and inflation has yet to be implemented. Determining an appropriate localization is difficult due to the spectral nature of the "data" being assimilated: low-degree spherical harmonics defining a magnetic potential near the core-mantle boundary. Our results show a significant improvement in forecasts of the magnetic field, particularly at smaller, less computationally demanding ensemble sizes.

Accurate forecasting of the ionosphere-thermosphere conditions is critical to radio communication, navigation, positioning, and satellite tracking. Located at the intersection between geospace and the Earth's atmosphere, the ionosphere-thermosphere is exposed to drivers from both space and terrestrial weather that operate over a wide range of spatial and temporal scales. With an increased availability of geospace data from recent missions such as NASA GOLD and NASA ICON as well as COSMIC-II, the use of a single seamless system, extending from the ground to geospace, to assimilate observations from both Earth and geospace observing systems is becoming a real possibility. This paper will report on recent progress with research efforts to develop a capability to assimilate geospace satellite data into a coupled whole atmosphere-ionosphere-plasmasphere model as an integral part of the NOAA National Weather Service's operational ensemble forecasting and data assimilation systems.

The Global-scale Observations of Limb and Disk (GOLD) imager scans the Earth in the far ultraviolet wavelengths. Spectral measurements from GOLD are used to retrieve column integrated thermospheric neutral temperature (Tdisk) and oxygen to molecular nitrogen column density ratio (O/N_2) over about one fourth of the globe. The present investigation assesses the impact of GOLD disk temperatures and O/N_2 on the Whole Atmosphere Community Climate Model with thermosphere-ionosphere eXtension (WACCMX) using Data Assimilation Research Testbed (DART) ensemble Kalman filter. Observing System Simulation experiments (OSSEs), run with and without GOLD measurements, show that assimilating the two GOLD observations improves the root mean square error (RMSE) and bias of forecast and analysis states. Assimilation of actual GOLD Tdisk observations also shows improvement when compared to independent thermosphere and ionosphere measurements. Using a Specified Dynamics WACCMX (SD-WACCMX) run as the control simulation, we found that the RMSE improvements in the analysis effective temperature and O/N_2 are about 10.8% and 22.6%, respectively. Also, RMSE improvement in analysis electron column density is about 10% compared to the control simulation. Moreover, improvement in TEC RMSE is about 25% as observed from OSSE experiments that assimilated synthetic GOLD O/N_2 observations. These results demonstrate that assimilation of GOLD temperature and O/N_2 observations have a significant impact on the ionosphere-thermosphere model results.

Monthly to seasonal statistical hydrological forecasts based on teleconnections

DOI: 10.57757/IUGG23-0502 - LINK

Tamas Hirsch[1], Barbara Frielingsdorf[1], Dennis Meißner[1], Bastian Klein[1]
[1]Federal Institute of Hydrology, Water Balance, Forecasting and Predictions, Koblenz, Germany

The demand for accurate hydrological forecasts on longer time scales has been significantly increasing in many areas, e.g. waterway transport and flood protection. This, however, still presents a huge challenge using conventional dynamical models. As part of the project OptiVor of the Federal Institute of Hydrology (BfG), a new forecast method based purely on statistical relationships between meteorological/hydrological parameters and monthly river flow was developed and applied to German rivers. The main goal of this investigation was to find temporally stable, statistically significant connections on global and regional scales by learning from long historical data sets, with a time lag up to several months, in order to be able to use these in operational forecasting. Multiple linear regression was applied to create statistical models for each month and selected stations for lead times up to 8 months.

According to our investigation, global atmospheric teleconnections are of crucial importance regarding long-range hydrological predictions. Regional parameters, however, have a significant forecast value for the first 1 to 3 months. Preliminary results, also compared to conventional dynamical hydrological forecasts based on SEAS5 from ECMWF, are very promising and imply a potential basis for decision making. Further improvements are expected by combining statistical and dynamical methods, as well as applying machine learning tools in order to reveal even more valuable information from historical data sets. Another important point is the role of climate change that might have a large impact on existing meteorological and hydrological processes and thereby on the skill of data-driven methods.

In alpine regions, snow melt controls on freshwater availability, and the spatial variability of snow cover is large. Operational monitoring of snow water resources typically deploys snowpack models. However, snowpack models often struggle to capture the natural variability, because of shortcoming in either the meteorological forcing or the model itself. Data assimilation offers a way to bring models closer to reality, but reliable in-situ observations of the snowpack are not spatially exhaustive. In this situation, the performance of spatialized data assimilation typically suffers from two issues: equifinality between improved model results due to different adjustments, and a lack of robustness with respect to exceptional outliers in scarce observations.

In this work, we assess the potential of a Particle Filter (PF) to address both issues at the same time. To this end, we set up an ensemble of snowpack simulations [TJ1] with FSM accounting for meteorological and snowpack modelling uncertainties. The PF is applied to a dense network of snow depth stations covering entire Switzerland. Bi-weekly snow water equivalent and total density measurements are available on some of these (snow pit stations). We first assess the ability of our PF application to address equifinality by validating alternative simulations against independent multi-parameter observations. Then, we use a new inflation technique to mitigate the effect of outlier observations when propagating information across the whole network. This data assimilation framework is compared against an operational version of the snow model to assess its potential in a fully spatialized setting over the whole Switzerland.

Extreme geomagnetic storms are likely to have catastrophic impacts to our modern increasingly technology-reliant society. Historical New Zealand magnetograms recorded on photographic paper from 1916 to 1991 (start of digital era) at the Amberley and Eyrewell geomagnetic observatories contain valuable information for statistical forecasting of extreme geomagnetic storms. To provide a digital long-term dataset as input for statistical models, the around 22,000 magnetograms that capture the continuous variations of the local Earth's magnetic field D, H and Z components have been scanned into images at high resolution and are now being converted into digital values at a 1-minute resolution.

We present our approach of using a combination of manual and automated digitisation techniques we have developed to translate the data from analogue traces into digital nanotesla values. The manual process that uses ArcGIS software as a tool focuses on the large geomagnetic storms with local k-index 7 and larger. We so far have captured 131 storm days from 1950-1990, with each storm taking up to 2 ½ hours of manual work. Software development (currently in MATLAB) for an automated "button-press" approach using image recognition techniques is targeting the lesser storms and quieter times. As part of quality control, the digitised values are cross-checked with published historical hourly mean values. The challenges we are encountering include hand-written notation, lack of labelling, gaps, offsets, overlapping and off-scale traces, varying line width and incomplete metadata.

Shortly after Gauss's absolute method for measuring magnetic fields was invented (1832), and the bifilar device for observations of the geomagnetic field was constructed and put into operation in Göttingen (1837), geomagnetic observations also started at the Prague Clementinum observatory (1839). The beginnings of the observations at Clementinum were tightly connected with Karl Kreil, who become familiar with this new field of science at the Milan observatory. In Prague, he organized regular geomagnetic observations that even went on after his moving to Vienna (1851) to establish the Central Institute for Meteorology and Geomagnetism. The regular measurements in Prague persisted until 1917. The results were printed in yearbooks Magnetische und Meteorologische Beobachtungen zu Prag. The measurements were carried out manually. The declination was observed using the magnetic compass principle, while a bifilar apparatus was used to measure the horizontal intensity. Data from the period 1839-1871 were published in the divisions of the scale of the instrument. These data we analysed, transformed to physical units and made available to the users. In addition to regular daily observations, two categories of data with a higher cadence were provided in the first decade: (1) magnetic storms and (2) joint measurements organized in the frame of Göttingen Magnetic Union. In addition to the observatory practice at Clementinum, in the period 1843-1845, Kreil also carried out a magnetic survey in Bohemia, the first survey of this sort in the Central Europe. In the following years he continued the survey in other parts of the Austrian Empire.

A large collection of photographic paper magnetograms, covering globally an entire century is preserved in the archives of Chambon-la-forêt magnetic observatory, France. It contains magnetograms from various instruments and observatories: the National magnetic observatory (it moved from Parc-Saint-Maur, to Val-Joyeux, to Chambon-la-forêt), Bangui (Central African Republic), M'bour (Senegal), Pamatai (French Polynesia), and other observatories in metropolitan France at the beginning of the 20th century. Only values from tables of hand-written hourly values from the National magnetic observatory and overseas observatories had been digitised and made available to the scientific community.

In order to access additional information on the magnetic variations recorded on the magnetograms, we developed a recovering software: RECOV. It is based on MATLAB and can be run either as a MATLAB App, or as a standalone desktop application, with MATLAB Runtime. It provides an interface for manual selection of magnetic traces that are converted into magnetic variations and calibrated time series, if definitive hourly time series are available. The user can recover magnetograms of different quality, even cases when the magnetic traces cross the temporal axis, or wrap-around traces appear during the strongest storms. We aim obtaining recovered time-series with sampling every minute, with a reliability depending on the size and resolution of magnetic traces. We present results of recovered magnetic variations during magnetic storms of 1958 and comparisons between different instruments.

Dedicated scientific measurements of the strength and direction of the Earth's magnetic field began at Greenwich and Kew observatories in London, UK, in the middle of the 19th century. Using advanced techniques for the time, light-sensitive photographic paper and light-levered reflections from magnetized needles, allowed continuous analogue magnetograms to be recorded. By good fortune, both observatories (which were located around 20 km apart) were in full operation around the so-called Carrington storm in the early September 1859 and the precursor storm in late August, providing as complete a record as possible. Based on digital images of the magnetograms and information from the observatory yearbooks and subsequent scientific papers, we extract and scale the measurements to SI units, allowing us to extract minute cadence values. The magnetogram records have several missing periods, lost as the traces moved off-page due to the magnitude of the storm. We present the most complete digitized magnetic records to date of the ten-day period from 25th August to 5th September 1859 encompassing the Carrington storm and its lesser recognized precursor which may have been just as large. We discuss some of the issues encountered in deciphering the old records and methods for cross checking and validating the output values.

In 2019, the World Data Center for Solar-Terrestrial Physics in Moscow digitized the archive of observations of the Earth's magnetic field carried out by the Soviet satellites Kosmos-49 (1964) and Kosmos-321 (1970). As a result, the scientific community for the first time obtained access to a unique digital data set, which was registered at the very beginning of the scientific space era. Herein, we first assess the quality of the obtained measurements by their comparison with the IGRF model. Second, we evaluate the historical models, which at that time were derived from the data of these two satellites. Third, we propose a new, improved model of the geomagnetic field secular variation based on the scalar measurements of the Kosmos-49 and Kosmos-321 satellites.
Space borne geomagnetic recordings of 1970 captured a strong magnetic storm on March 6-10, 1970. In addition to the data from the Kosmos-321 satellite, we also analyze geomagnetic data from the OGO-6 satellite, which was operational at the same time. We analyze time variations of external magnetic fields using satellite and ground-based observations. In particular, we identify the signatures of the storm-time ring current, equatorial and auroral electrojects.

[3]Nagoya University, Institute for Space-Earth Environmental Research, Nagoya, Japan

The Japan Meteorological Agency has been conducting long-term magnetic observations at Kakioka (1913-), Memambetsu (1952-) and Kanoya (1958-), and archived the observations in magnetograms. We have already converted these magnetograms into digital images at 600 dpi for the periods 1924-1983 (Kakioka), 1963-1984 (Memambetsu) and 1964-1984 (Kanoya). In 1956, time marks in the magnetograms were changed from 'gap' to 'vertical lines'. For the period after 1956, we have been producing 1-minute and 7.5-second digital values by our self-developed automated tracing software. The digitization was finished for the periods 1956-1983 (Kakioka) and 1968-1984 (Memambetsu and Kanoya), except for times of some abrupt phenomena. As automatic reading by the software is not applicable to such time intervals, we keep working on them with manual reading software.

Our ultimate goal is to complete digitization of all records prior to 1956, which involve a number of extreme events (PC, SFE, SC) including the 24 March 1940 event, the greatest SC event since 1868. 7.5-second data would be very useful resources for elucidating the Sun-Earth coupling processes. However, sharp peaks associated with SCs may not be adequately resolved even with those data. Additional information is desirably obtained by spotting apexes of individual peaks. Challenges to be addressed include: (1) difficulty in strict time identification due to the time mark gap, (2) difficulty in tracing lines due to dimness of the magnetograms, and (3) inaccuracy of the time axis due to paper distortion. New working tools and a certain amount of labor will be further required.

Auroras and other celestial phenomena in medieval Arabic sources: A database

DOI: 10.57757/IUGG23-2820 - LINK

Sajjad Nikfahm-Khubravan[1], *Nada Al-Haddad*[1]
[1]*University of New Hampshire, the Institute for the Study of Earth- Oceans- and Space, Durham, USA*

Medieval Arabic historical writings commonly included reports of natural phenomena occurring on the Earth, in the atmosphere, or in the sky. Since the methods for recording these phenomena were not developed scientifically, different authors were engaged differently with the details of these phenomena in their records. Yet, such records are valuable sources of knowledge for historians studying these natural phenomena in their historical contexts. A few studies on such records have been published, each of which focuses on one or several kinds of phenomena. Nevertheless, no systematic effort has been made to analyze the precision of these records, their methodology, and their possible reliance on earlier sources. In this project, we aim to present these records in the form of a digital platform that will allow scholars to study and investigate their accuracy. Special attention is paid to the literary aspects of these historical records.

In this work, we present the collective effort since 2016 to improve our knowledge of the solar activity of the last four centuries based on the daily counts of the number of sunspot groups. Multiple authors have shown that the main task that can improve our knowledge of the solar activity of the last four centuries is the revision and recovery of old telescopic observations of sunspots, especially in the 17th and 18th centuries where there are the largest gaps and the most important uncertainties. We place special emphases on the observations made during the Maunder Minimum (1745-1715), a time with a very low solar activity.

The ISIS Topside Sounder Project - Rescuing a Unique Ionospheric Data Set

DOI: 10.57757/IUGG23-4771 - LINK

Dieter Bilitza[1], Robert Benson[2]
[1]George Mason University, Department of Physics and Astronomy, Fairfax, USA
[2]NASA/Goddard Space Flight Center,
Geospace Physics Laboratory- Heliophysics Science Division emeritus, Greenbelt, USA

Modeling of the topside ionosphere (from F peak to ~2000 km) suffers from a scarcity of data because ground ionosondes only reach up to the F peak. Millions of topside ionograms had been recorded by the Alouette 1,2 and ISIS 1,2 satellites between 1962 and 1990 that were never fully analyzed. The satellites carried topside sounders, the satellite equivalent of the ground-based ionosonde, and provided the first global view of the topside ionosphere. The topside sounders were designed as analog systems that recorded ionograms on 35 mm film for analysis by visual inspection. Many nations participated in the data analysis process that involved manual scaling of the ionograms and inversion into electron density profiles. But because of the tedious manual process only a small percentage of the recorded ionograms was converted to electron density profiles. We were able to digitize a significant portion of the 60 satellite years of analog data before the tapes were discarded. In a second step we worked with a team at the University of Massachusetts Lowell who developed the Topside Ionogram Scalar with True-Height inversion (TOPIST) software for the automated scaling and inversion of the traces on the digital ionograms into electron density profiles thus avoiding the very limiting manual process.

As a result of our project close to a million digital topside ionograms and electron density profiles are now available for browsing/plotting/downloading at NASA's Space Physics Data Facility (https://spdf.gsfc.nasa.gov). We will review some of the science results based on the digital data.

A review of early graphical continuous record and their technical problems

DOI: 10.57757/IUGG23-3831 - [LINK]

Josep Batlló Ortiz[1]
[1]*Institut Cartografic i Geologic de Catalunya, Geophysics, Barcelona, Spain*

Obtaining continuous record of Earth variables, now a standard, has been a problem for centuries. First attempts for graphical continuous records started in the XVIII Century; but those early attempts did not generalize. It was necessary to wait until the second half of the XIX Century for their generalization.

The continuous record was hampered by technical problems. Continuous analogue records were obtained on paper support (smoked, ink photographical, etc.) and a main issue was to get enough power for the mechanism moving the paper sheets. A second problem was to get a stable speed for the records. All these problems were not really overcome until the second half of the XX Century, when electrical power generalized all over the world and allowed powerful and precise mechanism to sustain properly the advancement of the recording sheets.

Other problems were the limited amplitude and resolution posed by the sheet's dimensions and the paper speed, as well as the frequency band wide required. These problems forced original and specific solutions for each case. In fact, graphical continuous recording was a continuous trade between the desired record and the technical available solutions,

This presentation reviews the evolution of the analogue continuous record in several fields of geophysics (meteorology, seismology, oceanography, geomagnetism) pointing some insights allowing a better interpretation of the recorded series.

The continuous record was hampered by technical problems. Continuous analogue records were obtained on paper support (smoked, ink photographical, etc.) and a main issue was to get enough power for the mechanism moving the paper sheets. A second problem was to get a stable speed for the records. All these problems were not really overcome until the second half of the XX Century, when electrical power generalized all over the world and allowed powerful and precise mechanism to sustain properly the advancement of the recording sheets.

Other problems were the limited amplitude and resolution posed by the sheet's dimensions and the paper speed, as well as the frequency band wide required. These problems forced original and specific solutions for each case. In fact, graphical continuous recording was a continuous trade between the desired record and the technical available solutions,

This presentation reviews the evolution of the analogue continuous record in several fields of geophysics (meteorology, seismology, oceanography, geomagnetism) pointing some insights allowing a better interpretation of the recorded series.

Preliminary study of tectonic tremor location using analog seismograms on recording paper of the Kanto-Tokai Observation Network

DOI: 10.57757/IUGG23-2831 - LINK

Takanori Matsuzawa[1], *Tetsuya Takeda*[1]
[1]*National Research Institute for Earth Science and Disaster Resilience, Earthquake- Tsunami and Volcano Network Center, Tsukuba, Japan*

Slow earthquakes have been extensively studied since the discovery of tectonic tremor (hereinafter, tremor; Obara, 2002, Science). However, the past activity of tremor before 2000 is still not clear in the Nankai region, Japan. National Research Institute for Earth Science and Disaster Resilience operated the Kanto-Tokai Observation Network since late 1970, and has stored analog seismograms on recording paper. This is a unique dataset to reveal tremor activity in the Tokai region in 1980's. In our previous study, we developed a tool to digitize data from scanned images of these seismograms (Matsuzawa and Takeda, 2021, AGU). However, it was difficult to locate tremor using the digitized data directly, due to the contamination of time marks for each second. We report a preliminary result of tremor location using these seismograms, reducing the effect of time marks.
At first, we modeled the time series of time marks as repeating spike-like signals at the interval of 1 s. The modeled time series are subtracted from the original data to reduce the effect of time marks. By this correction, peaks at 1Hz and 2Hz are less dominant in the power spectrum. Then, we tried to locate tremor in the Tokai region at 5am on Apr. 27, 1988, using the corrected seismograms at four stations. We located tremor close to the Shimoyama station in the central Tokai region at 5:33-5:34am, based on the differences of arrival times which are estimated by the correlation of envelope waveforms.

The importance of preserving analog seismic data has been fully acknowledged in the seismological community for years. Now, the Federal Institute for Geosciences and Natural Resources (BGR), Germany, has announced a pilot study which aims to estimate the possibility of digitizing all seismic records in Germany. This study is performed by researchers from the Universities of Potsdam and Hamburg who have strong expertise in working with analogue seismic data.

There are at least 12 institutions in Germany which store more than one million analog seismic records and corresponding metadata. We have contacted the institutes representatives and have their support for the project. We plan to visit all archives to document their content in a comprehensive catalogue with detailed description of data and metadata.

In order to estimate the workload for scanning and digitizing all German archives and for quality control, a test run will be performed. This step includes the scanning and digitizing of a selection of paper seismograms into a digital time-series and scanning of paper bulletins and station books. The seismograms from three stations will be collected for a limited continuous time period. One or two events will be selected to determine earthquake source parameters (e.g., location, magnitude and focal mechanism). As a result, a guidebook with a feasible workflow, recommendations (e.g., for scanning facility, digitization software), and pitfalls (e.g., lacking proper scaling) will be prepared.

Finally, we will provide a long-term concept for preservation and digitization of all analogue seismic records and corresponding metadata available in Germany.

Filling a ~60 years void of instrumental parametric data in observational seismology

DOI: 10.57757/IUGG23-0474 - LINK

Domenico Di Giacomo[1]
[1]*International Seismological Centre, ISC, Thatcham, United Kingdom*

Before the introduction of online data sharing and computer-based archiving and processing of instrumental data, the results of observational analyses of seismograms were stored in printed bulletins produced by individual observatories and national as well as regional agencies around the world. Since late 2010, many digitization were undertaken by the International Seismological Centre (ISC, www.isc.ac.uk). With this contribution we aim to summarize the wealth of (new) data the ISC brings to the seismological community for earthquakes occurring as early as 1904. Therefore, the data digitized in these years fills a large gap in electronic bulletin data availability and complements the data freely available from the ISC Bulletin starting in 1964. We expect this data to be an asset for studies of earthquakes occurred in the pre-digital era as well as for seismogram digitization initiatives.

Over the last 150 years, the seismological community has accumulated millions of ground motion records on both paper and film. While almost all analog seismic recording ended by the late 20th century, replaced by digital media, the still-extant archives of paper and film seismograms are invaluable for many ongoing scientific applications. This long-running record of ground motion is crucial for developing understanding of how both natural and anthropogenic events have changed the Earth and its processes throughout the last century. Legacy seismic archives are the sole source of data from the remarkably large earthquakes of the 1960s, above-ground and submarine nuclear tests, and over a century of hurricane-related signals that are changing with global climate.Today, most of these records are housed in institutions with limited resources, which must prioritize certain objects or types of objects for preservation and access. For example, when seismologists today are forced to triage collections, the bulky paper-records are oftentimes more at-risk for deaccessioning than more compact film copies. However, alterations introduced in reformatting (i.e., paper to film) as well as preservation requirements of the various records are not often fully understood or appreciated. To make these decisions in an informed way, it is vital to know the stability of the recording media and the level of accuracy that can be obtained from these different records. For example, image distortion and available color depth in paper and microfilm copies can result in discrepancies in derived time series which could lead to significant errors in products such as nuclear test yield and location.We present lessons learned from recent experiences with modern archiving and processing of legacy seismic data. These include techniques for data rescue (including both scanning and conversion to time series), the importance of characterizing the full processing chain, and the importance of involving archivists and citizen science in preservation efforts.

We review in this work the activities carried out by our geoscience research group using historical data especially focused on the Extremadura region (SW Spain). We describe some recent works such as the use of correspondence by the Duke of Feria to create precipitation and temperature indices for the period 1750-1840 or the systematic recovery of old meteorological data (including data on unusual variables related to solar radiation). We also describe the work we are doing recovering news about events of interest in geosciences from regional newspapers (meteorological phenomena, earthquakes, fireballs, aurorae at low latitude, ...). Finally, we show a rare episode of great thunderstorms that devastated the Extremadura region in June 1925.

Recovering the Italian daily hydrological measurements with a citizen science approach

DOI: 10.57757/IUGG23-3414 - LINK

Paola Mazzoglio[1], Miriam Bertola[2], Luca Lombardo[1], Alberto Viglione[1], Francesco Laio[1], Pierluigi Claps[1]

Institute of Hydraulic Engineering and Water Resources Management, Vienna, Austria

The availability of long and reliable records of hydrological data is essential for hydrological analyses, especially under climate change.
In Italy the collection of hydrological data has been managed at the national level by the National Hydrological and Mareographic Service (SIMN) since early 1900. The dismantlement of the SIMN, that occurred about 30 years ago, resulted in data collection being transferred to the regional level. This change has determined problems in the availability of complete series for the whole country. Historical hydrological measurements are usually available only in the printed version of the Hydrological Yearbooks and limited efforts have been spent to digitize this collection. This lack of information is critical in a nation like Italy, with both a complex geomorphology and a changing climate.
Despite the remarkable improvements achieved in recent years by Optical Character Recognition software and machine learning / artificial intelligence techniques, in several cases the most accurate digitization approach is still based on manual transcription. Within the SIREN (Saving Italian hydRological mEasuremeNts) project we aim to digitize these data by crowd-sourcing the recovery of hydrological measurements from historical Hydrological Yearbooks to produce a consistent dataset. Phase 1 of the SIREN project will be devoted to recover more than 17000 annual tables of daily discharge measurements. This considerable amount of data not only will allow us to better understand the climate of the past century but will also serve to inform models whose objective is to estimate how the climate and the hydrological cycle will change in the future.

Using citizen science to rescue sea level data in danger

DOI: 10.57757/IUGG23-0938 - LINK

Andrew Matthews[1], Elizabeth Bradshaw[1], Joanne Williams[1]
[1]National Oceanography Centre, Permanent Service for Mean Sea Level, Liverpool, United Kingdom

Long term records of observations of sea surface height from tide gauges form the backbone of our understanding of variability in mean sea level, tides and storm surges. Unfortunately, many longer records are still inaccessible, as the data only exist as paper records, or have been scanned but never digitised into usable data. Recovering historical observations and making them freely available makes a vital contribution to our ability to understand the past and forecast what might happen in the future.

In 2021, we coordinated about 4000 volunteers through the Zooniverse website to transcribe scans of handwritten ledgers containing 15-minute tide gauge records from 1853 to 1903 from two sites in North West England. We report on the feasibility of using this process for other rescue projects, the unusual quality control requirements for volunteer transcriptions, and present the newly restored data with 19th century tides, storm surges and sea level. The 1903 data have contributed to reanalysis of a severe storm event, together with newly digitised pressure records.

We will also discuss plans for distributing the recovered data in a FAIR way, and we will also present some of our ideas to rescue more data, particularly from tidal charts.

We installed and made measurements on three ocean-bottom GNSS-Acoustic (GNSS-A) sites in 2017-21 spanning 3 sections of the Alaska subduction zone to determine the along-strike variability of megathrust coupling. Interpretation of the resulting time series requires the associated errors and their spatial and temporal correlation. The primary source of error for GNSS-A is change in the ocean sound speed field. Our observing strategy is designed to mitigate vertical changes in the sound speed profile, the impacts of lateral variations in sound speed, however, are only somewhat reduced through this observing geometry. Here we identify and estimate the magnitude of lateral sound speed variations on our GNSS-A measurements. The error structure reflects the contribution of many different oceanographic processes. For 10-60 min time periods perturbations from internal waves are the dominant feature. Longer period perturbations are generated by tidal currents, transient events such as eddies, and seasonal processes. We use an autocorrelation approach to examine the error structure within the GNSS-A residuals to estimate the period and magnitude of the internal waves during our observation campaigns. We use the Hycom high resolution numerical ocean model to explore the lateral variations of the sound speed field at longer spatial and temporal scales and provide a statistical characterization for the perturbations in centroid position estimates due to lateral gradients captured by the model. Combining these with predictions for the times of our observations full a-priori variance-covariance matrix can be created for modeling our position time-series.

Although GNSS-A (Global Navigation Satellite System–Acoustic ranging combination technique) observation is a technology that measures steady or sudden seafloor crustal deformations at the centimeter level, the technical capabilities are inferior to those of terrestrial GNSS observation in terms of accuracy and frequency. Therefore, many technological developments are currently underway.
We are conducting error factor analysis through simulation and experimental research in order to improve the observation accuracy and frequency of SGO-A, which is operated by the Japan Coast Guard. By investigating the effects of high-rate GNSS on GNSS-A, development of representation and modeling methods of underwater sound speed fields, and equipment and angle-dependent characteristics due to sonar characteristics, we are progressing in developing quantitative evaluation and correction methods for errors. The accuracy research of GNSS-A is closely related to the accuracy research of GNSS. In the near future, we would like to construct a unified error correction method for instruments and observation envirnments, similar to GNSS.
Regarding the observation frequency, we have reached the limit of observation frequency using ships around 2020, and the development of new sea surface platforms is necessary. For example, research on autonomous buoys (wave glider), moored buoys, and flying-boat type UAVs is underway. Various marine engineering applications other than GNSS-A are underway for a research field of sea surface platforms, and this field may be further updated in the future. In this presentation, we will also discuss new sea surface platforms for GNSS-A.

Decadal postseismic deformation of the 2011 Tohoku-oki earthquake revealed by GNSS-acoustic observations using manned and unmanned sea surface platforms

DOI: 10.57757/IUGG23-0753 - LINK

Takeshi Iinuma[1], Motoyuki Kido[2], Fumiaki Tomita[2], Ryota Hino[3], Yusaku Ohta[3], Tatsuya Fukuda[4], Plata-Martínez Raymundo[1], Takane Hori[1]

While 12 years have already passed since the 2011 Tohoku-oki earthquake (M9.0), postseismic deformation of the earthquake is still ongoing. In order to detect the postseismic deformation of the Tohoku-oki earthquake, we have been performing repeating observations at seafloor sites for the GNSS-Acoustic (GNSS-A) geodetic observation technique since 2012 using both manned research vessels and an unmanned surface vehicle, called Wave Glider (WG), as a sea surface platform. We developed and tested a system to conduct the GNSS-A observations using the WG in 2019 and have continuously operated the system twice a year since 2020, visiting many (around 15) observation sites. Based on the observation data collected using research vessels and the WG, we estimated the displacement time series of the seafloor transponder array of each site. The spatio-temporal variations in seafloor crustal deformation after the 2011 Tohoku-oki earthquake indicate that the viscoelastic relaxation is the primary cause of the westward motion around the main rupture area of the M9 event, while the afterslip on the shallow plate interface played an important role in producing eastward displacements in the region south to the main rupture area. With respect to the region north to the main rupture area, no distinct spatial deformation pattern has been observed. This implies that multiple factors, i.e., viscoelastic relaxation, afterslip, interplate locking, and episodic slow slip events, are responsible for the complicated spatial deformation in this region. We will also report the current conditions of the equipment for GNSS-A observations in the presentation.

As one of the seafloor geodetic techniques, precise seafloor positioning by the GNSS—Acoustic ranging combination technique (GNSS-A) is applied for the observations of the crustal deformation in the plate subduction zones (e.g., Spiess et al., 1998; Fujita et al., 2006). For the precise positioning with the GNSS-A, it is required to appropriately cancel or correct the effects of sound speed variation on acoustic travel time. We have developed static GNSS-A analysis methods where the sound speed effects were simultaneously corrected with well-distributed acoustic data, by introducing the perturbation field model (Watanabe et al., 2020). Based on the empirical Bayes approach, it was implemented in an open-source software GARPOS (the latest version is v1.0.1, https://doi.org/10.5281/zenodo.6414642), in which hyperparameters are selected to minimize the Akaike Bayesian Information Criterion (ABIC; Akaike, 1980). Watanabe et al. (under review, preprint https://doi.org/10.21203/rs.3.rs-1881756/v1) developed the upgraded version of GARPOS, i.e., GARPOS-MCMC (the latest version is v1.0.0, https://doi.org/10.5281/zenodo.6825238), with a full-Bayes GNSS-A analysis scheme, where the hyperparameters are also expressed as probability density functions. The parameters are estimated with the Markov chain Monte Carlo method, which enabled us to directly sample from the joint posterior of parameters including any hyperparameters and evaluate the correlations between those parameters. However, it requires computational resources as the number of acoustic data becomes large. To overcome the disadvantage, we introduced the widely applicable Bayesian information criterion (WBIC; Watanabe, 2013) for model selection for some hyperparameters, to partly take an empirical Bayes approach, and implemented it on GARPOS-MCMC.

Abstract: The performance of underwater acoustic positioning and navigation is greatly influenced by the systematic errors related to the time delays and the time-varying sound speed. Therefore, one of the key issues of underwater acoustic positioning and navigation is how to reduce the effect of the systematic errors. In this study, we propose a systematic error estimation and modeling method. The method firstly constructs an improved acoustic observation model based on the cubic B-spline curve and the nadir total delay (NTD), meanwhile, the transponder coordinates as well as the systematic errors related to the sound speed and the time delay are estimated. Then we use the polynomial fitting method to construct systematic error model and broadcast to underwater acoustic navigation user. Finally, the augmented underwater acoustic navigation is performed based on correction information. The proposed algorithm is verified by a real experiment for the underwater acoustic positioning and navigation in the South China Sea. The results demonstrate that the proposed algorithm can efficiently reduce the influence of systematic errors, thus improving the underwater acoustic positioning and navigation accuracy. The inside precision of seafloor datum positioning can reach cm level. The root mean square error (RMSE) of underwater acoustic navigation is about 1 m within the datum network compared to the results of global navigation satellite system (GNSS).

Keywords: Underwater acoustic positioning and navigation; Systematic error; Time delay; Sound speed error; Nadir total delay

Acknowledgments: The study is financially supported by Laoshan Laboratory (LSKJ202205104), National Key Research and Development Program of China (2020YFB0505804), National Natural Science Foundation of China(41931076), Foundation of Key Laboratory of Marine Environmental Survey Technology and Application, Ministry of Natural Resources, China (MESTA-2020-B013).

Geophysical Exploration of Deep-Sea Massive Sulphide Deposits

DOI: 10.57757/IUGG23-3278 - LINK

Katrin Schwalenberg[1], Hendrik Müller[1], Udo Barckhausen[1], Thomas Kuhn[1]
[1]Federal Institute for Geosciences and Natural Resources BGR,
B1.4 Marine Resource Exploration, Hannover, Germany

Deep-sea hydrothermal fields (HTF) associated with the formation of seafloor massive sulphides (SMS) may become a future source of high-tech metals, which are in high demand for the energy transition. The identification and evaluation of the deposits are challenging, as they are relatively small and form in complex terrain at mid-ocean ridges, island arcs, or back-arc spreading centres. Active HTFs are often accompanied by black smokers and have an abundant, environmentally sensitive fauna. Tt is generally agreed that they should be excluded from possible mining. The economically interesting inactive and extinct fields often miss the characteristic seafloor expressions and distinct vent fauna, and may be hidden under a thin layer of sediments. Thus, video observations and sampling are not sufficient to evaluate the extent of the SMS deposit.Since 2015, BGR undertakes annual research cruises to the German SMS license areas along the Indian ridges (INDEX project) with the aim to find prospective mineral deposits and establish environmental baseline studies. Several unknown HTFs have been identified using a multidisciplinary approach. An important aspect in mineral resource assessment is the inner structure and size of the deposits, which can be addressed by geophysical methods. In addition to magnetic and bathymetric surveys, we apply electromagnetic and self-potential methods on deep-sea sensor platforms. We can clearly relate electrical conductivity, magnetic and self-potential anomalies to previously identified sulphide sites of active and inactive hydrothermal areas. However, deriving spatial constraints is still one of the most challenging and vital disciplines of geophysical exploration in this context.

Computation of the electrical conductivity for rocks containing smectite

DOI: 10.57757/IUGG23-1288 - LINK

Electromagnetic surveys such as magnetotellurics are known to be sensitive to the presence of smectite, which is abundant in subduction zones. However, the contribution of smectite to bulk conductivity is complex and still needs to be quantitatively understood better. Therefore, in this study, we investigated the effect of smectite on bulk conductivity by numerical modeling using the finite element method. In our simulations, we investigated the effects of four conditions: porosity, fraction of smectite in the quartz matrix, temperature, and NaCl concentration of pore water. Here, we randomly assigned each element's conductivity tensor of either material: smectite, quartz, or pore water. In addition, we introduced an anisotropy to the conductivity tensor of smectite between the directions parallel and perpendicular to the T-O-T layer. Meanwhile, the conductivity tensors of quartz and pore fluid were considered isotropic. The simulation results showed that the spatial arrangement of the materials significantly affected the bulk conductivity for the porosity greater than 0.01. In contrast, for smaller porosity, the effect of the spatial arrangement was almost negligible, and the volume fraction of smectite, pore water salinity, and temperature controlled the bulk conductivity. These results suggest that proper parameterization of the element arrangement patterns is essential when calculating the bulk conductivity of smectite-bearing rocks.

Magnetotelluric (MT) signal is a natural electromagnetic (EM) response that can penetrate up to hundreds of kilometers deep in the earth's interior. When deployed at the seafloor, ocean bottom MT receivers provide us quality EM data that can decipher both regional and large-scale conductivity structures underneath the seafloor. Knowledge of such structures is critical in the studies of Earth's interior and marine geohazards. A key step in interpreting these deep sea EM data is accurate modelling of the data over various plausible marine conductivity models, where the existence of highly conductive sea water poses as a main challenge in improving the modelling accuracy. The accuracy degeneration issue caused by the seawater becomes more severe for three-dimensional (3D) studies in which fine discretizations of seawater layer are often required. To ensure modelling accuracy, we have developed high-order finite element (FE) modelling techniques in conjunction with unstructured triangular (2D) and tetrahedral (3D) meshes. Using the high-order FE methods, excessively large meshes are avoided since the seawater layer does not need to be finely discretized. Our modelling code has been tested and can provide accurate modelling results of marine MT data for a large range of frequencies. The modelling accuracy is demonstrated using both 2D and 3D examples. Using the newly developed code, we aim to study deep conductivity structures over various seafloors of interest.

Lithosphere-asthenosphere boundary dynamics revealed from magnetotelluric data at the Mid-Atlantic Ridge

DOI: 10.57757/IUGG23-4635 - LINK

Shunguo Wang[1], *Ståle Emil Johansen*[2]
[1]*NTNU, Department of Electric Systems, Trondheim, Norway*
[2]*NTNU, Department of Geosciences and Petroleum, Trondheim, Norway*

Lithosphere-asthenosphere boundary (LAB) is essential for tectonic plates as it is the base of the plates and enables movement of the plates. However, the nature of the LAB, including its depth, is still elusive. The definition of LAB varies from study to study by using different geophysical data. Oceanic LAB has a simpler history than continental LAB, therefore it is ideal to study the nature of LAB beneath the seafloor. Partial melt is one feature of LAB suggested in multiple geophysical and petrophysical studies. The magnetotelluric method is sensitive to partial melts and is one of the most effective methods to map partial melts and study LAB. Therefore, we have collected three different datasets in Northern Middle Atlantic Ridges to further study the electrical property of LAB. The eLAB at different latitudes is more dynamic than we previously thought. The resistivity model of LAB can be simple at one location and complicated at another location of the Mid-Atlantic Ridge. More interestingly, at some locations, the upwelling magma is not seen beneath the middle ocean ridge in the resistivity model, which is supposed to be the supplier of seafloor spreading materials. These findings enrich the understanding of the geodynamics of Earth and suggest that a more complicated model is necessary to represent LAB.

Seafloor Slumping due to Gas Hydrate dissociation : A Case Study from Krishna-Godavari basin

DOI: 10.57757/IUGG23-3159 - LINK

Jyothsna Palle[1], *Satyavani Nittala*[1]
[1]*CSIR-National Geophysical Research Institute, Seismic Group, Hyderabad, India*

The Krishna Godavari (KG) basin is a passive margin basin with slumps, mass flows occurred due to rapid sedimentation, gas hydrates etc. To understand the dissociation mechanism of gas hydrates on slumping/sliding, 3D seismic data from a small region in the KG basin is examined in the present study. Seismic Interpretation of the data reveals shoaling of the Bottom simulating reflector (BSR) followed by truncation further downslope, creating slope failure. The role of pressure and temperature in altering the hydrate stability is studied and found that the temperature change is the main parameter that controls the gas hydrate stability. The Base of the hydrate stability zone (BHSZ) during the Glacial time and the present day is computed with varying Geothermal Gradients (GTG) of 45 ± 3° C/ km. The obtained results show that the BHSZ has shifted by 80 m post-glacial at a water depth of ~ 1000 m. Our results also shown that changing the GTG in the range of 43-48° C/ km has caused only a ten-meter change in the shift, but changing the seafloor temperature from 4-6.5°C has caused 80 meters shift in the BHSZ. We find a close correlation with the depth of dissociation inferred from interpretation of seismic data and dissociation temperature computed. Two slumping features were observed in the seismic data of varying size; the smaller one is attributable to the over pressurized zone below the BSR and the larger one (~21km), seems to have formed as a result of gas hydrate dissociation.

Bathymetry changes from ICESAT-2 -A case story from Moreton Bay Australia

DOI: 10.57757/IUGG23-4660 - [LINK]

Ole Andersen[1], *Xiaoli Deng*[2], *Richard Coleman*[3]
[1]*DTU Space, Geodesy and Earth Observation, Kongens Lyngby, Denmark*

[3]*University of Tasmania, Institute for Marine and Antarctic Studies IMAS, Hobart- Tasmania, Australia*

The bathymetry of coastal bay environments, like Moreton Bay around Brisbane in eastern Australia, is constantly reworked because of changes in the patterns of energy dispersal and related sediment transport pathways. Updated and accurate bathymetric models are a crucial component for scientific, environmental, and ship safety studies.

NASA's Ice, Cloud, and Land Elevation Satellite-2 (ICESat-2) was launched in September 2018 and carries a single instrument, ATLAS (Advanced Topographic Laser Altimeter System). ATLAS is a green wavelength, photon-counting lidar, enabling global measurement and monitoring of elevation with a primary science focus on the cryosphere. However, ATLAS's green laser frequently penetrates the air–water interface, and under the right conditions and in shallow waters (<40 m), these photons are reflected back to ATLAS after interaction with the ocean bottom.

An Australian Research Council funded research project "Enhancing marine bathymetry using new-generation satellite sensors" commenced in 2022. We present the first results from this project on the use of ICESAT-2 along selected 91-day repeat tracks across Moreton Bay to investigate changes in bathymetry over the past 4 years. Moreton Bay has had significant changes in bathymetry with time, but significant suspended sediment creates problems for ICESat-2 photons to propagate through the water column.

Monitoring seafloor deformation using bottom pressure and ocean models: An A-0-A experiment in the context of the Mayotte volcanic crisis

DOI: 10.57757/IUGG23-4991 - LINK

Yann-Treden Tranchant[1], Valerie Ballu[1], Denis Dausse[1], Laurent Testut[1]
[1]CNRS - La Rochelle Université, LIENSs, La Rochelle, France

The use of ocean bottom pressure (OBP) records is crucial to monitor seafloor motion caused by tectonic and magmatic processes. However, accurately monitoring seafloor deformation through time with OBPs is challenging due to instrumental drift and oceanic variations at different timescales. In the context of the Mayotte volcanic crisis in the western Indian Ocean in 2018, three RBR Ambient-Zero-Ambient (A0A) drift-controlled pressure gauges were consecutively deployed (2020-2022) to monitor seafloor vertical deformation. The A0A system estimates instrumental drift by periodically venting ocean pressure to a reference atmospheric pressure.

Since no significant vertical ground displacements have been recorded by ground GNSS stations since 2020, this study aims to assess the calibration method of the A0A system, reduce oceanic “noise” in corrected OBP records, and discuss the ability to observe any seafloor deformation offshore Mayotte. Numerical models, including ocean circulation (OGCMs) and barotropic models, were used to understand the influence of the different processes and to reduce the oceanic “noise” in drift-corrected OBP records. Additionally, temperature and salinity data collected by repetitive glider transects were used to validate OGCMs in the region and quantify the contribution of unresolved processes to OBP records.

Our results provide valuable insights into the feasibility of using numerical modeling for improving the accuracy of OBP-based monitoring in the context of the Mayotte volcanic crisis as well as for other seafloor deformation monitoring. It also has important implications for future A0A deployments and in the perspective of the planned MARMOR seafloor cabled observatory.

OBP (Ocean bottom pressure-gauge) is an essential sensor in crustal deformation observation in the marine region. Still, non-tidal oceanographic fluctuations in OBP data are a significant source of noise in seafloor transient crustal deformation observations, including SSEs (slow slip events), so it is essential to evaluate them properly. To extract and assess the significant characteristics of the oceanographic fluctuations, we applied PCA (principal component analysis) to the DONET (Dense Oceanfloor Network System for Earthquakes and Tsunamis, southwest margin of Japan) OBP time series of 40 stations for three years (2016–2019). PCA could separate several oceanographic signals based on the characteristics of their spatial distributions. The higher-order modes of the PC were distributed in a varying manner with sea depth, and we interpreted that they were caused by the strength and meandering of the ocean geostrophic currents based on similar spatial distribution with the global ocean models. Since PCA cannot detect the significant tectonic signal in observed data, we applied a synthetic ramp simulating SSE to the observation to evaluate the performance of PCA in tectonic signal detection. The assumed synthetic ramp could be separated into an independent principal component according to its amplitude (i.e., the scale of the events). We proposed a detection method of a transient event using the spatial distribution change of the principal component with and without the synthetic ramp using their normalized inner product. Our method was able to detect the tectonic signal of events of M_W5.9 or larger from the OBP time series.

It is essential to comprehend how fluid concentration in rocks affects the hydrocarbon reserve and monitor fluid concentration for a sequestration or enhanced oil recovery programme. A prediction of saturation is highly uncertain due to the prior assumption that gas distribution is uniform or patchy in a rock physics theory. We therefore use the capillary pressure equilibrium theory (CPET) to develop a reservoir model that corresponds to the physics of capillary-induced fluid invasion and avoids the uncertainty associated with the type of gas distribution in pores. Assuming that the rock frame has not significantly changed throughout the field, we develop a CPET model utilising the reservoir parameters of the clean and unconsolidated sandstone formation of the Sleipner field, North Sea, which is the first industrial-scale CO_2-injection operation ever. The fluid content of the Sleipner field is then estimated by interpreting the time-lapse seismic inversion results using the model. According to our research, CO_2 is similar to a uniform distribution at higher concentrations, whereas it is mostly a somewhat patchy type at lower concentrations, or somewhere in between patchy and uniform distribution. Maximum CO_2 saturation is predicted using the CPET as 75% of the pore space. The topmost layer's CO_2-plume footprint is expanding from zero in 2001 to 7X105 sq. m. in 2010, according to a quantitative interpretation of six time-lapse seismic data sets from 1999 to 2010. Our model predicts that 50 years after the start of injection, CO_2 from all layers below will migrate to the top layer.

The recent proliferation of broadband ocean bottom seismometer (BBOBS) deployments has generated datasets from diverse marine environments, improving our understanding of tectonics and earthquake processes. In turn, the community of scientists using this data has expanded. This growth in BBOBS data collection is likely to persist with the arrival of new seismic seafloor technologies, and continued scientific interest in marine and amphibious targets. However, the noise inherent in OBS data poses a challenge that is markedly different from that of terrestrial data. As a step towards improved understanding of the sources of variability in this noise, we present a new compilation and analysis of BBOBS noise properties from 15 years of US-led seismic deployments. We find evidence for similarity of noise properties when grouped across a variety of parameters, with groupings by seismometer type and deployment water depth yielding the most significant and interpretable results. Instrument design, that is the entire deployed package, also plays an important role, although it strongly covaries with seismometer and water depth. We find that the presence of tilt noise is primarily dependent on the type of seismometer used (covariant with a particular subset of instrument design), that compliance noise follows anticipated relationships with water depth, and that shallow, oceanic shelf environments have systematically different microseism noise properties (which are, in turn, different from instruments deployed in shallow lake environments). We discuss implications for the viability of commonly used seismic analysis techniques, and future directions for improvements in the efficiency of analysis of BBOBS data.

The recent Surface Water Ocean Topography (SWOT) altimeter mission measures two-dimensional SSHs along two 50-km-wide swaths and one-dimensional SSHs along the nadir track, providing a significant opportunity to improve the accuracy and resolution of geoid gradients essential for marine gravity modeling. This study investigates the accuracy of determining north and east components of geoid gradients using simulated SWOT SSHs in the northern part of the South China Sea. SWOT SSH data were simulated using ocean depths from multi-beam and the GEBCO_2020 bathymetry model and the DTU mean sea surface. According to the unique characteristic of high-resolution two-dimensional SWOT SSH observations, we developed a new method that determines north and east components of geoid gradient at the grid point based on geoid gradients computed in along-, cross- and middle-track directions using the least-squares adjustment (LSA). For comparison purpose, the gradient components were also computed using the least-squares collocation (LSC). The accuracy of determined gradient components is assessed using the quasi-true values of gradients computed by numerical differentiations from the SWOT simulation model. The RMSE results are 0.51 (0.42) microrad and 1.12 (0.91) microrad for LSA (LSC) estimates of north and east components, respectively, in the study area. The results indicate that the LSA gradient solution is computationally efficient and compatible with those by the LSC. The SWOT mission significantly improves the accuracy of estimated gradient components when compared to Jason-2 and Cryosat-2.

EMSEV's first chairperson, Professor Seiya Uyeda passed away on January 19, 2023, at the age of 93. Electromagnetic monitoring of active faults and volcanoes was driven by hopes of predicting earthquakes and eruptions in the 1970s to the 1990s. Groups from many countries across the world installed instruments and the newly obtained results were presented at many meetings (IUGG, IASPEI, IAGA, IAVCEI, AGU, etc.).

These new efforts also led to many lively discussions by groups of researchers on the future formation of an Electromagnetic Studies Working Group to bring together isolated researchers located in many different countries throughout the World. Prof. Seiya Uyeda was one of the most active leaders in this field.

The discussion started anew during the 1999 International IUGG GA in Birmingham (UK). This time, Prof. Uyeda's breakthrough concept was to build a joint Inter-Association (IAGA, IASPEI, and IAVCEI) Working Group to link these isolated scientific groups for developing interconnected field research. Finally, the recommendations were submitted to the IUGG Executive Committee to form an inter-association Working Group focused on a common understanding of the physical processes related to earthquake ruptures and volcano eruptions. Thus, the EMSEV (Electromagnetic Studies of Earthquakes and Volcanoes) Working Group was born.

Since then, EMSEV has continued to be active, holding its own general meeting every two years and contributing to the development of electromagnetic research. In the presentation, we would like to praise Professor Uyeda's achievements and introduce the role that EMSEV has played in this field.

De Santis et al. (EPSL 2017) detected that for the first time in Swarm satellite data some magnetic field anomalies associated with the 2015 Nepal M7.8 earthquake, with similar S-shapes for the cumulative number of satellite anomalies and earthquakes, providing an empirical proof on the lithospheric origin of the anomalies. Following the same approach, De Santis et al. (Atmosph. 2019) obtained other promising results for 12 earthquakes in the range M6.1-8.3, in the framework of the ESA funded SAFE (SwArm For Earthquake study) Project. Then, almost five years of Swarm magnetic field and electron density data were analysed with a Superposed Epoch and Space approach finding a robust correlation with major worldwide M5.5+ earthquakes (De Santis et al. Sc.Rep. 2019). The work also confirmed the Rikitake (1987) law, initially proposed for ground data: the larger the magnitude of the impending earthquake, the longer the precursory time of anomaly occurrences. An analogous analysis was also applied in the framework of the ASI funded Limadou-Science Project to the Chinese Seismo-Electromagnetic satellite (CSES) electron density providing similar results (De Santis et al. N.Cim. 2021). Marchetti et al. (Rem.Sens. 2022) confirmed the same result over a longer time series , i.e. 8 years, of Swarm satellite data. Furthermore, we demonstrated in several case studies (e.g. Marchetti et al. JAES 2019, Akhoondzadeh et al. Adv.S.R. 2019; De Santis et al. Fr.E.Sc. 2020) that the integration of CSES and Swarm data with other measurements from ground an atmosphere reveals a chain of processes before many mainshocks.

JA07a - Interdisciplinary Observations of Pre-Earthquake Processes. The Concept of Lithosphere- Atmosphere- Ionosphere Coupling (IAGA, IASPEI (EMSEV)

Recent topics on the ionospheric changes immediately before large earthquakes

DOI: 10.57757/IUGG23-1037 - LINK

Kosuke Heki[1]
[1]*Hokkaido University, Dept. Earth and Planetary Sci., Sapporo-city, Japan*

Densification of continuous GNSS (global navigation satellite system) networks enabled us to observe changes in ionospheric TEC (Total Electron Content) associated with large earthquakes. Here I focus on anomalies immediately before M8-9 class earthquakes. Such preseismic anomalies were first found after the 2011 Mw9.0 Tohoku-Oki earthquake (Heki, 2011 GRL) and later for all the earthquakes in this century with Mw 8.2 or more (Heki & Enomoto, 2015 JGR; He & Heki, 2017 JGR). ~20 examples exhibit scaling laws, (1) leading times range from ~15 minutes (M8) to ~45 minutes (M9) and scale with fault lengths, and (2) anomaly strengths range from ~1 % (M8) to ~10 % (M9) of the background values and scale with fault areas. 3D tomography (Muafiry & Heki, 2020 JGR) showed that the positive/negative anomalies grow simultaneously at low/high altitudes above land and line-up along the geomagnetic field, suggesting crustal electric field responsible for the electron redistribution. Here I also report a few new examples not well studied before, e.g., the 2008 Wenchuan earthquake in China and the 2023 February 6 earthquake in southern Turkey. One difficulty in using this information for practical short-term earthquake forecasting would be its discrimination from space weather origin disturbances. I present a case immediately before the 2022 eruption of the submarine volcano in Tonga. A typical "pre-eruption" ionospheric changes were found, but I demonstrate it was a fake precursor caused by space weather.

Large and shallow earthquakes (minimum magnitude 6.5) generate distinctive ionospheric disturbances detectable using radio signals emitted by Global Navigation Satellite Systems (GNSS). In the recent years, the number of satellites has increased drastically, allowing a refined coverage of the Earth, including the earthquake-prone zones. The subduction zones (e.g. Japan, Indonesia, South America), where most tsunamigenic earthquakes occur, are poorly instrumented because located offshore, far from the coasts. By measuring the integrated quantity of electrons along the satellite-receiver paths, the Total Electron Content (TEC), GNSS satellites offer the capability to sound the ionosphere in all directions, including far from the receiver when satellites can be tracked at low elevation. Besides the enhanced coverage, we further investigate the new capabilities carried out by the new frequencies (L5, E5) offered by the US Global Positioning System (GPS), the European Galileo as well as the Indian Regional Navigation Satellite System (IRNSS) for seismic source studies. We investigate past earthquakes with a multi-GNSS scenario and discuss how such observations can be usefully included in tsunami early-warning systems for the case of an underwater earthquake poorly instrumented. More specifically, we study the morphology of co-seismic TEC signatures derived from numerical modeling results of seismo-acoustic waves. Simulated using an acoustic ray tracing method, atmospheric perturbations are coupled with the ionospheric plasma through transport mechanism by the local geomagnetic field. The electron density perturbation is finally integrated along the known satellite-station line-of-sights, based on the information of GNSS satellite orbits.

Being the first geophysical fields observation satellite mission, CSES-01 has operated for 5 years as scheduled by Feb.02, 2023 and on the basis of its fine performance, CSES-01 will prolong its life until CSES-02 lunching in orbit and collaborative work each other in orbit.

The last 5 years, in retrospect, CSES-01 acquired an amount of data such as geomagnetism field, low frequency electromagnetic waves, in-situ plasma content and temperature, charged particles as well ionospheric plasma CT, in which, more than 50 earthquakes with magnitude greater than 7 and 500 greater than 6 are recorded in globe, together with a series of space weather and volcano phenomenon were recorded. So far, we result positive knowledge on earthquake precursors according to the statistical research and case study of most of these events, and develop the Lithosphere-Atmosphere-Ionosphere Coupling mechanism focusing on its electromagnetic wave channel.

The following prospect plan, CSES-02 is under developing by China-Italy joint team and is due to launch in 2024, which means that we'll have 2 CSES satellites in orbit from 2024. Now we're demonstrating the new mission of IMCP-International Meridian Circle Project, which should be a ground-based observation network with its main objectives on monitoring the geomagnetical field, space weather and interaction among Lithosphere-Atmosphere-Ionosphere. And the main tasks of IMCP are global data sharing, joint research on space weather and natural hazards as well global change, and so on.

The interaction of electric field in LAI coupling mechanism around strong earthquakes in China

DOI: 10.57757/IUGG23-0324 - LINK

Xuemin Zhang[1], *Lei Nie*[1], *Lei Dong*[1]
[1]*Institute of Earthquake Forecasting- China Earthquake Administration, Short-term and impending earthquake forecasting, Beijing, China*

The electromagnetic satellite observations show typical advantages in short-term earthquake prediction due to the strong ionospheric perturbations before earthquakes in 1 week, but the coupling mechanism among lithosphere-atmosphere-ionosphere (LAI) is still a big problem to be faced. Based on the previous models in LAIC, it is found that electric field in atmosphere and ionosphere play significant roles in the coupling processes. Since the launching of CSES in 2018, it has operated for 5 years unitl now. During this time period, there occurred more than 10 earthquakes with magnitude larger than 6 in China, where the biggest one is Maduo Ms7.4 earthquake in May 2021. Around these earthquakes, a lot of disturbances have been detected by satellite and ground based electromagnetic observations. The closer the time to the occurrence time of earthquakes is, the more the parameters with disturbances occurred. 3 or 4 parameters exhibited anomalies simutaneously within 2 weeks or just 1 week prior to half of the earthquakes, to illustrate the close relationship among them. Taking an example, the Yangbi Ms6.4 and Maduo Ms7.4 occurring successively in 4 hours on 21 May 2021 was analyzed in detail. And the electric field in atmosphere and ionosphere was focused on with the observations at ground and satellite. It is concluded that: (1) The atmospheric electric field is illustrated with upward disturances in epicentral region; (2) The relationship between atmospheric electric field with ionospheric electric field and other plasma parameters was validated to improve the reliability of anomaly detection before earthquakes.

We present a multi-parameter study of transient phenomena observed in the Earth's atmosphere-ionosphere environment plausibly associated with the latest major seismic activities in 2021. The year 2021 was the most active period for global seismicity since 2007, with 19 major earthquakes (M7+), three of which were over M8.0. The M 7.2 in Haiti was the deadliest for 2021, with 2,476 fatalities (USGS).

We monitored critical processes in the atmosphere /ionosphere that modify the Earth's plasma environment system under various geophysical conditions, including earthquakes. We collected operational data from several instruments:1. Electric field and plasma observations from the China/Italy Seismo-Electromagnetic Satellite (CSES1); 2/ Outgoing long-wavelength radiation (OLR) obtained from NPOESS); 2/ Atmospheric chemical potential (ACP) obtained from NASA assimilation models; and 3/ Electron density variations in the ionosphere via GPS Total Electron Content (GPS/TEC).

We observed a synergetic abnormal response of satellite OLR data, plasma data from CSES, and GPS/TEC and ACP starting two weeks before the M 8.1 - South Sandwich; M 8.2 – Alaska, US; M 8.1 - Kermadec Islands, NZ, and M 7.2 - Nippes, Haiti earthquake. Our integrating data search reveals different abnormal patterns inside the Dobrovolsky-Bowman estimating earthquake preparation zone. We show that by combining the near-space and ground data accordingly to the physical concept of the Lithosphere-Atmosphere-Ionosphere Coupling (LAIC), we could identify, on a regional basis, abnormal patterns of pre-earthquake-related features in the atmosphere-ionosphere environment. The implications of studying major earthquake events are discussed.

On 6 February 2023 at 01:17 UTC, an M7.8 earthquake occurred in South-Eastern Turkey (37.2°N 37.0°E, 10.0 km depth), and several strong aftershocks have also been observed in the region, notably a magnitude M7.5 (38.0°N 37.2°E, 10 km depth) at 10:24 UTC the same day. Spatial analyses of the total electron content (TEC) of the global ionosphere map (GIM) are employed to observe the latitude-longitude distributions of seismo-ionospheric anomalies (SIAs) during January-February 2023. A global search of 5183 (=73x71) lattices shows that SIAs of significant TEC increases specifically appear near the epicenter on day 24-22 (12-16 January) and 2-0 (4-6 February) before the two earthquakes. The ion density and ion velocity measured by the science payload of Advanced ionospheric Probe (AIP) onboard the FORMOSAT-5 (F5) satellite and the EIA (equatorial ionization crest) distances between northern and southern hemispheres of GIM TEC are used to find the ionospheric electric fields over the epicenter area during the two periods of 12-16 January and 4-6 February 2023.

A long-term (2004-2015) analysis of the fluctuations of Earth's thermally emitted radiation, measured by the Spinning Enhanced Visible and Infrared Imager (SEVIRI) on board the Meteosat Second Generation (MSG) satellite in the thermal infrared (TIR) spectral range (i.e. 10-12 μm), have been performed in order to investigate the complex process of preparation of earthquakes in that area.

Such analysis showed that more than 67% of all identified (space-time persistent) anomalies occur in the pre-fixed space-time window around the occurrence time and location of earthquakes (M≥4), with a false positive rate smaller than 33%. Moreover, Molchan error diagram analysis gave a clear indication of non-casualty of such a correlation, in comparison with the random guess function.

In this paper, the characterization of the signal, in terms of punctual expected values and related variability, have been extended up to 2022 and the Robust Satellite Technique (RST) and RETIRA (Robust Estimator of TIR Anomalies) index applied to identify possible Significant Sequences of TIR Anomalies (SSTAs) in 2023 in relation with the seismic sequence that hit the region of Kahramanmaraş starting with the February 6th, M7,8 EQ.

On Feb 6, 2023, M7.8 and M7.5 earthquakes struck Turkey within 9 hours difference, and with a more than 100 km rupture, were the deadliest earthquakes in Turkey/Syria this decade. We study critical lithosphere/atmosphere /ionosphere coupling processes that precede earthquake events. We combine observations from non -correlated ground and space monitoring systems for the first time, such: 1/ Vertical static pendulums data from the European network; 2/ Outgoing long-wavelength radiation (OLR) obtained from NPOESS; 3/ Ionospheric plasma observations from China/Italy Seismo-Electromagnetic Satellite (CSES1); and 4/ Atmospheric chemical potential (ACP) obtained from NASA assimilation models. The deformation anomalies started at all European pendulum instruments on Jan 23, 2023. The most significant anomaly was recorded in cave No.13 (the Moravian karst). The pendulum is located on the N-S-oriented fault corresponding to the East Anatolian Fault activation (NE-SW). NOAA satellite thermal observations of the epicentral area show an increase in infrared radiation starting in Dec 2022 and riches the maximum on Jan 13 and Feb 1, 2023, near the epicentral area. Increases in OLR from the satellite data coincided with an intensification in the atmospheric chemical potential, Feb 1-4, measured near the epicentral area. The plasma electron and oxygen ion density from the CSES1 satellite showed an abnormal increase on Jan 27-28, which is highly correlated with the earthquake occurrence given the stable space weather index during this period. We show that by combining ground and near-space data accordingly to the physical concept of LAIC, we could identify abnormal patterns of pre-earthquake-related features.

The ionospheric anomalies possibly associated with large earthquakes have been reported by many researchers. In this paper, Total Electron Content (TEC), Ionosonde, and tomography analyses have been applied to investigate the spatial and temporal anomalies of ionospheric electron density prior to the 2011 Off the Pacific Coast of Tohoku earthquake (Mw9.0). Results show significant TEC enhancements and an interesting three dimensional structure prior to the main shock. As for temporal TEC changes, the TEC value increases 3-4 days before the earthquake remarkably, when the geomagnetic condition was relatively quiet. In addition, the abnormal TEC enhancement area in space was stalled above Japan during the period. Tomographic results show that three dimensional distribution of electron density decreases around 250 km altitude above the epicenter (peak is located just the east-region of the epicenter) and increases the mostly entire region between 300 and 400 km. Details and statistical tendency and differences from the case of geomagnetic storms will be also shown in our presentation.

Strong natural hazards events are assumed to be significant sites to investigate the lithosphere-atmosphere-ionosphere coupling (LAIC), showing possibly a multitude of processes up to high altitudes. Until now there is no clear consensus on how specific mechanisms affect the different layers and important questions persist.

In this study we analyse European earthquake events with magnitudes M ≥ 5 based on the USGS catalogue, a second focal point is a particular class of volcanic eruptions selected from Mt. Etna (Sicily, Italy) activity periods.

We examine electric field variations in the earth-ionosphere waveguide along radio paths between narrowband VLF/LF transmitters and ground-based receiver facilities (INFREP network). Those observations are combined with in-situ satellite magnetic field measurements from the missions Swarm and CSES-1 at LEO altitudes. For both investigations spatio-temporal proximity to the event sites is necessary. The selected bundling of the two field parameters enables the steady VLF/LF electric-field measurements from the lithosphere up to the ionospheric D/E-region and the satellite measurements assess parts at the end of the propagation channel in the ionospheric F-region at about 500 km altitude.

Results for volcanic eruptions show a decrease in the VLF/LF electric fields of up to 10 dB with fluctuations in the frequency range of atmospheric gravity waves (AGWs). Earthquakes exhibit larger VLF/LF amplitude values after the event (night-time amplitude method). We find no clear signatures in the ionospheric satellite magnetic field measurements, but future missions like CSES-2 double the revisiting frequency above natural hazards prone areas and will facilitate further in-detail investigations.

In normal mode seismology, the atmosphere and the solid Earth are generally considered to be decoupled, and the seismic wave energy from the Earth's interior is difficult to propagate into the atmosphere. However, a growing number of studies have shown that earthquakes, volcanoes and tsunamis can disturb the Earth's atmosphere due to various coupling effects. Therefore, it is an open question whether normal mode (especially in low frequency) signals can be detected in atmospheric observations. In our study, experiments were conducted to investigate the existence of normal mode signals in surface atmospheric observations using the improved multi-taper method, based on the seismographs and ground-based atmospheric observations of the Global Seismic Network before and after the 2021 Mw8.2 Alaska earthquake. Then, the results showed that the normal mode signal can be detected in the pressure observations by comparing the pre-earthquake, post-earthquake and theoretical calculations. However, since the signal-to-noise ratio varies greatly between stations and modes, direct correction of the barometric pressure by the admittance method may lead to large deviations in the estimation of normal mode parameters. Furthermore, we investigate the generation mechanism of seismic normal modes in surface atmospheric observations, which suggests that these signals originate from crust-atmosphere coupling in the same frequency band, and this possible coupling should be considered in normal mode seismology research.

Over the last few years, the scientific community has made a significant effort to detect and interpret electromagnetic signals that might be related to seismic activity. Recent studies have shown how during or even before strong earthquakes the ionosphere shows characteristic electromagnetic interactions observed as plasma variations or electromagnetic (EM) emissions (both in the ELF and VLF bands). These EM emissions were detected both by ground-based [Pulinets and Boyarchuk 2004] and by space-based [Ouzounov et al. 2011, Pulinets and Ouzounov, 2011] instruments.

However, a robust identification of such EM emissions should start from the definition of statistical distribution of the ionospheric electromagnetic (EM) waves energy in absence of seismic activity and other anomalous inputs (such as the ones derived by solar forcing). In this way, a background in the ionospheric EM emissions over seismic regions can be determined. Only after this step, a proper detection of an EM signal possibly correlated with the seismic activity can be accomplished: every EM signal which differs from the background (exceeding a statistically meaningful threshold) should be considered as a potential event to be investigated.

Therefore, in this study, we performed a multiscale analysis of the ionospheric environmental background, using the entire CSES-01 (China Seismo-ElectroMagnetic Satellite) electric and magnetic field dataset (2018 - 2023), by creating the map of the averaged relative energy (ε_{rel}) over a 1° x 1° latitude-longitude cell, depending on both spatial and temporal scale of the ionospheric medium. The analysis was performed by means of the newly developed Fast Iterative Filtering (FIF) technique.

Geomagnetic activity conditions are considered by the means of the Sym-H index in order to make a proper discrimination between external (atmospheric, ionospheric, magnetospheric, solar and cosmic activities) and internal (earthquakes, volcanoes) sources generating anomalous signals.

Here we present the background obtained for various seismic regions and results obtained for some recent earthquakes.

Over the last few years, the scientific community has made a significant effort to detect and interpret electromagnetic signals that might be related to seismic activity. Recent studies have

shown how during or even before strong earthquakes the ionosphere shows characteristic electromagnetic interactions observed as plasma variations or electromagnetic (EM) emissions (both in the ELF and VLF bands). These EM emissions were detected both by ground-based [Pulinets and Boyarchuk 2004] and by space-based [Ouzounov et al. 2011, Pulinets and Ouzounov, 2011] instruments.

However, a robust identification of such EM emissions should start from the definition of statistical distribution of the ionospheric electromagnetic (EM) waves energy in absence of seismic activity and other anomalous inputs (such as the ones derived by solar forcing). In this way, a background in the ionospheric EM emissions over seismic regions can be determined. Only after this step, a proper detection of an EM signal possibly correlated with the seismic activity can be accomplished: every EM signal which differs from the background (exceeding a statistically meaningful threshold) should be considered as a potential event to be investigated.

Therefore, in this study, we performed a multiscale analysis of the ionospheric environmental background, using the entire CSES-01 (China Seismo-ElectroMagnetic Satellite) electric and magnetic field dataset (2018 - 2023), by creating the map of the averaged relative energy (ε_{rel}) over a 1° x 1° latitude-longitude cell, depending on both spatial and temporal scale of the ionospheric medium. We study the space weather variations like magnetic storms and their impact on earthquake processes. We have found that about two months after creating a new radiation belt in the inner magnetosphere due to a geomagnetic storm, an increasing seismic activity may occur near the magnetic field lines' footprint of a newly created radiation belt. The Combined Release and Radiation Effects Satellite (CRRES) detected a new radiation belt after a geomagnetic storm on March 24, 1991. Shortly after that, on May 30, 1991, a strong M7.0 earthquake occurred in Alaska in the footprint of geomagnetic line L~2.69. Additionally, on October 28, 2012, a strong M7.8 earthquake occurred in Canada near the footprint of L~3.3, which was close to the magnetic lines of a new radiation belt detected by a satellite "Van Allen Probes" after a geomagnetic storm on September 3, 2012. We demonstrate the possible existence of two ways of solar-lithosphere coupling processes: (i) the disturbances in the lithosphere accompanying the earthquake preparation process can modify the electric field in the global electric circuit (GEC), and the vice-versa mechanism, (ii) the solar wind-generated disturbances in the magnetosphere and ionosphere, can modify the electric field in the GEC, that will result in appearing of disturbances in the lithosphere.

An in-land earthquake of magnitude 5.6 struck Cianjur, West Java, Indonesia on November 21, 2022, at 13.21 local time causing severe damage with at least 602 deaths and the destruction of 58.000 houses. The mainshocks–aftershocks analysis suggests that the earthquake resulted from an unmapped fault with a debatable strike orientation. To investigate the subsurface structure of the affected region, we conduct a magnetotelluric (MT) survey, which has been shown to effectively image the faults at the deep subsurface level. In this study, four magnetotelluric stations were installed along a 3 km line profile through the earthquake epicenter with an acquisition time of approximately 20 hours. The MT soundings 2-D modeling inversion results show the resistivity contrast along the profile, revealing the low-resistivity zone interpreted as the existence of an unmapped fault with a depth of up to 10 km that is most probably correlated with the earthquake's hypocenter location. Our findings also provide valuable insights into identifying weak zone in the region for further analysis and seismic hazard assessment.

The Kachch region of western India is characterized by multiple intraplate seismic sources in the form of several east-west trending faults. A 7.6 magnitude earthquake occurred near the city of Bhuj here in 2001 resulting in severe loss of life and property. Seismicity in this area continues with several moderate crustal earthquakes of 3.5-4.5 magnitude occurring each year. Studies to identify precursors, were initiated in 2009. Geomagnetic data from magnetic observatory at Desalpar (DSP) situated near to the Kachchh Mainland Fault in close proximity to the seismic cluster, is examined for anomalous signatures associated with lithospheric process. The diurnal variations in the geomagnetic Z component (ΔZ) have been studied for the duration of 2010-2018 to extract anomalous signatures, after removing seasonal effects. Effects of ionospheric and magnetospheric phenomena are also eliminated. The residual anomalous signatures in ΔZ are attributed to lithospheric origin. Such anomalies in ΔZ are observed 2-5 days before the earthquakes, on an average.

The geoelectric data contain important anomalous information for short-term earthquake prediction. Timely and accurate identification of seismic electric anomalies is important for disaster prevention. However, identifying anomalies is challenging due to the huge volumes of data and noise disturbance. In this study, we develop a real-time automatic search engine (RASE) that incorporates an unsupervised convolutional denoising network (UCN) module and a supervised LSTM network (SLN) prediction module to automatically search for important anomalous signals in real-time. Experiments demonstrate that the RASE provides excellent detection accuracy and efficiency for synthetic and field data, which takes only dozens of seconds for a common PC to provide accurate detection results for data collected over a 24-hour period. The RASE has excellent flexibility and developability, as its internal modules can be adapted by more suitable technologies for better performance in various application scenarios. Comparison of multiple module combinations shows that the RASE configured with UCN and SLN has the highest detection accuracy. Our proposed search engine can reduce the human labor required for complex and repetitive detection work and fully realize the potential of geoelectric field observation in earthquake monitoring and disaster prevention.

Electrical Resistivity Tomography (ERT) is a robust and well-consolidated method largely applied in near-surface geophysics. Nevertheless, the mapping of the spatial resistivity patterns of the subsurface at a depth greater than 1 km was performed in just a few cases by the ERT method, called deep ERT (DERT). Information on the electrical properties of the rocks beyond ~1 km depth has been obtained only from direct soundings or passive electromagnetic measurements (e.g., Magnetotelluric—MT) so far. In this work, a critical review of the recent results obtained during geophysical field surveys carried out with the DERT method is presented. The limits and the advantages related to the application of the DERT method in the geophysical exploration of seismic and volcanic areas are identified and discussed. The study focuses both on the purely methodological aspects (e.g., geoelectrical data processing in low noise-to-signal ratio conditions; 2D and 3D tomographic algorithms for resistivity data inversion) and on the technological features (e.g., sensor layouts, multi-array systems). Furthermore, great attention has been devoted to the novel applications of the AI-based methods and machine learning for geoelectrical data processing. The results of this work envisage the possibility of studying geophysical problems that are still unsolved and/or poorly studied in seismic and volcanic areas, as the fluid and gas migration from deep geological environments. Finally, future research directions are identified and discussed.

Northeast Japan is one of the world's most active subduction zones, having great earthquakes and volcanic eruptions, such as the M9.1 Tohoku Earthquake in 2011. Efforts to understand the subsurface structure via magnetotelluric studies have been extensive because electrical resistivity is sensitive to fluids in the crust and upper mantle. As a result, the deep, regional resistivity structure has been obtained beneath the northern and central parts of Northeast Japan (Ogawa et al., 1986; Ichiki et al., 2015). In this study, we aimed to image the southern part. This area has quaternary volcanoes on the backbone range and the back-arc side, active deformation regions, and shallow to deep seismic activities. Such activities are generally viewed to be caused by fluids in the crust and upper mantle that originated from the subducting slab (e.g., Iwamori, 1998; Wallace, 2005). So, we performed a wide-band magnetotelluric study by deploying electromagnetic field recording stations on three parallel NW-SE profile lines across the island arc. Each line consists of about 15 stations with nearly 10 km intervals. We estimated the MT impedance, vertical magnetic field transfer function (VMTF), and inter-station horizontal magnetic field transfer function (HMTF) at periods 0.03 - 13,000 seconds using the BIRRP code (Chave and Thomson, 2004). FEMTIC inversion code (Usui, 2015; Usui et al., 2017) was used for three-dimensional inversion because it can jointly invert the three response functions. In the presentation, we discuss the resulting resistivity structure and its correlation with active volcanoes and seismic activities.

As is well known, the last eruption of Mt. Fuji was the Hoei eruption in 1707, and there has been no eruption for more than 300 years. It is common knowledge in volcanology that Mt.Fuji is a very young volcano and it is 100% certain that an eruption will occur in the future. Because of its proximity to the Tokyo metropolitan area, it is believed that an eruption would cause enormous damage to Japan, which has become IT-oriented.

In October 2020, our group set up a permanent total magnetism observation point at an altitude of 1400m, which will serve as a reference point for future geomagnetic observations.

In evaluating observation data, in order to judge whether it is an artificial change due to a physical change in the position of the sensor (sensor pole tilted due to force majeure, etc.) or a true change in the natural world is very important. Therefore, in the summer of 2022, we conducted geomagnetic preliminary observations from the summit to the vicinity of the 6th station and succeeded in selecting candidate sites for future permanent observation points.

In the future, we intend to conduct electromagnetic monitoring of Mt. Fuji as the IUGG-EMSEV project.

We apply multi-temporal 1D-magnetotelluric (MT) surveys to identify space-time anomalies of apparent resistivity in the upper lithosphere in the Antarctic Peninsula (border between the Antarctic and the Shetland plates). We use time series over several weeks of the natural Earth's electric and magnetic fields registered at one MT station of the Universidad Nacional de Colombia (RSUNAL) located at Seymour – Marambio Island, Antarctica. We associate resistivity anomalies with contrasting earthquake activity. Anomalies of were detected almost simultaneously with the beginning of a seismic crisis in the Bransfield Strait, south of King George Island (approx. 85.000 events were reported close to the Orca submarine volcano, with focal depths < 20 km and $m_b < 6.9$). We explain the origin of these anomalies in response to fluid migration near the place of the fractures linked with the seismic swarm, which could promote disturbances of the pore pressure field that reached some hundreds of km away.

There are many reports on variations in the electromagnetic (EM) field in association with occurrence of earthquakes. However, the reliability of their existence is still a topic of dispute. It should be tested by referring many events to secure the statistical significance. In the present study, we referred EM dataset acquired just after the 2016 Central Tottori earthquake. The data were originally recorded for the EM sounding around the focal area. The characteristic variations in the EM time series were tried to be identified and the timing of their occurrence was compared with the aftershocks to confirm the hypothesis that variations in the electromagnetic do occur in association with earthquakes. To perform an exhaustive and objective counting, we proposed an automatic procedure to detect EM signals in the time series. A template waveform was defined by stacking representative waveforms that were picked up by visual inspection. The EM signals were identified by comparing the EM time series and the template waveform. By using the proposed procedure, we confirmed that the number of signals occurred during a several time-range before and after earthquakes are larger than that expected when it occurred randomly. We also performed a statistical test for the increase in the signal occurrence rate and confirmed that the recognized increase in the signal occurrence rate was significance with the 95% reliability. These results suggest that EM variations recorded in the EM time series include earthquake-related signals, at least for the case of aftershocks of the 2016 Central Tottori earthquake.

Large earthquakes and volcanic eruptions disturb ionosphere in various ways, and we can observe them with global navigation satellite system receivers as changes in total electron content (TEC), number of electrons along the line-of-sights connecting the receivers and the satellites. I first review ionospheric disturbances related to earthquakes. They appear ~10 minutes or later after earthquakes as sudden TEC changes propagating with three different speeds, ~4 km/s (Rayleigh wave), ~0.8 km/s (direct acoustic wave), and ~0.25 km/s (internal gravity wave). The disturbances caused by direct acoustic waves from the epicenters are useful to estimate moment magnitudes of earthquakes, although we should take care of the influences of geomagnetic fields and line-of-sight geometries on the observed amplitudes. Slow fault slip signatures were recently found to emerge as the large amplitudes of internal gravity wave signals relative to those by acoustic waves. Secondly, I discuss ionospheric TEC changes by large volcanic eruptions. They emerge in two distinct forms, long-lasting harmonic oscillations or short impulsive changes, often associated with Plinian continuous eruptions and Vulcanian explosive eruptions, respectively. In both types, disturbance amplitudes normalized by background vertical TEC provide useful measures of the eruption intensities. I also review observations of ionospheric responses to the 2015 January eruption in Tonga, where several brand-new TEC changes have been observed, e.g., the Lamb waves circulating the Earth multiple times, long-lasting harmonic oscillations caused by atmospheric modes, and sudden electron depletion possibly by the injection of water vapor molecules into the upper atmosphere.

Forecasting the impact that a tsunami might have on the coastal areas requires accurately locating where the tsunami has been initiated. This is especially challenging since tsunamis often start far from seismological and geodetic networks. However, tsunami waves often induce ionospheric Total Electron Content (TEC) disturbances that can be detected by using Global Navigation Satellite Systems (GNSS). Tracing where these disturbances come from makes it possible to retrieve the initiation area of the tsunami. Previous studies have tested this approach. Still, it is generally done using (1) a 'quasi-homogeneous' model to propagate the disturbances within the atmosphere and (2) arbitrarily fixing the height of the ionosphere. These approximations lead to relatively large uncertainties about the location of the initiation area of the tsunami. This is why, in this study, we attempt to check if using a 1D model for the atmospheric structure can reduce these uncertainties and by including in the inverse problem the search for the optimal height of the ionosphere. To do so, we use a Bayesian approach to invert the onset times of the TEC disturbances. At first, we test our method on synthetic data to determine the potential gain in accuracy between using a 'quasi-homogeneous' and a 1D-model for the atmosphere. Then, we apply our approach to study the 2010 M7.7 Mentawai tsunami earthquake. Finally, we discuss how we envision including such data in future tsunami early-warning systems.

The ability to issue timely tsunami warnings is a key challenge in GNSS Ionospheric Seismology research.

In this context, Total Electron Content (TEC) estimates represent an important parameter to sound the ionosphere using Global Navigation Satellite Systems (GNSS) observations. Earthquakes and tsunamis are, indeed, known to generate acoustic and gravity waves (AGWs), able to reach the ionosphere and cause perturbations in TEC values, known as Travelling Ionospheric Disturbances (TIDs).

In this study, we use the VARION algorithm, able to estimate TEC variations in real time, to investigate the eventual TIDs connected to Mw 7.0 Samos earthquake (37.8360° N 26.8080° E) that occurred on 30 October 2020. We employ 10 GNSS receivers from the Turkish and Greek networks (respectively TUSAGA-Akitf and HEPOS). We consider both raw and filtered VTEC variations. Specifically, we adopt bandpass and polynomial filters. We highlight small TEC variations possibly linked to the passage of acoustic-gravity waves. Spectral analysis shows peak frequency around 1-2 mHz.

The challenge of this study is, indeed, to eventually retrieve and highlight small amplitude TEC variations connected to the earthquake and tsunami. To this aim, we also use tide gauges (IOC_UNESCO) data to retrieve information on the tsunami waves.

In conclusion, the obtained results emphasize the importance of using GNSS ionospheric data to study and complete other known methods used for tsunami hazard estimation in the Mediterranean Sea.

The ability to issue timely tsunami warnings is a key challenge in GNSS Ionospheric Seismology research.

In this context, Total Electron Content (TEC) estimates represent an important parameter to sound the ionosphere using Global Navigation Satellite Systems (GNSS) observations. Earthquakes and tsunamis are, indeed, known to generate acoustic and gravity waves (AGWs),

able to reach the ionosphere and cause perturbations in TEC values, known as Travelling Ionospheric Disturbances (TIDs).

In this study, we use the VARION algorithm, able to estimate TEC variations in real time, to investigate the eventual TIDs connected to Mw 7.0 Samos earthquake (37.8360° N 26.8080° E) that occurred on 30 October 2020. We employ 10 GNSS receivers from the Turkish and Greek networks (respectively TUSAGA-Akitf and HEPOS). We consider both raw and filtered VTEC variations. Specifically, we adopt bandpass and polynomial filters. We highlight small TEC variations possibly linked to the passage of acoustic-gravity waves. Spectral analysis shows peak frequency around 1-2 mHz.

The challenge of this study is, indeed, to eventually retrieve and highlight small amplitude TEC variations connected to the earthquake and tsunami. To this aim, we also use tide gauges (IOC_UNESCO) data to retrieve information on the tsunami waves.

In conclusion, the obtained results emphasize the importance of using GNSS ionospheric data to study and complete other known methods used for tsunami hazard estimation in the Mediterranean Sea.

On 30 October 2020 at 11:51 UT, a magnitude 7.0 earthquake occurred in the Dodecanese sea (37.84°N, 26.81°E, 10 km depth), that generated a tsunami with an observed run-up of more than 1 meter on the Turkish coasts. Both the earthquake and the tsunami produced acoustic and gravity waves that propagated upward, triggering co-seismic and co-tsunamic ionospheric disturbances.

This paper presents a multi-instrumental study of the ionospheric impact of the earthquake and related tsunami based on ionosonde data, ground-based and Swarm-based GNSS receivers, and Jason3/DORIS [L1] receivers in the Mediterranean region.

Our study focuses on the Total Electron Content derived from the European GNSS network, Swarm, and Jason3, to describe the propagation of Medium Scale Travelling Ionospheric Disturbances (MSTIDs), possibly related to gravity waves triggered by the earthquake and tsunami. We use simultaneous vertical ionosonde soundings to study the interactions between the upper and lower atmosphere.

The results of this study provide a detailed picture of the Litosphere-Atmosphere-Ionosphere coupling in the scarcely investigated area that is the Mediterranean region.

On 27 November 2022, an eruption started at the Mauna Loa (Hawaii; USA) volcano after about 38 years of quiescence. The eruption took place at the summit caldera; the day after, it migrated to the upper Northeast Rift Zone, where lava effusion initially occurred from three fissure vents. In this work, we investigate the Mauna Loa 2022 eruption, ending on 13 December, by means of a virtual network of multi-sensor infrared satellite observations. In particular, we show the results achieved by implementing the Normalized Hotspot Indices (NHI) on GOES-R ABI data, at 10 min temporal resolution, and by using Sentinel-2 MSI and Landsat-8/9 OLI/OLI-2 observations at mid-high spatial resolution via the Google Earth Engine tool developed to map volcanic thermal anomalies at global scale. Both the eruption onset and the short-term variations of thermal activity were well identified by NHI, using GOES-R ABI data. Moreover, an accurate mapping and characterization of active lava flows was performed. These results confirm that SWIR (short wave infrared) observations, at different temporal and spatial resolution, if properly analysed, may support the monitoring and surveillance of active volcanoes from space.

Volcanic eruptions are key scenarios for developing new tools for volcanic monitoring. Among the geophysical techniques, electromagnetic methods are not extensively used in volcano monitoring. However, these methods are very sensitive to temporal changes in the subsoil due to the movement of fluids, which strongly affects the electrical resistivity of the subsoil.

During the volcanic eruption that started on the island of La Palma on September 19th, 2021, and the subsequent post-eruptive process, we deployed several magnetotelluric (MT) stations in the vicinity of the new volcano to test the performances of such instrumentation as an effective volcanic monitoring tool. Magnetotelluric stations have been installed for continuous monitoring, recording electric and magnetic fields along the N-S and E-W directions. We have obtained good quality transfer functions for the period range of 0.01 - 100 s. The main objective of this MT experiment was to detect possible variations of the apparent resistivity and phase curves and to compare them with other geophysical and geochemical studies conducted in the same area.

The preliminary results show slight changes in the resistivity over time that could be related to the development of a shallow hydrothermal system around the volcano.

Furthermore, in comparing the pre-eruptive 3D resistivity model of the island, we observed that regions with low resistivity were almost aseismic, possibly due to the presence of ductile rocks like clays.

The occurrence of some natural hazards in the troposphere may lead to creation of Internal Gravity Waves (IGWs). These waves transfer energy from the lower troposphere to upper layers, and to the ionosphere. When these IGWs reach the ionosphere, they create significant variations in the ionospheric parameters such as Total Electron Content (TEC) and electron density. Therefore, they have considerable effects on performance of Global Navigation Satellite Systems (GNSS) receivers.

In this study, we used double-frequency measurements of GNSS ground-based stations from GEONET network in New Zealand to detect the IGWs created by the tsunami induced from the 2022 Tonga volcanic eruption. In addition to GNSS measurements, radio occultation (RO) data from FORMOSAT-7/COSMIC-2 (F7/C2), and SWARM data were also used to study these IGWs.

It is known that IGWs and tsunami waves have similar characteristics such as horizontal speed, frequency, and arrival time. But as the volcanic-originated IGWs spread in cone-shape pattern, it is possible to detect them earlier than the tsunami waves, reaching the tide gauges or DART buoys. In our study, we could detect the first patterns of IGWs at the New Zealand GNSS stations, two hours earlier than the first tide gauges and DART buoys near the New Zealand peninsula, which is located approximately 1.600 km from the Tonga Volcano.

It can be concluded that IGWs can be used to warn tsunamis faster than the current early-warning systems, which make use of tide gauges and DART buoys.

The low ionosphere, height ~ 60-70 km, is highly sensitive to disturbances of extraterrestrial origin as quiet and disturbed solar electromagnetic emissions, as well as strong atmospheric and/or geological events. This is the case of the ionospheric disturbance observed on January 15, 2022 associated to the shock wave generated by the eruption of the Hunga-Tonga volcano. In this work, we present evidence of the propagation at lower ionospheric layers, specifically in the D region of the shock wave produced by this volcano explosion. Through simulations and a detailed analysis of the effects of the wave over the VLF path, between the NAA transmitter (USA) and the receiver station at Mexico City (CdMx), located at ~ 14 000 and ~ 10 000 km, respectively from the Hunga-Tonga volcano. We estimated that the shock wave propagated at ~ 880 m/s, which is faster than the propagation speed reported at higher ionospheric altitudes.

Conventionally, two-dimensional spatio-temporal variations and one-dimensional temporal variations such as GNSS-based TEC fluctuations and ionosonde data have been used for ionospheric disturbances. Ionospheric disturbances such as Pre-earthquake phenomena, and triggered by seismic ground motions, tsunamis, and typhoons, for which the physical mechanisms have not yet been elucidated, were also studied using GNSS-based TEC and Ionosonde data. In this study, we introduce the newly developed an ionospheric tomography system that is stable even during disturbances and can reconstruct the three-dimensional ionospheric electron density distribution. And we apply the developed tomography method to the GEONET data with typhoon signature and earthquake-related disturbances around Japan. Based on the obtained the three-dimensional structure, it is highly suggestive that ionospheric disturbances caused by typhoons were excited by atmospheric gravity waves, seismic fluctuations by sound waves, tsunami-induced fluctuations by atmospheric gravity waves, and earthquake precursors by electric fields. Details will be shown in the presentation.

Joshimath is an Indian Himalayan town built on a paleo landslide and fragile mountain slope of a landslide-prone region. By the end of 2022, local people identified numerous cracks in the buildings and grounds of Joshimath. The local administration ordered to demolish the unsafe structures to minimize socioeconomic losses, resulting in conflict between people and the administration. The leading cause of these crack developments or land subsidence are the construction activity of NTPC's Tapovan-Vishnugad hydro project, rapid urbanization, and population overgrowth. However, the local geological conditions, including lithology and thrust zone, control the magnitude of land subsidence. Microwave Remote sensing, mainly the Persistent Scatterer Interferometry Synthetic Aperture Radar (PSInSAR) technique, has emerged as a promising tool for monitoring land subsidence with millimetre precision. Hence, in this study, we have used 32 Sentinel-1 SLC images acquired from January 2022 to January 2023 along ascending orbit to track land subsidence over the Joshimath area. The StaMPS algorithm processed the InSAR images by considering 0.4 as the amplitude dispersion threshold, 3 patches in range and 2 patches in azimuth. The results revealed a significant land displacement rate of -0.5mm/year to -65mm/year. High displacement rates are observed in various locations on debris of paleo landslide. Similar subsidence has been reported by local news channels at various other locations in Himalayas. Further, work can be carried out to estimate the rates of deformation at other locations as well, such as Shimla, Dharamshala, Theog, Kufri, Almora, Nainital, Mussoorie, and other mountainous regions around the globe.

The increasing effect of climate change and anthropogenic activities have left the mountains under great stress, resulting in Natural Hazards. Among all other natural hazards, landslide poses a significant threat to life and property. In recent decades, plenty of literature has been available on the application and methodology adopted in preparing landslide susceptibility maps (LSMs), mainly focusing on the Himalayan region. However, fewer attempts have been made to compare the susceptibility in North-Western and North-Eastern Himalaya. Hence, in this study, LSM is prepared for 2 districts; one district of northwest i.e Kangra, Himachal Pradesh and one district of northeast i.e. Tamenglong, Manipur. The landslide inventory was prepared using available data, field data and satellite image interpretation, and nine causative factors were used in LSM preparation using frequency ratio (FR). The results showed that in the Kangra district, the weight of lithology was highest followed by distance to road and lineament, while in Tamenglong, the importance of distance to road was highest. 16% area in Kangra and 31% in Tamenglong district falls in high and very high landslide suscpetibile area. In addtion, Tamenglong district had more significant portion of high and very high suscpetibile area compared to Kangra district. The AUC value of LSM for Kangra and Tamenglong district was 0.91 and 0.89, respectively. Generally, due to excessive precipitation, fragile geology, earthquake and tectnoic activities it is seen that, in northeast areas are more susceptible to landslide as compared to northwest Himalaya.

Some of the most destructive mountain cryosphere hazards are those that generate far-traveled flows, most notably glacial lake outburst floods (GLOFs), but also mass wasting or glacial collapse triggered flows. These events can travel 10s to 100s of kilometers downstream through the fluvial network, and the processes that take place during this propagation may play a significant role in the magnitude and type of impact that such events have on both downstream communities and the fluvial system. While there has been substantial progress in our understanding of the past occurrence, potential sources and triggers, and initial stages of such events, particularly GLOFs, there are still a number of key open questions about their subsequent behavior. Understanding the interaction between propagating flows and the water, sediment, and channel properties they encounter as they propagate downstream is critical for the accurate estimation of the hazard potential of possible flow sources. These questions are highlighted by the complexity of several recent large events in the Himalaya, including the 2021 Chamoli event, the 2021 Melamchi flood, and the 2016 Bhote Koshi GLOF. Using new techniques such as environmental seismology, combined with advances in remote sensing and observer documentation, we can make progress towards understanding the evolution of such events as they propagate downstream.

The Chilean Central Andes have been under severe hydrological stress due to the uninterrupted megadrought for the last 13 years. The region is known for being the denser populated zone of the country and it hosts a wide variety of glaciers along with the largest ice masses outside Patagonia.

This work presents a susceptibility assessment for glacier hazards in the Rio Volcan basin (-32.82°/-70.00°), located 40 km east of Santiago city. The region is characterized for elevation ranges from 3380 to over 6000 m a.s.l. at the active and glacier-covered San José Volcanic Complex. Its closeness to the capital favours outdoor activities, tourism, urban and hydroelectric power development. Nowadays, there are accounted 195 glaciers in the area, including 46 glaciarets, 16 mountain glaciers and 8 valley glaciers.

The susceptibility of 5 different phenomena is evaluated based on an analytical hierarchic process method through the determination of a susceptibility index. The multiple processes evaluated include ice avalanches, surges, low-angle glacier detachments, GLOFs and eruption-triggered lahars.

The results show that within the Rio Volcan basin 4 glaciers are highly susceptible for ice avalanches, 1 for surges, 2 for sudden low-angle detachments, 3 for GLOFs whereas 19 glaciers, mainly glaciarets (68 %), are highly susceptible for eruption-triggered lahars. Only the 7 km-long Loma Larga glacier is highly susceptible for 4 out of 5 assessed processes excluding lahars.

It is concluded that the proposed method can be used in other regions after adjustments regarding the work scale and conditioning factor’s weight are applied.

Its closeness to the capital favours outdoor activities, tourism, urban and hydroelectric power development. Nowadays, there are accounted 195 glaciers in the area, including 46 glaciarets, 16 mountain glaciers and 8 valley glaciers.

The susceptibility of 5 different phenomena is evaluated based on an analytical hierarchic process method through the determination of a susceptibility index. The multiple processes evaluated include ice avalanches, surges, low-angle glacier detachments, GLOFs and eruption-triggered lahars.

The results show that within the Rio Volcan basin 4 glaciers are highly susceptible for ice avalanches, 1 for surges, 2 for sudden low-angle detachments, 3 for GLOFs whereas 19 glaciers, mainly glaciarets (68 %), are highly susceptible for eruption-triggered lahars. Only the 7 km-long Loma Larga glacier is highly susceptible for 4 out of 5 assessed processes excluding lahars.

It is concluded that the proposed method can be used in other regions after adjustments regarding the work scale and conditioning factor’s weight are applied.

High risks from hidden lakes - Glacial lake outburst floods in the Trans-Himalaya of Ladakh, India

DOI: 10.57757/IUGG23-4231 - LINK

Susanne Schmidt[1], *Marcus Nüsser*[1]
[1]*Heidelberg University, South Asia Institute- Department of Geography, Heidelberg, Germany*

Cryosphere-related hazards are a growing but largely neglected threat for rural settlements, agrarian land use and local livelihoods in the cold-arid Trans-Himalaya. Despite the growing number of studies on cryosphere-related hazards, the occurrence, frequency and magnitude of glacial lake outburst floods (GLOFs) are almost entirely overlooked for the region of Ladakh. Due to the small size and high elevational location of glaciers above 5200 m a.s.l. also the glacial lakes are of small size. In the recent past several GLOF events occurred which destroyed infrastructure and agricultural area. It becomes obvious that even these small glacial lakes might be a permanent threat for local livelihoods and socioeconomic development. This is even more problematic as the number and size of lakes has significantly increased over the past decades. A comprehensive inventory of glacial lakes for the entire Trans-Himalayan region of Ladakh was carried out. This includes several almost permanently ice-covered high altitude lakes. Changes in the extent and number of glacial lakes have been quantified since 1969 in order to assess the potential threat of future GLOFs in the region. The lake development of selected former reported GLOF events and disappeared glacial lakes were analysed in detail to reconstruct lake level changes which possibly indicate earlier GLOF events. Based on high temporal resolution remote sensing data, a sophisticated monitoring concept needs to be realized to indicate the development of short-lived lakes on glaciers or on debris landforms with buried ice or fast glacial lake growth.

Glacial Lake Outburst Floods (GLOFs) are a major hazard in high mountain areas, and can significantly impact transportation infrastructure, human settlements, water supplies, agricultural land, and important cultural and religious locations. Dynamic flow models are widely used for hazard assessment, preparedness planning and to support Early Warning Systems for other destructive sediment flows including flash floods and debris flows, and here we present results of their application and calibration for GLOFs. We use the LaharFlow model (www.laharflow.bristol.ac.uk), a dynamic sediment flow model for hazard assessment, which solves conservation equations for mass and momentum under the shallow layer approximation, to compute the flow dynamic properties. LaharFlow includes parameterizations for erosion and deposition, and the variation in flow solids concentration, friction and landscape change that result, and is freely-available as a webtool.

We applied the model to recent case studies that represent a range of GLOF sizes: at Ghulkin (Pakistan, 2022), Shisper (Pakistan, 2020) and Lemthang Tsho (Bhutan, 2015), and also to potential future impacts on Paro (Bhutan). Source conditions were constrained using estimates of lake volumes and idealised hydrographs corresponding to an instantaneous moraine wall failure and slow drainage. The modelling shows good agreement for observed flow depths, speeds, erosion patterns and arrival times using parameters calibrated for other large debris flow settings. For the Paro example, we show how dynamic models can be used to identify locations for, and calibrate, early warning systems, and to assess potential impacts of GLOFs on communities living in high mountain environments.

Permafrost-affected rockwalls are increasingly impacted by the effects of climate change and rising air temperature leading to rock slope failures. These events could be a threat for human lives and infrastructure, which underlines the need of better knowledge about their triggering mechanism and propagation. The aim of this study was to propose a regional mapping approach of susceptible release areas of rock slope failures and resulting runout distances. This information is a first step to identify hotspots for subsequent hazard assessment.

To do so, we used an inventory of 1389 rock slope failures (volume > 10^2 m^3) recorded in the Mont-Blanc massif on 2007-2019 period and determined the topographical and permafrost conditions that are most prone to their triggering using a digital terrain model and a permafrost map. These conditions are used in a multi-criteria GIS approach to identify potential unstable slopes at the French Alps scale. Then, the potential release area map is used as input to map the propagation of potential events, using a model based on a normalised area dependant energy line principle. The resulting maps of release and propagation areas will be used to point out human assets (mountaineering routes, high mountain infrastructure, tourism areas) and lakes (that can provoke cascading hazards) which could be impacted by rock slope failure hazards.

This work is a first step to identify hot spots for a regional hazard assessment where more in depth analyses will be required to evaluate potential risks at a local scale.

Glacier and slope instabilities pose significant hazards in mountain areas, with a high potential impact on the population. Forecasting glacier and slope instabilities remains challenging as sensing technology focusing on the surface might fail to detect damage and changes in subsurface elastic properties leading to large-scale failures. Seismic methods, such as seismic interferometry, can help address this observational gap by quantifying changes in material integrity. Here, we discuss two case studies in which seismology elucidates the development of cryospheric hazards: a hanging glacier instability and permafrost degradation on an active rockslide.

We first analyze seismic data from Switzerland's Eiger hanging glacier before a 15,000 m^3 break-off event. Our approach, based on an analysis of multiple icequake waveforms, allows us to measure seismic source migration. Combined with an analytical model based on damage mechanics our results quantify crevasse extension between unstable and stable ice masses. We then move to the second study site, an active rock slope near "Spitze Stei" in the Kandersteg region, Switzerland. The time series of relative seismic velocity variations (dv/v) constrain the lateral and depth-dependent extent of changes in the rock's elastic properties caused by pore pressure increase and potentially by permafrost thawing.

The presented case studies illustrate how seismology can give quantitative insights into material damage and allow separating effects of irreversible damage growth from reversible thermoelastic hydrologic variations. This knowledge is needed to better predict the development of large failures and thus improve warning systems.

Climate-change-induced seismicity: The recent onset of seasonal microseismicity at the Grandes Jorasses, Mt. Blanc Massif, France

DOI: 10.57757/IUGG23-4234 - LINK

Verena Simon[1], *Toni Kraft*[1], *Tania Toledo*[1], *Jean-Christophe Maréchal*[2]

Modeling studies suggest that climate change may cause a dynamic response of the geosphere, increasing geological and geomorphological hazards. These hazards include a potential rise in earthquake activity driven by climate-change-induced changes in the hydrological subsurface conditions. So far, evidence for this phenomenon is rare and often inconclusive.

Here, we investigate an ongoing earthquake swarm with thousands of shallow ML<3 events in the Mount Blanc Massif that shows an annual periodicity starting in fall 2015. Comparing its activity with runoff volumes and isotope data from the Mont Blanc tunnel indicates that the seismicity is driven by snow and glacier meltwaters. Since 2015, near-surface flow paths rearranged by permafrost and glacier retreat may have allowed these waters to reach the source region.

Our QuakeMatch-analysis (Toledo et al., 2023) combines matched-filter detection sensitivity and consistent magnitude estimation with high-precision relocation and statistical analysis. It reveals that the seasonal component of the seismicity shows high b-values supporting the meltwater-driven origin, while the non-seasonal component shows a tectonic b-value around 1.0 dominated by earthquake-earthquake interaction. The seismicity increase since 2015 is associated with an increase in the short-term seismic hazard (STSH). In the high-activity phases, the STSH increased by up to two orders of magnitude compared to the STSH level before 2015.

The meltwater-driven seasonality and the associated increase in STSH provide observational evidence that climate change can increase seismic hazard locally. Similar phenomena may be ongoing in glaciated regions worldwide. Our study can contribute to better quantifying the seismic risk for affected alpine communities.

We demonstrate the detectability of snow avalanches using Distributed Acoustic Sensing (DAS) with existing fiber-optic telecommunication cables. To achieve this, during winter 2021/2022, we interrogated a ~10 km long dark fiber that follows the avalanche-prone Flüelapass road in the Swiss Alps. In addition to other signals like traffic and earthquakes, the DAS data contain clear recordings of numerous snow avalanches, even though many of them did not reach the sensing cable itself, as revealed with automatic cameras and images taken by drone. The spatial resolution of the detection is of the order of few tens of meters. Avalanche signals can produce strong strain fluctuations exceeding 3 µm/m/s and they exhibit specific characteristics in terms of frequency content and apparent velocities which, we believe, can be used to discriminate them from other types of events. Our results open new perspectives for cost-effective, near-real-time avalanche monitoring over long distances using pre-installed fiber-optic infrastructure.

Avalanche occurrences in Norway deduced from meteorological data

DOI: 10.57757/IUGG23-4247 - [LINK]

Debmita Bandyopadhyay[1], Rune G. Graversen[2], Andrea Marinoni[2]
[1]The Arctic University of Norway - UiT and the Ministry of Earth Sciences- Govt. of India, Department of Physics and Technology in UiT, Tromsø- Norway and New Delhi-India, India

Avalanche formation depends on terrain characteristics, snowpack, and meteorological conditions. Of these, meteorological parameters, such as temperature, precipitation, and wind, strongly influence the possibility of a catastrophe in an avalanche-prone area. One-fourth of Norway´s public roads are exposed to the risk of avalanches; hence, the Norwegian Meteorological Institute (MET Norway) produces daily warnings on a scale of 1-5, 5 being the maximum danger level of risk of avalanche activity. The warnings are restricted to the winter period, i.e. December, January, February, March, and April. In this study, we identify the regions in Norway with high avalanche warnings (warning >= 4, named the `avalanche day´) based on the MET warnings. Four regions in Norway, namely Ofoten, Salten, Svartisen, and Hegeland, observed maximum avalanches (>= 35) between Dec 2017 and April 2022.

The two conditions that drive the instability of the snowpack are (i) loose snow and (ii) slab avalanches. In particular, wet snow instances and persistent weak layers in the snowpack of slab avalanches are responsible for most avalanches in these four regions. To understand the impact of meteorological variables on these avalanches, we utilise the long-term observational gridded datasets (1 km resolution) from MET Norway. Over the last five years (Dec 2017- April 2022), during the winter months, the daily mean temperature analysis shows an increase three days before the `avalanche day´, but the accumulated precipitation increases by 12.5% a day before the event. Future work entails analysing long-term climate data for avalanche monitoring and prediction studies.

Since 2005 quasi-annual jökulhlaups, or glacial lake outburst floods, are registered at the Zackenberg research station (74°28′N, 20°34′W), NE-Greenland. The jökulhlaups typically happen during the sommer months, but were also observed during winter and spring. The Zackenberg jökulhlaups exhibit rapid-rising outburst type characteristics with durations of 12-24 hours, and maximum discharges of 120 to 380 m^3/s. The source is a lake dammed by an outlet glacier of the A.P. Olsen ice cap about 35 km inland of the research station. The recorded maximum ice-dammed lake volumes are varying in between 5.7 to 15.6 $x10^6$ m^3.The year 2018 showed no drainage event and the lake remained filled until the 2019 melting season, accumulating the largest lake volume so far. The 2019 lake outburst happened with beginning of July rather early, but just drained slowly for more than a week to then switch to a rapid-type outburst emptying the lake in about half a day. The subsequent 2020 and 2021 floods continued to show characteristics of slower and mixed-type drainage events. The overall evolution of the 2019-2021 lake drainage patterns suggest a transition back to rapid-type jökulhlaup events. To our knowledge, the observed mixed-type drainage patterns within a single jökulhlaup event has been never reported before, and is challenging the current understanding of subglacial floods. We present all the available hydrometric data for the Zackenberg river and the ice-dammed lake to discuss potential causes for the observed jökulhlaup perturbations.

GNSS Measurements of GIA-driven crustal deformation in Antarctica

DOI: 10.57757/IUGG23-2206 - LINK

Terry Wilson[1], *Pippa Whitehouse*[2]
[1]*Ohio State University, Byrd Polar and Climate Research Center, Columbus, USA*
[2]*Durham University, Department of Geography, Durham, United Kingdom*

Continuously recording GPS stations have operated at permanent Antarctic research stations, mainly along the coast, for nearly 3 decades. In contrast, deployment of continuously recording autonomous GPS instruments in the continental interior of Antarctica started mainly during the 2007-08 International Polar Year. At present, the U.S. ANET-POLENET and UK-ANET projects maintain most GNSS stations across interior and remote coastal West Antarctica and the Antarctic Peninsula; these projects have limited-term support and are currently scheduled to end within the next 2 years. Cessation of data acquisition, due to lack of operational support and/or site decommissioning, is resulting in a crucial gap in observational constraints for GIA modeling. It also hinders a range of studies using GNSS data, spanning the deep Earth to the ionosphere.

Geodetic time series from autonomous GNSS systems distributed across Antarctica have revealed unexpected patterns and startling rates of crustal deformation due to GIA. Linked with seismic mapping and derived rheological properties of the Antarctic crust and mantle, and with new advances in GIA modeling capabilities, GNSS observations have transformed our understanding of the timescales of GIA response to ice sheet change. Rapid GIA response promotes cryosphere-solid earth interactions that can alter ice sheet behavior on decadal and centennial timescales, with significant implications for the contributions of marine-based sectors of the Antarctic Ice Sheet to sea level in the future. Continued progress in understanding how such feedbacks should be adopted in global sea level projections requires continuing and expanding our geodetic observations through international cooperation.

The mass balance of the Antarctic Ice Sheet (AIS) can be obtained from time-variable gravity fields from GRACE and GRACE-FO. This is useful to investigate the ice sheet's adaption to a changing climate and its contribution to the global mean sea level. However, the correction for the present-day glacial isostatic adjustment (GIA) in Antarctica is still the largest uncertainty contributor in gravimetric mass balances. Lacks of knowledge of the ice loading history and the solid Earth's rheology lead to a large spread of GIA predictions from forward modelling approaches. We developed a method (Willen et al. 2022, https://doi.org/10.1007/s00190-022-01651-8) that allows to spatially resolve GIA, ice mass changes, and firn thickness changes in Antarctica within a globally consistent framework using geodetic satellite data and results of climate modelling. From simulation experiments, we found that the signal separation is possible despite data limitations as long as accounting for spatial error covariances of the input data sets. Here, we present and discuss results from a global inversion of satellite gravimetry data (from GRACE/GRACE-FO), satellite altimetry data (CryoSat-2), regional climate modelling (from RACMO2), and modelled firn thickness changes (from IMAU-FDM) over the time period Nov 2010 to Dec 2020. Furthermore, we will discuss the advantage of implementing this methodology in a global sea level inversion framework.

Changing ice masses cause deformation of the solid Earth on different time scales. The classic view discriminates between elastic deformation and glacial-isostatic adjustment (GIA) due to present-day and past changes, respectively. The increasing availability of observational data and modelling advances allows our understanding of the complex pattern of solid Earth response to improve, including observation of rapid GIA.

Geodetic GNSS provides a technique to directly observe bedrock motion. In Antarctica, several studies already utilized such GNSS data but were limited in time or to a specific region, or could use recordings of only a limited number of stations. Within the SCAR-endorsed project GIANT-REGAIN a reprocessing of all available Antarctic GNSS data was realized, comprising data acquired by episodic and permanent recordings at about 280 bedrock sites between 1995 and 2021. Special attention was given to metadata which are indispensable for a correct assignment of the hardware set-up. The four processing centres applied precise point positioning or differential GNSS using different scientific software. Time series of consistent point coordinates were generated as the major product.

We will report on the comparison of the different solutions which allows to quantify time series analysis uncertainty. From the time series, coordinate velocities will be estimated. Here, we will discuss different aspects such as useful noise models, spatial correlations and suitable trajectory models. The treatment of the solid Earth response to ice-mass changes occurring over the last decades up to present day is currently under strong discussion and will be touched briefly.

Geodetic GNSS measurements on bedrock allow to determine secular trends of solid Earth deformation and, therefore, provide valuable constraints for modelling glacial-isostatic adjustment (GIA). There is a high discrepancy in GIA model predictions of vertical displacement rates in Antarctica regarding their spatial pattern and magnitude. While in West Antarctica, in the Antarctic Peninsula and in parts of Victoria Land a comparably large number of GNSS stations exists, East Antarctica exhibits big gaps in the GNSS coverage. The sparsity of bedrock outcrops and the difficult accessibility and logistics are reasons for this.In order to improve the spatial coverage we established a GNSS network in western and central Dronning Maud Land, East Antarctica, with first observations carried out already in the mid-1990ies and a latest observation campaign realized in the Antarctic season 2022/2023. Here we present results of a consistent processing of all episodic and permanent GNSS measurements in that region. We discuss how the long time basis of more than 20 years helps to improve the accuracy of the secular trend inferred from the GNSS time series. We remove the elastic deformation due to present-day ice-mass changes utilizing satellite altimetry observations and surface mass balance models. We discuss our resulting trends in comparison to existing GIA models in a region sparsely covered by GNSS prior to this study.

Determining recent ice volume changes from satellite measurements of ice height requires an estimate of contemporaneous vertical crustal deformation. This estimate must consider two main sources of crustal deformation: (1) ongoing glacial isostatic adjustment (GIA), that is, the deformational, gravitational and rotational response to late Pleistocene and Holocene ice and ocean mass changes; and (2) modern ice mass flux. The former has generally involved the adoption of global models of GIA defined by some preferred combination of ice history and mantle viscoelastic structure, while the latter has commonly been based on a simple, spatially invariant scaling of measurements of ice height. In the case of the Antarctic Ice Sheet, a scaling by ~1.02 has typically been adopted. We quantify the uncertainty and potential bias introduced in past estimates of the GIA signal using forward modeling results of various complexity. We also use modeling results to emphasize the spatially variable structure of the mapping between ice height changes and vertical crustal deformation associated with modern ice mass flux.

The deepest geoid low globally w.r.t. hydrostatic equilibrium is in the Ross Sea area. Nearby in West Antarctica is a residual topography high. Both are in a region with thin lithosphere, where a mantle plume has been suggested. Hence upper mantle viscosity could be regionally reduced, allowing for faster rebound than elsewhere upon melting of the West Antarctic Ice Sheet, one of the global climate system's tipping elements. To study possible causes of the geoid low / topography high combination, we compute the effects of disk-shaped density anomalies. With -1% density anomaly, geoid low and topography high can be explained with disk radius ~10° and depth range ~150-650km. Alternatively, there may be two separate disks somewhat laterally displaced, one just below the lithosphere and mainly causing a dynamic topography high and one below the transition zone causing the geoid low. In order to test the feasibility of such density models, we perform computations of a plume that enters at the base of a cartesian box corresponding to a region in the upper mantle, as well as some whole-mantle plume models, with ASPECT. However, these plume models have typically a narrow conduit and the plume tends to only become wider as it spreads beneath the lithosphere, typically shallower than ~300km, hence they would tend to rather under-predict the amplitude of the geoid compared to dynamic topography. We discuss how to possibly overcome the discrepancy between what is required to explain geoid and dynamic topography, and the outcome of numerical forward models.

On the path dependence of marine ice-sheet contribution to sea-level change

DOI: 10.57757/IUGG23-0356 - LINK

Surendra Adhikari[1], Lambert Caron[1], Eric Larour[1], Erik Ivins[1]
[1]California Institute of Technology, Jet Propulsion Laboratory, Pasadena, USA

The melting of ice sheets directly contributes to ocean mass and volume change. One key metric to keep track of ice-ocean mass exchange is the "ice-sheet contribution to sea-level change" (IS2SL), which is presumed to be a conservative metric that does not depend on what path an ice sheet takes to reach from its initial to final geometry. Conventionally, IS2SL is calculated by quantifying the change in ice volume above flotation. What appears to be a trivial book-keeping task unfolds a layer of complexities while quantifying IS2SL in real-world scenarios where ice sheets, solid Earth, and ocean geometries evolve continuously. Two research groups have independently proposed supposedly general formalisms to quantify IS2SL [1,2]. The two methods do not seem to agree, especially where an ice sheet transits from the grounded to the floating state, or the reverse, much of what happens in marine sectors of Antarctica or the former Laurentide Ice Sheet. In particular, one method appears to predict a path-dependent solution for IS2SL [1], challenging the utility of one of the most fundamental glaciological metrics. Here, with a simple kinematic analysis, we argue why IS2SL is inherently a path-dependent metric and caution the paleo- and modern glaciology communities regarding its utility for data and model intercomparisons.

Glacial isostatic adjustment (GIA) represents an important negative feedback on ice-sheet dynamics. The magnitude and time scale of GIA primarily depend on the upper mantle viscosity and the lithosphere thickness. These parameters have been found to vary strongly over the Antarctic continent, showing ranges of 10^18 - 10^23 Pa s for the viscosity and 30 - 250 km for the lithospheric thickness. Recent studies show that capturing these spatial dependencies are of significant importance for the long-term evolution of the Antarctic Ice Sheet (AIS). However, 3D GIA models are computationally expensive and sometimes require an iterative coupling for the ice sheet and the solid-Earth solutions to converge. As a consequence, their use remains limited, potentially leading to errors in the simulated ice-sheet response and associated sea-level rise projections. Here, we propose to tackle this problem by generalising the work of Bueler et al. (2007) and Coulon et al. (2021). FastIsostasy allows for an explicit accounting of the effects of spatially heterogeneous viscosity and lithospheric thicknesses and is computationally very efficient.

The inevitable emergence of anelasticity in climate driven surface load response

DOI: 10.57757/IUGG23-2057 - LINK

Erik Ivins[1], *Lambert Caron*[1], *Surendra Adhikari*[1], *Eric Larour*[1]
[1]*Jet Propulsion Lab- California Institute of Technology, Sea Level and Ice Group, Pasadena, USA*

A general assumption in geodesy is that solid Earth deformation in the presence of recent hydrological and ice loading is well approximated by a purely elastic response. If thermal or petrological conditions exist that favor vigorous high-the temperature creep behavior, such as in the mantle beneath Iceland, Patagonia, Alaska, Japan and Svalbard, many response models have been approximated by using a Maxwell viscoelasticity. However, non-Maxwellian transient viscoelastic rheology is required for models of post-seismic relaxation. Here we reconsider the solid Earth response in light of a temperature-dependent transient viscoelasticity currently favored in the mineral physics and seismological communities.

We develop a mantle response Green's function that accounts for the vertical isostatic motion of the mantle caused by acceleration of ice mass loss for Greenland and Patagonia measured by remote sensing since 1992 and 1945, respectively. The Green's function may be used to examine how anelasticity may express itself in the uplift associated with accelerated surface ice and water loss. We perform an extensive parameter exploration of the constants that define the Extended Burgers Material (EBM) model, a rheology having firm experimental and theoretical underpinnings, in order to isolate those material model parameters that have the greatest impact on anelastic-isostatic uplift over interannual and interdecadal time scales. Especially important are the contrasts among elastic, Maxwell and EBM predictions. Implications for the corrections for solid Earth vertical uplift in space gravimetric solutions for long-term hydrology and cryospheric change are also discussed.

Over 400 million people in Southeast Asia live in low elevation coastal zones and are susceptible to future relative sea-level (RSL) rise. Projections of future RSL rely on an accurate understanding of sea-level driving processes such as Glacial Isostatic Adjustment (GIA). Here we apply GIA models, paleo RSL records and instrumental data to demonstrate the evolution of RSL changes in Singapore and Southeast Asia and the associated impacts.

We reconstructed RSL since the Last Glacial Maximum (LGM) to quantify magnitudes and rates of RSL changes through time and used GIA model to assess paleotopography changes and impacts to human populations. We applied the Intergovernmental Panel on Climate Change (IPCC) RSL projections and used the geological past to provide probability perspectives when IPCC future projections were last exceeded in Singapore. Future projections under a moderate emissions scenario show RSL rising 0.95 m at a rate of 7.3 mm/yr by 2150 which was only exceeded (> 99% probability) during rapid ice melting events (MWPs) ~14.5 and ~9 ka BP. We inferred the human population history using 763 high-coverage whole-genome datasets. Integrated paleotopographic and population genomic analysis demonstrates the earliest documented instance of forced human migration driven by rapid sea-level rise (e.g., WMPs). We investigated the mid-Holocene highstand sensitivity revealing that Earth model variation affects the magnitude and ice model variation changes both the timing and magnitude of the highstand. Lastly, we produced a highstand “treasure map” to guide future highstand data collection efforts as the highstand is poorly constrained currently.

Can glacial isostatic adjustment modelling confirm potential signs of glacially triggered faulting in Canada?

DOI: 10.57757/IUGG23-1736 - LINK

Holger Steffen[1], *Rebekka Steffen*[1]
[1]*Lantmäteriet, Geodetic Infrastructure, Gävle, Sweden*

Glacial isostatic adjustment (GIA) leads to remarkable stress changes in the subsurface which can be potentially released along favourably orientated pre-existing fault structures, a process nowadays termed glacially triggered faulting. A notable vertical shift of some meters can occur. In coastal areas this can affect the measured elevation of relative sea level markers. In such case these markers must be corrected before they can be used in palaeo-sea level investigations.

Compared to Fennoscandia, the vast area of Canada does, so far, not contain any prominent traces of glacially triggered faulting which has led to interesting speculations in the literature. We will briefly review any suggested glacially induced faults in Canada and then analyze GIA-induced stress changes from a 3D finite element model of North America. We thereby test different stress regimes and (hypothetical) fault configurations to identify the most plausible fault parameters for reactivation. We will highlight the best parameter combinations for each fault or location of concern and compare them to available field observations. We will show that glacially triggered faulting has very likely affected most parts of Canada, including intraplate areas and Arctic islands. One example suggests that some relative sea level markers should be carefully used because faulting may have shifted the sample to a new elevation.

High-resolution modeling of dynamic vertical land movement in the Northern Hemisphere due to changing ice sheets and glaciers

DOI: 10.57757/IUGG23-0644 - LINK

Carsten Ludwigsen[1], *Ole Andersen*[1], *Shfaqat Abbas Khan*[1]
[1]*Technical University of Denmark, DTU Space, Kgs. Lyngby, Denmark*

The impact of elastic vertical land movement (VLM) on relative sea levels along the world's coastlines is significant. In Northern Europe, VLM is mainly due to the effect of Glacial Isostatic Adjustment (GIA). However, the rapid melting of ice in the Arctic is causing a substantial elastic uplift with both a local, but also a long-range footprint of 1000-3000 km from the point of ice loss. When VLM estimates from GNSS are unavailable, sea-level studies based on tide gauges often rely on a GIA-only VLM model to correct any ongoing uplift, but in Arctic regions, this can lead to underestimation of the uplift or overestimation of the absolute sea-level change due to significant changes in present-day ice loading (PDIL).

Here, a high-resolution time-varying elastic VLM model (5x5 km) is developed from high-resolution estimates of glacial and Greenland Ice Sheet mass balance is presented. The elastic VLM model is combined with a GIA model to create a complete VLM model that is comparable with GNSS-measured VLM rates (in a center of mass frame). Additionally, far-field elastic effects from the Antarctic and Terrestrial Water Storage are included to create a complete vertical deformation map for the Northern Hemisphere, that can complement sea level studies in areas with few or no GNSS measurements.

The impact of elastic vertical land movement (VLM) on relative sea levels along the world's coastlines is significant. In Northern Europe, VLM is mainly due to the effect of Glacial Isostatic Adjustment (GIA). However, the rapid melting of ice in the Arctic is causing a substantial elastic uplift with both a local, but also a long-range footprint of 1000-3000 km from the point of ice loss. When VLM estimates from GNSS are unavailable, sea-level studies based on tide gauges often rely on a GIA-only VLM model to correct any ongoing uplift, but in Arctic regions, this can lead to underestimation of the uplift or overestimation of the absolute sea-level change due to significant changes in present-day ice loading (PDIL).

Here, a high-resolution time-varying elastic VLM model (5x5 km) is developed from high-resolution estimates of glacial and Greenland Ice Sheet mass balance is presented. The elastic VLM model is combined with a GIA model to create a complete VLM model that is comparable with GNSS-measured VLM rates (in a center of mass frame). Additionally, far-field elastic effects from the Antarctic and Terrestrial Water Storage are included to create a complete vertical deformation map for the Northern Hemisphere, that can complement sea level studies in areas with few or no GNSS measurements.

In the 1980s, a series of articles explored the potential importance of transient rheology in the glacial isostatic adjustment (GIA) process (e.g., Peltier et al., *Geophys. Res. Lett.*, 1980; Sabadini et al., *Geophys. Res. Lett*., 1985; Yuen et al., *J. Geophys. Res*., 1986). However, in the absence of observational evidence for a time dependent viscous response, this level of additional modeling complexity fell out of favor in the GIA community. Recently, a comparison of viscosity models inferred from Holocene relative sea level data and modern crustal uplift rates in Greenland – the latter suggestive of a significantly lower Maxwell viscosity than the former – has renewed interest in the intriguing possibility of transient mantle creep (Adhikari et al., *Earth Planet. Sci. Lett.*, 2021). However, an unambiguous argument that transient rheology is necessary must rule out the possibility that a class of (Maxwell) viscosity models with general depth and lateral variability may reconcile both data sets. We present numerically derived 1-D sensitivity kernels for the relative sea level and uplift rate observations that demonstrate that these two data sets have independent sensitivities to variations in depth-dependent mantle viscosity. Moreover, we explore – within a broad class of such 1-D models – the level of fit that can be achieved to these data using a multi-layer Maxwell viscosity profile. Future work on this important, outstanding issue should extend this analysis of uniqueness using 3-D sensitivity kernels derived via adjoint methods (Crawford et al., *Geophys. J. Int.*, 2018).

Changes in sea level and vertical land motion associated with glacial isostatic adjustment (GIA) are embedded in paleo and geodetic data sets used to constrain the past and future evolution of the Greenland ice sheet. Thus, understanding of ice sheet evolution goes hand in hand with our ability to simulate the GIA signal accurately. We aim to improve the accuracy of Greenland GIA simulations by interrogating regional geophysical data sets to determine better 3-D models of Earth structure in this region. We use a self-consistent Bayesian joint inversion framework (LitMod) to constrain lithosphere and shallow mantle properties and their uncertainty from multiple data sets. The inversion results indicate a high sensitivity to the input seismic dataset, so we incorporate a new, regional high-resolution surface wave dataset based on the two-station interferometry method. In terms of simulating GIA, a key inversion output is the regional temperature field. We sub-sample a high variance set of 25 temperature fields to define 25 models of the lithospheric thickness (LT) and 50 models of sub-lithosphere viscosity structure (using two different scalings). Our results indicate that viscosity and LT vary, respectively, by 3-4 and 2 orders of magnitude across Greenland. So the predicted GIA signal shows significant differences compared to simulations based on the more traditional 1-D (spherically symmetric) viscosity models. We will present results based on these 50 Earth models and two different ice history models and compare them to geological reconstructions of relative sea-level change and GNSS observations of vertical land motion.

The Influence of Topography and Sediment Cover Change on Pleistocene Glacial Cycles and the MPT with Coupled Ice Sheet-Climate-Sediment Physics

DOI: 10.57757/IUGG23-5010 - LINK

Matthew Drew[1], *Lev Tarasov*[1]
[1]*Memorial University of Newfoundland, Department of Physics and Physical Oceanography, St. John's, Canada*

A change from a low to high friction bed under the North American Ice Complex through the removal of pre-glacial regolith has been hypothesized to play a critical role in the mid-Pleistocene transition from 41 to 100 kyr glaciations. However, this regolith hypothesis requires constraint on pre-glacial regolith cover and topography, mechanistic constraints on what amount of regolith can be removed, and complete process coupling to infer the net effect from topography and sediment changes. This landscape evolution has not yet been simulated for a realistic, 3D North American ice sheet fully considering basal processes (e.g. sedimentary, basal hydrology, and the solid earth response to changing sediment and bedrock load). Constraints of the pre-glacial bed are sparse and the bounds are wide.

What constraint does the present day sediment distribution offer and how do topography and sediment change influence glacial cycles? Using varied pre-glacial topographies, sediment thicknesses, and fully coupled climate, ice, sediment and subglacial hydrology model parameterizations, we show the constraint on mean pre-glaciation sediment thickness provided by the present day surface sediment distribution and regional estimates of bedrock erosion. More broadly, we find that this landscape evolution has a strong influence on the strength and duration of early Pleistocene glaciations. The ice, climate, and sediment processes encapsulated in this fully coupled Earth systems model capture the evolution of the Pleistocene North American glacial system: the 41 to 100 kyr glacial cycles transition, early Pleistocene extent, sea level change, last deglacial margins, and broad present-day sediment distribution within uncertainty.

Space geodetic data contain a glacial isostatic adjustment (GIA) signal, which is most prominent in formerly glaciated areas with present-day crustal uplift rates exceeding 10 mm/year in NE Canada and Central Sweden. Employing GNSS, VLBI, DORIS, and SLR data ingested into the latest international terrestrial reference frame (ITRF2020) we create a global dataset of GIA present-day uplift rates. We employ a multi-analysis-centre ensemble of GNSS station and geocentre motion coordinate solutions. Tectonic and weather signatures were reduced in estimating GNSS-derived velocities, and the trend signal is extracted from these GNSS time series with the STL method (seasonal-trend decomposition based on Loess). In addition, we develop a validation method for GIA model – data comparisons. As the geodetic stations are unevenly distributed, we employ a weighting scheme that involves network density and cross-correlation of the stations' displacement time series. As measures of agreement for global and regional cases, we employ the weighted root mean square error (RMSE) and the weighted mean absolute error (MAE). We apply the validation method to a large suite of GIA model simulations capturing uncoupled and coupled Solid Earth – Ice Sheet models, as well as laterally homogeneous and heterogeneous viscosity structures of the Earth's mantle, which are derived from a broad spectrum of geophysical data. The results suggest constraints on global and regional GIA model parameterisations in view of the considered observational data.

Among the geophysical techniques used to monitor volcanic unrest, only gravimetry can supply direct information on changes in the distribution of underground mass over time and can thus provide unique insight into processes such as magma accumulation in void space or gas segregation at shallow depths. Despite its great potential, time-variable volcano gravimetry is not widely adopted, mainly due to the high cost of instrumentation and the difficulty in assessing the relatively small volcano-related gravity changes against unfavorable environmental conditions.
Several past studies from Mt. Etna have highlighted the value of gravity observation for improving our understanding of how volcanoes work and characterizing volcanic hazards. In the early stages of application at Mt. Etna, time-lapse and continuous gravity measurements were accomplished using spring gravimeters. Successively, gravimeters based on different technologies have been employed, including superconducting and quantum devices. In most cases, these applications were world firsts at an active volcano.
Here, results from different gravimeter types, that have been used to monitor and study Mt. Etna, are presented. Furthermore, the perspectives opened by emerging technologies are highlighted.

Lake Nasser, which was formed as a result of the construction of the High Dam, located in southern Egypt and Northern Sudan with a length of 500 km and a storage capacity of about 133.8 km 3. The seismic activity recorded in this region clearly indicates its connection with a tectonic pattern in the earth's crust, in addition to the change in the water level in the lake according to its annual water cycle for charging and unloading, which leads to breaking the equilibrium state in the lake by changing the weight of the lake resulting from the change in the water level and sediments accompanying it. Thus, the process of monitoring and evaluating alluvial sediments along the lake is of great importance because of its impact on the storage capacity of the lake as well as the navigational path of the lake in addition to the economic importance of these sediments. The availability of accurate gravitational data for Lake Nasser greatly contributes to determining the subsurface geological structures and stratigraphic sequences (depth of the base rocks and the thickness of the alluvial deposits at the bottom of the lake).

On the current research, high resolution marine gravity survey has been conducted along the main course of the Lake. Moreover, satellite altimeter data has opened new perspectives on determining the gravity field on the marine region. Therefore, satellite altimeter data has been utilized as integration with the marine gravity survey to evaluate the whole gravity field of the Lake.

Falling corner cube gravimeters (FCCG) pose the current state-of-the-art instruments for absolute terrestrial gravimetry. However, already in the early 1990s, experimental quantum gravimeters have been demonstrated: a fundamentally different principle for measuring gravity based on probing the free-fall trajectory of ultracold atoms via quantum matter wave interference. In recent years, the community's interest in quantum gravimeters has strongly increased as they have progressed from experimental prototypes towards commercially available instruments intended for end-users in geodetic applications.

The commercially available iXblue Absolute Quantum Gravimeter (AQG) B-series instrument is a field-compatible successor to the A-series AQG, which is restricted to indoor use. Here, we present our first results of evaluating the AQG-B10 instrument for lab and field operation in BKG's routine measurement campaigns. We assess the instrument precision, stability, accuracy and reproducibility based on comparison measurements at the Geodetic Observatory Wettzell employing a continuous gravity reference function. This reference is derived from the combination of measurements with the Micro-g LaCoste FG5 FCCG, currently dominating absolute gravimetry, with highly precise superconducting gravimeters, and is linked to the EURAMET.M.G-K3 regional comparison of absolute gravimeters. Moreover, we compare the AQG-B10 to the Micro-g LaCoste A10 FCCG, the current state-of-the-art instrument for absolute field measurements.

Absolute gravity measurements at the level of 10 $nm.s^{-2}$ based on atom interferometry were demonstrated in the laboratory in 1992. Since then, quantum gravity sensors using laser-cooled atoms have received an increasing interest from the geophysics community. Like classical absolute gravimeters, these sensors measure the acceleration of free-falling test masses, atoms, but the working principle relies on the wave nature of matter postulated by quantum mechanics. Quantum gravimeters thus provide a technology inherently different from traditional gravimeters, which can be of interest if absolute measurements are to be checked by alternative technologies.

In 2015, Exail (formerly Muquans/iXblue) launched on the market the first commercial gravimeter based on the quantum manipulation of laser-cooled atoms, the Absolute Quantum Gravimeter (AQG). Exail's cutting-edge technology developments have bridged the gap between the complex academic setups and compact transportable instruments, which reaches the appropriate level of robustness and autonomy to sustain field-deployment. Several units have now been built and deployed for various geophysical applications, including hydrology and volcano monitoring. In this talk we present recent advances in the instrument performances, as well as examples of field-deployment. We focus on a 9-month gravity time series from a site close to the summit of Mt Etna volcano. Through this case study, we discuss the operational advantages offered by quantum technology to the field of volcano gravimetry.

Quantum sensors utilising atom interferometry offer new perspectives for future gravity missions. The atom interferometer therein promises long-term stable measurements and high accuracy, complementing or possibly replacing established sensor concepts.

Several different experiments based on this principle demonstrated measurements of gravitational accelerations and gravity gradients. Additionally, dedicated setups showed operation in microgravity environments and tested concepts for future space missions. A core feature of these setups is the robust generation of Bose-Einstein condensates with subsequent matter-wave collimation to generate a well-defined input state extending interferometry times and suppressing error terms.

We will present the state-of-the-art in interferometers using Bose-Einstein condensates, focused on the Quantum Gravimeter QG-1 and our microgravity activities, and discuss concepts for the implementation in future space missions.

Supported by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) in - Project-ID 434617780 - the SFB 1464 TerraQ within the projects A01, A02 and A03, and under Germany's Excellence Strategy - EXC-2123 QuantumFrontiers - Project-ID 390837967.

Optomechanical inertial sensors for geodesy

DOI: 10.57757/IUGG23-5007 - LINK

Felipe Guzman[1]
[1]*Texas A&M University, Aerospace Engineering & Physics, College Station, USA*

We report on the progress of our novel low-frequency optomechanical inertial sensing technologies for gravimetry and space geodesy. Our technologies are designed to be compact, portable, and are comprised of monolithically fabricated mechanical resonators that incorporate compact and highly sensitive laser interferometric displacement sensors.

Current laboratory prototypes have demonstrated mechanical quality factors *Q* of 4.77x10^5, an *mQ*-product above 1200 kg, a fundamental mechanical resonance of 4.7 Hz, which highlight their high sensitivity with acceleration noise floor nears 1x10^{-11} m s^{-2}/√Hz. Such compact systems are excellent candidates for future applications in gravimetry, geodesy, geophysics, and hydrology.

A prototype packaging has been developed to reduce losses caused by typical mechanical mounts. We have conducted comparison measurements with commercial low-frequency systems to an excellent agreement. Recent measurements taken with the resonator mounted in this packaging atop a vibration isolation platform have indicated that our system is seismically limited above 1 mHz. Noise floors in the order of 82 pico-g/√Hz at 0.4 Hz has been demonstrated in our laboratory.

We will present recent updates on our optomechanical inertial sensors, including up to date measurements of the resonator and interferometer sensitivity, as well as that of the combined system.

Cold Atom Interferometer (CAI) accelerometry is proposed for future generations of satellite gravimetry missions. The technique can achieve high sensitivity and provide long-term stability and precise measurements of the non-gravitational accelerations acting on the satellites. This would reduce the overall instrumental errors and improve the observation of the Earth's gravity field and its change over time and enable a better understanding of several geophysical phenomena, also related to climate change. The current CAI accelerometers have shown great performance, especially in the lower frequencies. They have been able to considerably reduce the bias which is usually seen in the measurements of conventional electrostatic accelerometers. However, noise sources such as satellite rotation can degrade the CAI solution if they are not carefully compensated.

In this study, we model the most impactful error sources which perturb the measurements of a CAI accelerometer onboard a GRACE-like satellite. We further investigate the sensitivity of the instrument to the various error sources, including detection noise, aberrations of laser wavefront, contrast loss due to the Coriolis acceleration and laser intensity inhomogeneity. We also consider the potential improvements which can be expected for satellite-based CAI accelerometers in the near and far future (e.g. longer interrogation time, rotation compensation in different scenarios, and increasing the laser waist). Additionally, we study their potential benefit for future satellite missions and the retrieval of the Earth’s gravity field.

Satellite gravity missions give unprecedented insights in the Earth system. However, a further improvement in spatial and temporal resolution is required to better monitor the various geo-processes. When considering the sensors of satellite missions, the accelerometers are the limiting factors. Cold Atom Interferometry (CAI) accelerometers are characterized by their long-term stability and an accurate knowledge of the scale factor.

Closed-loop simulations are performed in order to quantify the influence of different accelerometer performances on the gravity field recovery. The impact of the scale factor knowledge on the acceleration measurement is evaluated in terms of a requirement based on the non-gravitational acceleration signal and the accelerometer noise. Furthermore, the variation of the non-gravitational acceleration signal within one interferometer cycle is studied. It is demonstrated that both aspects are significant. The impact on the acceleration measurements can be reduced to an acceptable level by drag compensation. Moreover, the addition of a CAI cross-track gradiometer to a low-low Satellite-to-Satellite Tracking mission is investigated, as supplemental observations in east-west direction are provided. This combination enhances the estimation of the high-degree coefficients and reduces the striping effects in north-south direction.

An accurate model of the Earth's gravity field is beneficial for practical engineering and many applications in geosciences. ESA realized the GOCE gradiometry mission between 2009 and 2013. However, the observation accuracy of the GOCE mission suffered greatly due to the low-frequency drift of the onboard electrostatic accelerometers. Advances in electrostatic and quantum technology offer new measurement concepts for future gradiometry missions. In this study, we evaluate the contributions of several types of accelerometers through numerical closed-loop simulation which rigorously maps the accelerometers' sensitivities to the gravity field coefficients. In comparison to the simulated results of the GRADIO gradiometer used in GOCE, it is demonstrated that the MicroSTAR-type gradiometer has superior precision up to degree and order 100 and provides more signal information in the off-diagonal components of the gradient tensor. The precision of the gravity field model recovery using a hybrid gradiometer that includes quantum technology can benefit from the applied cold atom interferometry (CAI). A hybrid gradiometer with a CAI performance up to 10^-11m/s^2/Hz^1/2 will increase the retrieval of the gravity field remarkably. With an orbital rotation compensation mechanism, the CAI gradiometer can perform with higher accuracy than a classical instrument alone. If not, the accuracy when using the hybrid gradiometer might only be superior up to degree and order 50.

An important source of noise in the current global monthly time-varying gravity field obtained on the basis of GRACE-like missions (GRACE, GRACE-FO) is the error due to the aliasing of the high frequency non-tidal atmospheric and oceanic mass changes (AOD error). And due to the orbital configuration, the inter-satellite ranging system (K-band ranging system, KBR; laser interferometer, LRI) of gravity satellites is under-sampled in the east-west direction, leading to striping errors in the north-south direction. In our study, we introduced a new independent observational quantity called the angular velocity of the line-of-sight (LOS), i.e. the orientation change of the LOS caused by the gravity field, which has complementary information perpendicular to the LOS obtained from KBR/LRI. We call the combination of angular velocity sensing (AVS) and ranging observations GRACE-3D because it contains three-dimensional gravity observations, not just along the line-of-sight as in GRACE. We developed observation equations for AVS based on the dynamic approach and on the acceleration approach and solved them jointly with the observation equations generated by GPS and KBR/LRI using two independent software suites for cross-validation. The simulation results show that the AVS-based gravity field can reduce the effect of AOD error and significantly improve the north-south strip error when compared to the results obtained using only a combination of KBR/LRI and GPS. And the optimum results are achieved when GPS, LRI and AVS are combined. Finally, We will also briefly discuss how AVS measurements could be obtained in future missions.

Accurate quantification of the atmospheric state is achieved by assimilating numerous and disperse observations into numerical weather models (NWM). The spatio-temporal atmospheric density distribution, a derivative of essential meteorological variables, affects among others how electromagnetic signals traverse Earth's atmosphere and how satellites orbit through Earth's gravity field. Atmospheric refraction in the electrically neutral atmosphere is quantified e.g., during the GNSS data analysis, and holds valuable information about the water vapor distribution in the vicinity of the ground stations. Satellite gravimetry as realized by the GRACE and GRACE-FO missions is sensitive to mass redistribution within Earth's fluid envelope, including but not limited to the atmosphere and the terrestrial water storage, and to high-frequency variations stemming from the time-integrated effect of precipitation and evapotranspiration. In this work we employ two state-of-the-art meso-beta scale NWM (ECMWF's latest reanalysis ERA5 and DWD's operational model ICON-global) as well as ERA5's ensemble members to demonstrate that tropospheric moisture distribution and net atmospheric freshwater fluxes are quite uncertain in modern NWM in comparison to other quantities such as hydrostatic atmospheric mass and that certain space geodetic observing systems such as GNSS and GRACE-FO are appropriate tools to monitor them, thus enhancing the accuracy of numerical weather prediction.

for the CARIOQA-PMP consortium

CARIOQA-PMP (Cold Atom Rubidium Interferometer in Orbit for Quantum Accelerometry – Pathfinder Mission Preparation) aims for the development of atom interferometry for a future application in earth observation. Atom interferometers offer the perspective of complementing established sensor technology, implying an improvement in the gravity field recovery.

Whereas quantum sensors based on atom interferometry are studied worldwide and commercial gravimeters are available, the adaptation and qualification for a satellite mission imposes new challenges. Activities in Europe investigating this technology in microgravity facilities show promising results, but are limited by the available microgravity time. Consequently, a pathfinder mission is conceived as the next step towards quantum-sensor-enhanced gravity missions.

Within CARIOQA-PMP, the consortium will develop an engineering model for an accelerometer based on atom interferometry adapted for the accommodation on a satellite. It includes scientists supporting the development and evaluating future mission concepts.

This contribution will outline the background and the scope of the CARIOQA-PMP project.

CARIOQA-PMP is a joint European project, including experts in satellite instrument development (Airbus, Exail SAS, TELETEL, LEONARDO), quantum sensing (LUH, SYRTE, LP2N, LCAR, ONERA, FORTH), space geodesy, Earth sciences and users of gravity field data (LUH, TUM, POLIMI, DTU), as well as in impact maximisation and assessment (PRAXI Network/FORTH, G.A.C. Group), coordinated by the French and German space agencies CNES and DLR under CNES lead. Funded by the European Union.

Future satellite gravimetry missions may harvest the potential of highly sensitive quantum sensors. The scope of the DLR-funded project Quantgrav is to explore the potential of quantum sensors in space for the analysis of mass variations in the Earth system, towards a better understanding of global change processes such mass loss of continental ice shields and glaciers, changes in global water cycle and budget, or sea level variations.

In this project, different mission scenarios are evaluated, both full quantum gravimetry missions and hybrid missions combining quantum and classical monitoring techniques. In a first step, the error characteristics of potential quantum sensors are described. These are compared to classical observation technologies to determine their benefits. Mission scenarios involving these sensors are then applied in numerical simulations to identify their possible resolution in time and space. The scenarios are then analyzed with respect to their value for science- and service-oriented applications, as a basis for evaluating requirements for a quantum-based gravimetry mission towards a possible future pathfinder mission.

Here we present the results of the evaluation of aforementioned mission scenarios for hydrological applications. The focus is on a) the assessment of error characteristics of the scenarios for resolving water storage variations in the 500 largest river basins worldwide, and b) the potential of these missions to identify extreme hydrological events in these basins, i.e., droughts or floods.

The geosciences need to know the mass variations of the Earth with high spatial-temporal resolution and accuracy. Using appropriate sensor technology in optimized satellite missions is essential to monitor the various climate change processes at the required level. Here, it is crucial that novel technologies and dedicated observation concepts for Earth's gravitational field are developed for future missions.

First, we discuss the error properties of various quantum and hybrid gradiometer concepts. Cold Atom Interferometry (CAI) accelerometers and gradiometers exhibit white noise behaviour at low frequencies, making them perfectly complementary to classical electrostatic sensors. We show that accelerometers and gradiometers using atom interferometry, alone or in a hybrid constellation, can dramatically benefit gravity satellite missions. Comparing classical electrostatic gradiometers and CAI-based gradiometers in the spectral domain illustrates the differences of the concepts, also with respect to the GOCE case.

Based on simulated atom-interferometric and hybrid gradient measurements along one or more gradiometer axes in GOCE-like orbits, we discuss the pros and cons of the various approaches.

Geosciences have benefited greatly from the GOCE, GRACE and GRACE-FO missions, especially regarding how the observations of terrestrial mass variations is used to understand and track climate change processes. Furthermore, future gravimetry missions are planned to keep monitoring the static and time variable Earth gravitational field. A limiting factor in gravity field recovery resolution is the sensitivity of the spacecraft's accelerometers, responsible for distinguishing the non-gravitational accelerations from the gravitational signal. Novel accelerometer designs with enhanced sensitivity would therefore be valuable for gravimetry.

To facilitate this venture, we built a tool to model and simulate accelerometers and gradiometers. ACME (Accelerometer Modeling Extended) is a MATLAB/Simulink toolbox that numerically simulates parametrically generated accelerometers and gradiometers, including the dynamics of test mass, capacitances and actuation forces from the electrodes, system frequency response and noise budget (with noise sources such as gas thermal, capacitance sensor, contact potential difference, actuation, and so on). It also includes different sensor models, such as capacitive sensing and laser interferometric readout.

In order to simulate the in-flight behaviour of the instrument, it can be integrated with an orbital dynamics simulator with high-fidelity gravitational field model (XHPS). The generated amplitude spectral densities and mock data series are passed onto gravity field recovery software to evaluate the possible science return. Additionally, simulating legacy instruments allow us to validate the workflow. We'll present the development progress of the toolbox and some illustrative results of what it can achieve.

More than 20 years of satellite gravimetry missions have provided unique data about mass redistribution processes in the Earth system. Ongoing climate change underlines the urgent need to continue this kind of measurements with enhanced concepts and sensors. Here, we focus on accelerometers (ACC).

Drifts of the electrostatic accelerometers (EA) are one of the limiting factors in the current space gravimetry missions dominating the error contribution at low frequencies. The focus of this study is on the modelling of enhanced EAs with laser-interferometric readout, so called 'optical accelerometers' and evaluating their performance at Low Earth Orbit (LEO). Contrary to present-day EAs, which measure capacitively the TM displacement and actuate it electrostatically, optical ACC, beside a similar actuation scheme, track the TM with laser interferometry.

Our research is based on promising results of the mission LISA-Pathfinder which demonstrated the benefit of using a drag-free system in combination with optical accelerometry and UV TM discharge which allowed sensing of non-gravitational accelerations several orders of magnitude more accurate than it is realized in current gravity missions.

In this presentation, we now introduce a framework for modeling novel EA with laser-interferometric readout mainly developed by IGP including major noise sources, like actuation noise, capacitive sensing, etc. Also, parametrization of the developed ACC model will be discussed including different TM weights and TM-electrode housing gaps. Finally, improved results of the recovered gravity field will be shown for various mission scenarios applying optical accelerometry and gradiometry.

This project is funded by: Deutsche Forschungsgemeinschaft (DFG) – Project-ID 434617780-SFB 1464.

More than 20 years of satellite gravimetry missions have provided unique data about mass redistribution processes in the Earth system. Ongoing climate change underlines the urgent need to continue this kind of measurements with enhanced concepts and sensors. Here, we focus on accelerometers (ACC).

Drifts of the electrostatic accelerometers (EA) are one of the limiting factors in the current space gravimetry missions dominating the error contribution at low frequencies. The focus of this study is on the modelling of enhanced EAs with laser-interferometric readout, so called ‘optical accelerometers’ and evaluating their performance at Low Earth Orbit (LEO). Contrary to present-day EAs, which measure capacitively the TM displacement and actuate it electrostatically, optical ACC, beside a similar actuation scheme, track the TM with laser interferometry.

Our research is based on promising results of the mission LISA-Pathfinder which demonstrated the benefit of using a drag-free system in combination with optical accelerometry and UV TM discharge which allowed sensing of non-gravitational accelerations several orders of magnitude more accurate than it is realized in current gravity missions.

In this presentation, we now introduce a framework for modeling novel EA with laser-interferometric readout mainly developed by IGP including major noise sources, like actuation noise, capacitive sensing, etc. Also, parametrization of the developed ACC model will be discussed including different TM weights and TM-electrode housing gaps. Finally, improved results of the recovered gravity field will be shown for various mission scenarios applying optical accelerometry and gradiometry.

This project is funded by: Deutsche Forschungsgemeinschaft (DFG) – Project-ID 434617780-SFB 1464.

With GRACE Follow-On in orbit for almost five years, developments for the next generation of gravity missions have begun. Firstly, there is the continuation mission of the US-German collaboration that already realized GRACE and GRACE Follow-On. Secondly, ESA is pursuing the so-called Next-Generation Gravity Mission (NGGM) for a launch around 2031. Both pairs are expected to form a constellation with optimized orbit geometry, i.e., a so-called Bender configuration. All of these activities include an improved version of the laser ranging or tracking instrument (LRI/LTI) as the primary ranging instrument, which will be the subject of this presentation.

We will present the operating principle of the LRI/LTI and address the key requirements and challenges of the instruments needed to achieve a ranging noise below the requirement of 40...80 nanometer/sqrt(Hz) for the 200 km satellite separation. We will highlight some of the adaptions needed to evolve the technology demonstrator from GRACE-FO to a primary instrument and discuss the lessons learned so far. Since microwave ranging is not available in future missions, the LRI/LTI scale factor given by the absolute laser frequency needs to be determined by other means, which will also be covered.

GRACE Follow-On, the successor of the GRACE mission, continues the legacy of Earth gravity field recovery missions. This experiment's data is an essential contribution to observing and understanding Earths changing climate conditions by, e.g., observing changes in groundwater levels and the mass of ice shields. Activities on successor missions to guarantee an uninterrupted observation of the gravity field are ongoing.
The primary instrument in these missions will be a heterodyne laser interferometer based on the success of the GRACE-FO mission and its superior noise performance compared to the previous microwave ranging. In this talk, we discuss the effect of distorted optical wavefronts on the length readout. We are developing tools to measure the wavefront on ground and extrapolate it over the long distance to the remote spacecraft. We also investigate the potential influence of such distortions together with pointing jitter of the spacecraft.

A space-wise approach based on collocation for SST mission data processing

DOI: 10.57757/IUGG23-4180 - LINK

In the framework of gravity field modelling from satellite mission data, the PoliMi group had designed and developed a space-wise approach based on multi-step collocation, which has been applied to process gradiometric data, like those observed by GOCE. Briefly, this space-wise approach consists of an along-orbit filtering to reduce noise variance and correlation, a local gridding over data patches, and a spherical harmonic analysis by numerical integration; the scheme is iterated till convergence. While the gradiometric observation is directly a functional of the gravity field, with satellite-to-satellite tracking (SST) missions, like GRACE or NGGM/Magic, the main observable becomes a geometric quantity, namely the range or range-rate between pairs of satellites.

To properly process this kind of observables by the space-wise approach, a conversion from the geometric quantity to an along-orbit gravity functional is required. For example, potential can be retrieved by energy balance approach, first derivatives by Hill's equations, second derivatives by exploiting accelerometers on board the satellites as a gradiometer. The space-wise approach has been properly adapted to take one of this functional as input. The main modification is at the gridding level, where suitable covariance modelling is required, also considering the time-variable gravity signal.

The proposed algorithms are applied to different simulated scenarios, assessing the accuracy of the solution by Monte Carlo sampling. In these simulations the payload is considered to be quantum instrumentation, and the performances of the space-wise approach in retrieving both static and time-variable gravity field with gradiometric and SST mission profiles were analysed.

The Gravity Recovery and Climate Experiment Follow-On (GRACE-FO) mission is observing the time variable gravity field by measuring distance variations between two satellites. The first Laser Ranging Interferometer (LRI) between distant spacecraft uses a so-called Fast Steering Mirror (FSM) to satisfy the narrow LRI pointing requirements despite the larger spacecraft pointing variations. The position readout of these mirrors allow to compute the inter-satellite pointing angles yaw and pitch w.r.t. the line-of-sight connecting both satellites. The nominal pointing variations have a magnitude of a few 100 µrad. Typically, the attitude information of roll, pitch and yaw angles is derived from three star cameras and fibre optic gyroscopes.

Since we are particularly interested in the characterization of the FSM at low-frequencies, we compare the FSM readout with star camera measurements for the time-span of December 2018 until December 2022. The residuals show temperature induced changes which are related to the varying orientation of the orbital plane and the sun, expressed through the angle **β**'. We will present our analysis that attempts to attribute and model the residuals.

This analysis is of interest for future gravity missions, where the FSM could be implemented as an additional attitude sensor to control the satellite orientation.

We proposed an approach to directly measure the gravitational potential (GP) along the orbit of a satellite, especially for the Low-Earth Orbit (LEO) satellite. The LEO satellite is connected with several Geosynchronous Equatorial Orbit (GEO) satellites through frequency signal links. Arming all the LEO and GEO satellites with precise atomic clocks, the GP difference between LEO and GEO can be measured at any time based on the gravity frequency shift approach. Supposing that the GP of GEO satellites is given, then the GP along the orbit of the LEO satellite can be determined. In this study, we conducted simulation experiments, considering the GRACE-type satellite as the LEO satellite, connected with three evenly distributed GEO satellites. The results show that the precision of the obtained GP along the orbit of the LEO satellite is mainly determined by the precision of onboard atomic clocks. If optical atomic clocks reach an instability level of $1\times10^{-17}\tau^{-1/2}$ (τ in second), the gravitational potential along the orbit of the LEO satellite can be determined at the decimeter level with a resolution of 5'×5'. The GP information along the orbit of an LEO satellite is valuable, for it can be utilized to improve the Earth's gravity models. This study is supported by the National Natural Science Foundation of China (NSFC) (Grant Nos. 42030105, 41721003, 42274011), and Fundamental Research Funds for the Central Universities.

Determination of low-degree temporal variations in the Earth's gravity field using novel optical clocks on-board of low earth orbiters

DOI: 10.57757/IUGG23-3083 - LINK

Akbar Shabanloui[1], *Hu Wu*[1], *Jürgen Müller*[1]
[1]*Institute of Geodesy, Leibniz University of Hannover, Hannover, Germany*

The current progress of optical clocks has reached a fractional frequency uncertainty of $1.0\text{x}10^{-18}$ which corresponds to a geopotential difference of 0.1 m^2/s^2. Those gravitational potential differences can be observed as gravitational redshift when comparing the frequencies of optical clocks. Even temporal potential variations might be determined with precise optical clocks on low-orbiting satellites, e.g., at altitudes of SLR-like (e.g. LAGEOS-1/2), GRACE-like and GOCE-like missions.

In this simulation study, the potential of space-borne precise novel optical clocks for the determination of temporal variations of low-degree gravity field spherical harmonic coefficients will be discussed. We will demonstrate that optical clocks at current achievable level of uncertainty are able to reveal long-wavelength seasonal and secular gravity changes. Different configurations of satellite orbits, i.e. at different altitudes (between 250 and 6000 km) and inclinations, are selected as well as certain assumptions on the clock performance are made. We will quantify how well degree-2 coefficients can be estimated from those optical clock measurements and how it compares to results from SLR data.

Keywords: Optical clock measurements in space, temporal long-wavelength Earth's gravity field variations, Relativistic Geodesy

Terrestrial applications of chronometric geodesy

DOI: 10.57757/IUGG23-0701 - LINK

Asha Vincent[1], Juergen Mueller[1]
[1]Leibniz University Hannover, Institute for Geodesy, Hannover, Germany

The novel method of relativistic geodesy using clock networks has reached an accuracy level that will enable interesting applications in the near future. High-performance clocks with a fractional frequency uncertainty of 10^-18 can detect a gravitational-potential change of 0.1 m^2/s^2 or a corresponding height difference of 1 cm between two clock sites. Here, we explore the advantages of terrestrial clock networks for the detection of time-variable gravity signals and for height system unification by simulations where we consider realistic observation scenarios. On the deformable Earth, terrestrial clock observations contain potential variations due to mass changes and surface displacements. Four case studies were conducted in the Himalayas, Amazon, Greenland, and Fennoscandia to study different mass change processes like seasonal precipitation, present-day ice mass loss, and glacial isostatic adjustment (GIA).

Height system unification involves the estimation of different errors (e.g. tilts and offsets) between the local/regional height reference systems. As a test case, an a priori height system was classified into local systems where various errors have been added. The reunification and estimation of error parameters were carried out using simulated clock measurements. The considered errors include tilts along latitude, tilts along longitude, offsets, tilts that depends upon the distance from the tide gauge, tilts associated with certain levelling lines, systematic noise associated with the elevation of the levelling points, etc. Also, the tidal effects on the clock observations are investigated. Moreover, the optimal number and spatial distribution of the clocks are determined for each scenario.

According to general relativity theory, the geopotential difference can be determined by comparing the clocks' vibration frequencies or running rates. We conducted experiments to determine the geopotential difference between two remote sites with a height difference of about 1,245 m using two sets of hydrogen maser systems via precise point position time-frequency transfer technique. Two equipment sets were installed at one site or two remote sites to form the local or remote time-frequency transfer link. The gravity frequency shift between two hydrogen masers at two remote sites is derived from the resolved clock offset series, taking into account the local time-frequency transfer link as calibration. Then the geopotential difference is determined as 12,142.3 (112.4) m^2/s^2, quite close to the value 12,153.3 (2.3) m^2/s^2 computed by the EIGEN-6C4 model. Results show that the method proposed here for determining geopotential difference is promising for broad applications. This study is supported by the National Natural Science Foundation of China (NSFC) (Grant Nos. 42030105, 41721003, 42274011), Space Station Project (2020)228, and Fundamental Research Funds for the Central Universities (2022).

The National Institute of Information and Communications Technology (NICT) has developed a Sr optical lattice clock and optical ion clocks employing In+ and Ca+. The centimeter-level uncertainty of site elevation is the cause of 10^(-18)-level frequency uncertainties of optical frequency standards. It is significantly important to understand frequency changes caused by solid-earth tides that often range from 10 to 20 cm in amplitude, by oceanic tidal loading, crustal deformations due to earthquakes, and ground movements with groundwater changes for the stable operation of optical atomic clocks.

NICT and partners including the Geospatial Information Authority of Japan (GSI) have been jointly conducting leveling surveys and relative gravimeter observations at NICT's headquarters in Koganei. These observations reduce the contribution of gravitational redshift to the total uncertainty of the optical lattice clock to the 10^(-19) level. With the support of National Institute of Polar Research (NIPR), absolute gravity measurements were performed in August 2019 and May 2022 to evaluate the effects of the 2011 off the Pacific coast of Tohoku Earthquake on postseismic crustal movement. The obtained absolute gravity change between the two periods was -43.8 μGal, which matches the trend of GNSS vertical movement obtained by GSI. We have introduced a Micro-g LaCoste's gPhoneX gravimeter for continuous gravity measurements nearby the optical clocks in the end of 2021 and have started to investigate the temporal variation of the ground water level in Koganei. We will present preliminary results of these geodetic measurements.

International reference frames are cornerstones for all metrological applications related to Earth sciences covering global change research, global deformation, and mass transport. Over the last two decades, the precision of underlying measurements on which the reference frame is based improved to a millimeter level. However, the overall achieved accuracy remains at centimeter-level errors. In this contribution, we will introduce a promising approach examining imperceptible error sources which influence all types of measurement equipment and which are not captured by any calibration. To make them visible, combinations of different kinds of techniques are needed. The recently established DFG funded research unit “Clock Metrology” introduces the new measurement constraint based on accurate optical clocks to demonstrate the direct measurement of a physical height difference between the Geodetic Observatory Wettzell and the Physikalisch-Technische Bundesanstalt based on optical time transfer. The investigation of systematic errors is based on the introduction of a new timing tie into a measurement and analysis process, guaranteed by the preservation of clock coherence used for systems calibration. Within this research unit, we will develop a new calibration technique that expands local coherence to the measurement process of satellite positioning. We will achieve this by transmitting an artificial Galileo signal preciously synchronized to a common clock.

[1]Methods for Model-based Development in Computational Engineering, RWTH Aachen, Aachen, Germany

Reusability of research data is one of the four FAIR principles. Envisioning future data reuse scenarios early in the data life cycle requires anticipation, since data reuse is often not carried out by the data producers, and reuse scenarios are constantly evolving. Data reuse is especially challenging when the data reuser is active in a different domain than the data producer. The application of data science methods, for instance, poses a growing demand on the (meta-)data information quality. In Earth Sciences, the development of data-driven models or data-integrated predictive simulations often first requires to assemble a homogenous and sanity checked data compilation as training data, which is made up of individually heterogeneous and non-consistent data sets. In order to do that in an efficient way the data sets have to comply with the FAIR paradigms. Here, we share our experience from creating a data compilation from sea ice core data with focus on temperature and salinity measurements. First, we will report on the FAIRness of publicly available sea ice data. The heterogeneous character of the data morphology and metadata availability makes interoperability challenging and reuse laborious. To overcome these deficiencies, we developed a workflow to create data compilations. We will conclude with a descriptive analysis of the sea ice core data compilation.

FAIR assessment: A subjective qualitative interpretation or a domain-specific and quantitative measure?

DOI: 10.57757/IUGG23-4389 - LINK

Angelo Strollo[1], Susanne Hemmleb[1], Laura Hillmann[1], Peter Evans[1], Javier Quinteros[1], Robert Huber[2], Florian Haslinger[3]

Findability, Accessibility, Interoperability and Reusability have become important principles in the geoscience community as it makes standardisation and openness a priority, so that these keywords are nowadays in focus for any new project at institutional, national and international levels. In seismology and its community that uptake has been extremely rapid and the level of FAIRness reached can be considered well above average within geoscience. But what "well above average" means and how to quantitatively assess FAIRness within this domain and compare seamlessly to others remains challenging.

Taking advantage of ongoing national and international projects, a group of data managers from the EPOS seismological community started a collaboration with the FAIR-IMPACT project and its F-UJI developers aiming at enhancing the FAIR assessment process for specific domains. The group went through a process of mutually increasing awareness and understanding of FAIR definitions and their interpretations, including machine readability. Outcomes included F-UJI developers becoming more aware of the overall granularity and conception of research datasets including standard data and metadata formats used in seismology; revisions to landing pages; and updating guidelines to harmonise DataCite metadata for datasets within the domain.

In this presentation we outline the liaison process established by the seismological data managers with F-UJI and introduce the first outcomes. We present the initial guidelines developed, a summary of selected FAIR assessments and finally we propose to further discuss FAIR assessment within the seismological formal governance body, namely the International Federation of Digital Seismograph Networks (FDSN) as a commission of IASPEI.

In the Inter-university Upper atmosphere Global Observation NETwork (IUGONET) project, we have been creating metadata for ground observation data in space physics and populating them into the database since 2009 (http://www.iugonet.org/). These metadata followed the IUGONET metadata schema version 2.4.0.1, which is an extension of the SPASE (Space Physics Archive Search and Extract) metadata schema version 2.4.0.The IUGONET metadata database is very useful for researchers to search for data that they need and to obtain detailed information about data, but the metadata search is available only through the IUGONET page or NASA Heliophysics Data Portal. To promote data usage by a wider research community or the general public, it is needed to convert the metadata database from SPASE to more general schema so that the metadata can be ingested into other metadata databases. For that purpose, we developed a mapping table from SPASE to the JPCOAR (Japan Consortium for Open Access Repository) schema, which has been widely used for scholarly communication and data publication in Japan. Based on the mapping table, we converted part of our metadata, which describe data created in Nagoya University, to those in the JPCOAR schema. The converted metadata were registered in the institutional repository of Nagoya University (https://nagoya.repo.nii.ac.jp/). These metadata are consequently harvested by Institutional Repositories DataBase (https://irdb.nii.ac.jp/), Data Catalog Cross-Search System (https://search.ckan.jp/), and Google Dataset Search (https://datasetsearch.research.google.com/). We plan to do the same action for the other IUGONET metadata. This will significantly enhance findability and accessibility of the IUGONET metadata and their describing data.

GeoNet New Zealand: Recent Open Data and other key Initiatives

DOI: 10.57757/IUGG23-2193 - LINK

Jonathan Hanson[1], Elisabetta D'Anastasio[1], Joshua Groom[1], Mark Chadwick[1], Jerome Salichon[1], Elizabeth Abbott[1], GeoNet Programme Team[1]
[1]GNS Science, Data Science and Geohazard Monitoring, Lower Hutt, New Zealand

Aotearoa New Zealand's GeoNet programme was launched with an open data framework to support research, monitoring, and geohazard response at its core. Open data has proven to be hugely successful for GeoNet funders and user community and continues to be at the heart of GeoNet. GeoNet is now evolving to develop new services, storage, processing, and dissemination mechanisms to meet emerging data usage requirements (for example: requests to access large data volumes).

Over the last few years, GeoNet has taken some major steps forward in supporting data access, usability, and resilience in data operations:

- GeoNet moved its diverse data collection, processing and storage to the cloud (Amazon – Web Services). This includes the development of a data lake strategy;
- GeoNet released TILDE, a system to disseminate low to medium sample rate datasets in a common format, that supports access via an Application Programming and a Graphical User Interfaces;
- GeoNet partnered with AWS Open Data Sponsorship Programme to make a copy of its data freely available for large data query access.

GeoNet continues to face other challenges: understanding and tracking impact and data use (user registration and authentication for data access?), quality monitoring, adoption and impact of new initiatives (e.g. citizen science), improving integration of Te Ao Māori, and significant expansion of data volumes and variety. But with challenges come opportunities and GeoNet looks forward to working with the broader international community and fostering discussions to how best to balance data funders/providers/users needs whilst keeping open data as a core principle.

How to bridge data knowledge gaps in hydrology? A priority area in the new phase of UNESCO-IHP (and beyond).

DOI: 10.57757/IUGG23-4656 - LINK

Stephan Dietrich[1], Luna Bharati[1], Matthias Zink[1], Philipp Saile[1], Claudia Färber[2], Looser Ulrich[2], Harald Koethe[1]

The need for improved data and information exchange in freshwater-related observations has been a long-standing issue for scientists. Despite progress in hydrological cycle observations, the Global Climate Observation System (GCOS) still identifies the need for improvements in data exchange. We summarize past and recent efforts to improve data sharing globally and regionally, focusing on technical efforts and agendas at UN level. The main barriers are known and related to a) lack of capacity to apply international standards for data and metadata exchange and b) restrictive data policies that hinder data exchange. To bridge these data knowledge gaps we will introduce a subtopic of the IX. phase of UNESCO-IHP, the Output 3.3 dealing with “Comparing and validating open access data on water quantity, quality and use and their sharing by the scientific community supported for sustainable water management.” The presentation covers

- recent developments by the WMO in advocating for open data policies and improving interoperability, including the role of globally operating data centers federated in the Global Terrestrial Network - Hydrology (GTN-H). We will provide insight into recent efforts of the GEMS/Water Data Centre to improve interoperability of water quality data and show the success of the GRDC in implementing a new data portal,
- a report on the UN 2023 Water Conference and its focus on sharing water observation data to achieve SDG6 goals.

The presentation additionally aims to encourage discussions on how to improve scientific data comparison and cross-validation across domains by facilitating standards to improve compatibility and harmonization across teams and disciplines.

The open data paradigm spurred the sharing of data through different pathways determining the generation of different versions of the same datasets. This might depend on different factors: the data delivery process, the data center managing the dataset or the marine data infrastructure collating it.

A data provider should define a data quality assurance and long term curation strategy along with the data lifecycle, which implies the possibility of reprocessing a dataset according to the latest quality control procedures and standards. To this, it is important to combine data with complete metadata description allowing interoperability, traceability and transparency of the information process. In particular, some key metadata is crucial in climate science because it allows to re-analyze historical data, quantifying and reducing uncertainties of key ocean monitoring indicators such as the Ocean Heat Content.

The objective of this work has been to reprocess all the raw data and metadata available from about 3800 XBT (eXpendable BathyThermograph) probes launched in the Ligurian and Tyrrhenian Seas between 1999 and 2019 by applying an improved delay mode and almost completely automatic quality control procedure. The dataset contains the most complete set of metadata collected during the monitoring activity, not available in any previous data version. The data has been encoded and formatted following the latest community standards and FAIR principles with the aim of implementing an operational workflow for the new monitoring activities and the Near Real Time delivery of data through ERDDAP server.

Integration of biophysical data in a hydrologic knowledge graph precursor for water and carbon tradeoffs

DOI: 10.57757/IUGG23-4784 - LINK

Hasnat Aslam[1], *Francisco Munoz-Arriola*[1]
[1]*University of Nebraska-Lincoln, School of Natural Resources, Lincoln, USA*

Data integration and analytics platforms play a critical role in better understanding natural systems and laying the foundations for modeling them as complex adaptive systems—for example, how carbon and hydrological cycles can track the functionalities of (agro)ecosystems. Also, the resultant databases and other digital resources are the precursors of knowledge graphs. Nonetheless, data-driven models have become widely used in water resource planning and management; these models require datasets that incorporate the diversity and variability of patterns that occur in nature, including those driven by land use, crop management, and climate variability and change, for model generalization. Further, the use and integration of data can be constrained to a few sources due to the availability of datasets and the time, skills, and efforts required to blend multi-disciplinary heterogeneous datasets. The main goal of this study is to integrate biophysical variables (crop, land cover and soil information) to the recently designed open-source web platform. The objectives are to (1) design a job schedular for data retrieval at the regular temporal interval, (2) data preprocessing, quality control, and data integration pipelines, (3) design of NoSQL (MongoDB) database for a flexible, efficient, and reliable data storage for heterogeneous and semi-structured datasets that support parallel processing and complex geospatial queries for data analytics. We expect to foster the exploration of the underlying biophysical processes associated with the intensity of the intertwined carbon and water cycle and eventually a better management of carbon budgets by developing and training data-driven models and analytics for stakeholders and decision-makers.

The Global Runoff Data Centre – Facilitator between data providers and the hydrological research community

DOI: 10.57757/IUGG23-2838 - [LINK]

Claudia Färber[1], *Thomas Recknagel*[1], *Henning Plessow*[1], *Ulrich Looser*[1]
[1]*Federal Institute of Hydrology BfG, Global Runoff Data Centre GRDC, Koblenz, Germany*

River systems are an integral part of the water cycle. Observational runoff data are fundamental for the sustainable management of water resources and for the validation of hydrological models across all scales.

The Global Runoff Data Centre (GRDC) operates under the auspices of the World Meteorological Organization (WMO) at the German Federal Institute of Hydrology (BfG). Established in 1988, it holds the most substantive collection of quality assured river discharge data worldwide. GRDC has been a key partner in a number of data collection and data management projects and provides the link between national hydrological and hydrometeorological services and the international research community.

Currently, the Global Runoff Database contains river discharge data collected at daily or monthly intervals from more than 10,000 stations in 160 countries, dating back up to 200 years. As a trustworthy source for runoff data, GRDC has been integrated into the WMO Catalogue for Climate Data, supporting climate research and environmental risk assessment. In addition, GRDC provides different sets of geospatial data products that have formed an important basis for various modelling studies. As the awareness for open data and reproducibility has increased in recent years, GRDC is working to simplify data provision to its users. GRDC data and products are accessible online for non-commercial use (https://grdc.bafg.de/). However, there are still hurdles on the way to a completely open and free exchange of data such as restrictive data policies and a lack of data standardization.

Turning publications into data – imagining a world of linked hydrologic knowledge

DOI: 10.57757/IUGG23-0835 - LINK

Lina Stein[1], *Thorsten Wagener*[1]
[1]*University of Potsdam, Institute of Environmental Science and Geography, Potsdam, Germany*

As a science, hydrology faces diverse sets of interacting processes combined with a vast heterogeneity of our environment. Ideally, one would be broadly knowledgeable in all processes of the water cycle, but taking such a holistic approach to our science has become problematic due to the vast number of hydrologic case numbers published. Exponential publication numbers make it impossible to keep up with the current literature, not to mention the knowledge acquired over time.

These publications comprise a vast source of information and data that is not being utilised at the moment. One solution that has been discussed is to extend our article metadata to relevant hydrologic information in support of search and synthesis of hydrologic knowledge. There is a wide range of relevant metadata: for example, research topic, study location, models used, time period covered, data availability…. In regard to data services, it could be used to link data collections or networks with the models that use that data, the researchers who employ the models, and the publications that summarise the knowledge gained.

For this data to be useful and used by the community, it will need a collaborative platform to host this information. We discuss the use of Wikidata, a free, accessible, machine-readable, and editable by all, database, for this task. An added benefit is that Wikidata can easily link to existing data repositories and persistent identifiers, thus making the concept not only of interest for article metadata but also a potential interoperable approach for data services.

Modern scientific endeavours already have the capacity to call upon a vast variety of data, often in huge volumes. However, the challenge is not only how to make the most of such a resource, but also how to make it available to the wider scientific community. Fifty-one institutions from 13 countries are currently working together in the Geo-INQUIRE (Geosphere INfrastructure for QUestions into Integrated REsearch) project.

The goal of this new project is to enhance, give access to, and make interoperable, key datasets of the Geoscience community. This will include "big" data streams and high-performance computing codes which are critical to studying the temporal variation of the solid Earth, forecasting multi-hazards, evaluating Georesources and the analysis of the interface between the solid Earth as well as oceans and atmosphere. About 150 access points – both on-site and virtually are involved.

Several European Research Infrastructure Consortia take part, namely the European Plate Observing System (EPOS) for solid Earth and geodynamics observations, the European Multidisciplinary Seafloor and Water Column Observatory (EMSO) for deep-sea and coastal observations, and ECCSEL for CO2 capture, utilization, transport, and storage, and geoenergy. This 16 million Euro project started in October 2022, within the Horizon Europe Infrastructure program.

The presentation will briefly describe the project and give examples of curiosity-driven research topics which will be made possible through such a multi-disciplinary project. We will finally present the challenges and efforts made to comply with FAIR principles and accompany the dissemination of the data with innovative and cross-disciplinary training activities.

This 16 million Euro project started in October 2022, within the Horizon Europe Infrastructure program.

The presentation will briefly describe the project and give examples of curiosity-driven research topics which will be made possible through such a multi-disciplinary project. We will finally present the challenges and efforts made to comply with FAIR principles and accompany the dissemination of the data with innovative and cross-disciplinary training activities.

Harmonized oceanographic cruise databases for connecting ocean datasets

DOI: 10.57757/IUGG23-4313 - LINK

Elena Tel[1], *Sonsoles Gonzalez-Gil*[2], *Gonzalo Gonzalez-Nuevo*[3], *Fernando Redondo*[1], *Manuel Ruiz-Villarreal*[3]
[1]*Instituto Espanol de Oceanografia IEO-CSIC, Central Headquarters. National Oceanographic Data Center, Madrid, Spain*

[3]*Instituto Espanol de Oceanografia IEO-CSIC, C.O. A Coruna, Madrid, Spain*

First steps towards digital oceans rely on connecting datasets, harmonizing criteria and providing data access to wider user communities, but along the time, different storage codes have been adopted by the data providers according their own needs. The National Oceanographic Data Centre (NODC) is performing a strong effort in order to unify its datasets, making easier their identification and access. In the framework of (International Oceanographic Data Exchange, (UNESCO/IOC/IODE) initiatives, the IEO maintains a standardized catalogue of oceanographic surveys (CSR), integrated in international repositories as SeaDataNet or POGO. Although this activity has suffered ups and downs over 50 years of activity, the updating results sums up more than 4000 entries, including foreign surveys in national waters.

Linked to it, the whole discrete water sampled analysis dataset has been renamed, profile by profile, following the same adopted naming criteria that CSRs. This assesses the uniqueness, prevent duplicates an improve their accessibility. More than 16000 profiles have been revised and updated following this approach, improving data access and allowing better storage protocols. The initiative accomplishes the european adopted criteria for metadata and data storage formats. A Geonetwork -OGC standard- catalogue possibilities the access to this information and data to a wide end-users community.

As a case study, the information of the monthly standard oceanographic section of A Coruna (NW of Spain) is implemented in a local Geonetwork catalogue. Information about cruises and profiles is freely available. The technological harvesting capacities and machine to machine connections, increases the data visibility and reusing.

Quality control procedure and bias assessment for the global oxygen profile dataset

DOI: 10.57757/IUGG23-2994 - LINK

Viktor Gouretski[1], *Lijing Cheng*[1], *Juan Du*[1]
[1]*Institute of Atmospheric Physics- Chinese Academy of Sciences, International Center for Climate and Environmental Science, Beijing, China*

Global archive of dissolved ocean profile data is characterized by a high degree of heterogeneity with data obtained both by the Winkler chemical titration method and by different electrochemical and optical sensors. Respectively, the accurate assessment of the secular change of the oxygen content critically depends both on the quality control of oxygen data and the estimation of the sensor data bias relative to the reference Winkler method data. Based on the earlier studies on data quality control within the International Quality-Controlled Ocean Database initiative (IquOD) we developed the quality control procedure for the ocean oxygen profile data and applied it to the global World Ocean Database. Selected high quality oxygen profiles were used to estimate the effectiveness of the procedure in identifying data outliers. Analysis of data outliers reveals significant differences in data quality between the Winkler method and sensor data with data from CTD profiles showing higher outlier percentages compared to the ship-based Winkler method data and data from Argo floats. The co-located quality controlled oxygen profiles were used to estimate systematic offsets between the sensor and Winkler method data. We find significant time-varying negative overall oxygen offset for Argo oxygen profiles, with mean offset decreasing from about -10 to -12 mkmol/kg before 2010 to -5 mkmol/kg after about 2015.

Citizens AND HYdrology (CANDHY): On the application of a framework for benchmarking citizen science projects in hydrology

DOI: 10.57757/IUGG23-3998 - LINK

Fernando Nardi[1]
[1]*University for Foreigners of Perugia, WARREDOC, Perugia, Italy*

The CANDHY Working Group (WG) by IAHS aims to foster scientific exchange among academic, institutional, business and citizen communities by promoting discussion and sharing of knowledge, information, data, and ideas related to "Citizen AND Hydrology". CANDHY seeks to harness the potential of citizen involvement and crowdsourced data to advance hydrologic research on water resources management, hydroclimatic risk mitigation, and disaster preparedness. Indigenous knowledge and new data coming from increasingly accessible mobile technologies are some of the topics of interest of the Group. CANDHY aims to join efforts with social sciences in identifying novel frameworks for integrating diverse socio-cultural and demographic dynamics, citizen perception and behavior into hydrological study. CANDHY promotes studies that engage citizens as human sensors and management actors of hydrological and societal change.

The first CANDHY community paper presented a novel framework for benchmarking citizen science projects in hydrology. This community paper conceptualized the application of the framework for assessing citizen science projects of interest for the hydrological and geophysical sciences. The framework may be visually represented by a radar plot, which provides a schematic visualization of the benchmarking and assessment framework to selected citizen science projects.

The CANDHY working group is interested in merging efforts with social sciences and humanities for the 2nd community paper to co-identify citizen science projects and co-test the novel benchmarking framework. Particular interest is on sharing and transferring available knowledge, science and approaches for citizen and stakeholder engagement, cultural and behavioral change in addressing hydro-climatic challenges.

Data collection and management constitutes the foundation for all analysis and modeling tasks required for achieving water, food, energy, and environmental security. UN-Water identifies data and information as one of the five accelerators where efforts and investments should be concentrated to achieve the Sustainable Development Goal 6 (SDG 6). Availability of open and free data resources can greatly contribute to enhanced implementation capacity in water research. In this context, it is crucial that data are freely accessible, openly available, and reliable. Open datasets are available online, are accessible in machine-readable formats (i.e. not pdfs or reports), and are obtainable by the public. Free refers to the availability of datasets with licenses that allow sharing at no cost to individuals, researchers, institutions, or projects. However, such datasets are dispersed across various websites and repositories. This hampers visibility and findability, which in turn results in limited use for generation of new knowledge or transferability of insights. This highlights a critical need for improving visibility of existing hydrological datasets, dedicated projects, and repositories. Crowdsourced scientific data collection efforts enable collaborative work and provide potential solutions to these issues. In this talk, we present a crowdsourced hydrology initiative aimed at establishing a global catalog of open and free datasets. This inventory will provide a database of static links, data DOIs, description of datasets along with key references and supporting information. We report on our progress and challenges in designing such an initiative with the hope that others will benefit.

Business as usual is no longer an option in view of seriously engaging in the sustainable development agenda and robust climate action. The call from the UN Secretary General for providing early warnings for all within 5 years is a further incentive to act. These undertakings all require reliable, available and accessible hydrological data. To meet this need, many current hydromet monitoring systems need optimization of their efficiency and cost. Here, existing emerging technologies and approaches, including Artificial Intelligence, Internet of Things and Citizen Sciences offer new opportunities. Their operational uptake by National Meteorological and Hydrological Services (NMHSs) is however currently low, for various reasons including lack of trust and insufficient dialogue between innovators, hydromet services and their user communities.

In view of this, the WMO HydroHub offers a mechanism to support the operational uptake of existing and emerging technologies and approaches in a sustainable way, through partnerships, and by providing actors with capacity, innovation and engagement possibilities.

This Keynote will highlight some concrete examples of innovation-related activities the WMO HydroHub is taking forward. These include Innovation Calls, which identify and operationalize innovative solutions to hydrometric challenges, as well as Innovation Workshops, which bring together NMHSs, academia, private sector and others in view of better tailoring solutions to operational realities and directing research towards more pertinent topics. Other activities showcasing how the WMO HydroHub leverages multistakeholder dialogue platforms to generate ideas and synergies to tackle challenges will also be highlighted. Innovative ways to strengthen the sustainability of solutions will also be discussed.

Measuring weather data with a self-build low-cost sensor

DOI: 10.57757/IUGG23-4159 - LINK

Vincent Sobottke[1], Daniela Schoster[1], Henning Rust[1], Christopher Böttcher[1], Jonas Lehmke[1], Jana Ulrich[2], Marco Otto[2], Fred Meier[2]
[1]Freie Universität Berlin, Statistische Meteorologie, Berlin, Germany
[2]Technische Universität Berlin, Klimatologie, Berlin, Germany

Considering the fast urban growth and the rapid increase of the city population, urban areas are constantly changing. Additionally, the spatial heterogeneity of Berlin leads to a pronounced spatial variability of meteorological variables, which is impossible to capture with the existing network of urban measuring stations. Therefore, the Open Urban Climate Observatory Berlin aims to establish an open meteorological measurement network by involving the urban society, e.g. allotment gardeners, who maintain the measuring devices especially developed for this purpose. With this extension of the classical measurement network and a recently installed high-resolution precipitation radar for Berlin, a new data basis becomes available to answer relevant questions for the urban community.

In order to improve the quality of this data set, we apply a range of methods from the fields of Statistics and Machine Learning to filter faulty measurements and calibrate measurements using publicly available data from stations of the German-Weather-Service (DWD) and the network itself.

In collaboration with the citizens, research questions will be developed and addressed and the potential of possible applications will be explored during workshops. In this process, citizens will be supported by scientific staff with technology and knowledge about the urban climate. Ideally, the results will serve as a basis for the development of applications, e.g. a digital watering assistant that provides watering recommendations optimized for plant growth and resource utilization based on local measurements and appropriately processed precipitation forecasts.

We will report on the current status of the project and some preliminary results of data analysis.

What makes science-and-policy-dialogue successful? Impact analysis of a parliamentary evening in the German Bundestag

DOI: 10.57757/IUGG23-4046 - LINK

Marie Heidenreich[1]
[1]*Helmholtz Earth & Environment, SynCom, Berlin, Germany*

The term “Science-and-policy-dialogue” in contrast to “Science-to-policy-advise” indicates the need for a dialogue instead of a one-way-advice. Our communication must be needs-based, addressing what’s on the political agenda. The objective is science-based policymaking, which means politicians use high-quality information to inform political decisions. While science-and-policy dialogues face many challenges – e. g. different focal points and timelines of research and politics, no prospect of higher scientific reputation – they are worth the effort because, for apparent reasons, trial-and-error is not an option in Earth system politics.

SynCom is the overarching synthesis and communication platform of the research field 'Earth and Environment' of the Helmholtz Association. SynCom synthesizes research results and builds bridges across various disciplines. Functioning as an interface between science and society, SynCom supports evidence-based climate and environmental politics.

In this talk, I will present the results of an impact analysis of a parliamentary evening on the "climate-resilient city", which we held in November 2022 on the dome of the German Bundestag.

The Ice Age machine

DOI: 10.57757/IUGG23-3190 - LINK

Andreas Linsbauer[1], Guillaume Jouvet[2], Niklaus Heeb[3], Jonas Christen[3], Noemi Chow[3], Simon Broggi[3]
[1]University of Zurich, Department of Geography, Zürich, Switzerland
[2]University of Lausanne, Institute of Earth Surface Dynamics, Lausanne, Switzerland
[3]Zurich University of the Arts, Knowledge Visualization, Zurich, Switzerland

Over the last million years, cyclical changes in Earth's orbital parameters have been responsible for climate fluctuations and ice ages that have shaped our landscape. Current climate change, on the other hand, is caused by human greenhouse gas emissions and the CO2 content in the atmosphere exceeds the maximum value of the last 800,000 years by far. This is the main cause of current global climate change, which will affect human beings, and the whole ecosystem far into the future.

While public awareness of climate change has increased massively over the last years, many misconceptions are still widespread. In order to increase awareness about the human impact versus natural processes, we are designing an interactive «Ice Age Machine», which will be placed at popular vantage points in Switzerland from September 2023 onwards. These interactive stations will allow groups of users to actively experience past ice ages as well as the corresponding environmental changes thanks to an innovative design and new visualization techniques based on artificial intelligence. The visitors will learn about the history of glaciations in the Alps, the extreme impact of human being on climate and what the future effects could be. The users have the opportunity to retrieve a photo showing them in action at the station in front of the panoramic ice age view to share via social media. To increase the visibility of the machine beyond the vantage points, communication activities on site and in the digital space (website, social media) will accompany the project.

Experiencing climate change: Environmental education and public relations on vanishing glaciers

DOI: 10.57757/IUGG23-2072 - [LINK]

Andrea Fischer[1]
[1]*Austrian Academy of Sciences, Institute for Interdisciplinary Mountain Research, Innsbruck, Austria*

While interest and societal impact of climate science/geoscience increases, the accessibility of research results and knowledge decreases as a result of publication strategies: Articles published in scientific journals often do not use a common language, and scholarly knowledge is needed to understand the often very specific content. Teaching books in national languages are very rare in 21st century. Therefore, the gap between scientific frontier and basic education widens, leaving room for science sceptics or fake news, for example denying anthropogenic climate change in social media.

Environmental education helps to get in touch with the methods and results of geosciences. Several thousands of pupils participate in field courses and classroom activities of the National Parks. TV productions, podcasts, online and print media articles reach a much higher percentage of the population as the most popular high ranking journal article does.

To ensure that science prolongates it’s story of success, and being convincing for all people, the dissemination has to be broad. We established a science education centre right at Jamtalferner, an WGMS benchmark glacier and LTER site to foster the communication of scientific results together with the local museum and community, in cooperation with local guides https://www.umweltbildung-jamtal.info/. In the last years, media interest increased, and the interdisciplinary research has been subject of several press trips. We consider this an important part of scientific work, despite the lack of specific funding.

The WormEx II experiment to raise awareness about the importance of healthy soils and of their hydrological functions

DOI: 10.57757/IUGG23-4508 - LINK

Stefano Barontini[1], Marco Peli[1], Paolo Vitale[2], Elena Curti[2], Francesca Barisani[1], Roberto Ranzi[1], Giovanna Grossi[1]
[1]University of Brescia,
Department of Civil- Environmental- Architectural Engineering and of Mathematics, Brescia, Italy
[2]Liceo Scientifico Statale Copernico, Liceo Scientifico Statale Copernico, Brescia, Italy

Healthy soils provide many ecosystem services, among which some relevant ones belong to the hydrological sphere. In fact, healthy soils feed and filter freshwater reserves, whereas degraded soils can pollute water resources and make them unavailable or harmful to humans and plants. Besides, healthy soils are effective for both climate change mitigation, being the largest terrestrial carbon pool on the planet, and adaptation, thanks to their capacity of absorbing and retaining water thus reducing the hazard of floods and droughts.
However, these characteristics are nowadays endangered due to several challenges deriving from mismanagement of the limited soil resources, the consequent soil degradation phenomena (viz soil sealing, erosion, loss of biodiversity and of organic matter) often lacking the necessary awareness and visibility.
Aiming at contributing to disseminate the importance of healthy soils for the society and at highlighting the hydrological functions of an healthy soil, we designed the WormEx II experiment, that is an educational experiment to be performed in high-school classes. The experience takes the participants along the footsteps of Charles Darwin, who, studying the activity of worms, showed how great changes in Nature are often the result of the continuous superimposition of minimal processes. Researchers, teachers, high-school and university students set up a participatory experiment to repeat Darwin's observations on the ability of annelid digging activity to bury abandoned bodies on the soil surface. By this experiment, students will observe how soils with different annelid activity behave and how the annelid activity increases the soil infiltration capacity.

Seismic risk communication over the past 20 years: An overview of european publications

DOI: 10.57757/IUGG23-0917 - LINK

Susanna Falsaperla[1], *Gemma Musacchio*[2], *Angela Saraò*[3], *Anna Scolobig*[4]
[1]*Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Catania- Osservatorio Etneo, Catania, Italy*
[2]*Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Milano, Milano, Italy*
[3]*Istituto Nazionale di Oceanografia e di Geofisica Sperimentale, Sezione Centro Ricerche Sismologiche, Trieste, Italy*
[4]*University of Geneva, Institute for Environmental Sciences, Geneva, Switzerland*

The widespread lack of awareness of seismic hazard and the inadequate preparedness to protect people and property explains the high cost of damage caused by earthquakes worldwide to date. Efficient communication is of paramount importance as part of effective risk mitigation strategies. Over the past twenty years, efforts have been pursued at the local, regional, national, and international level to disseminate information on seismic hazard to populations at risk.

Focusing on Europe, we analyze the main features of seismic risk communication from 2000 to 2022, and present here an overview of the results obtained based on a scoping review of the scientific literature. Our review was conducted on publications selected from Scopus, Web of Science, and Google Scholar databases and the information was gathered on the basis of the 5 'Ws questions' (Who, What, When, Where, and Why). Overall, the selected publications document the relatively limited engagement of the scientific community in this risk field compared to other natural disasters. Nevertheless, the growing trend over time of publications dealing with seismic risk communication highlights the effort to attract selected targeted audiences (particularly children), using new contents, methods of implementation, and channels such as social networks and the Internet.

The widespread lack of awareness of seismic hazard and the inadequate preparedness to protect people and property explains the high cost of damage caused by earthquakes worldwide to date. Efficient communication is of paramount importance as part of effective risk mitigation strategies. Over the past twenty years, efforts have been pursued at the local, regional, national, and international level to disseminate information on seismic hazard to populations at risk.

Focusing on Europe, we analyze the main features of seismic risk communication from 2000 to 2022, and present here an overview of the results obtained based on a scoping review of the scientific literature. The transdisciplinary design of user-centred seismic risk products to increase societies' resilience towards earthquakes – the Swiss case

DOI: 10.57757/IUGG23-0258 - LINK

Irina Dallo[1], Michèle Marti[1]
[1]Swiss Seismological Service at ETH Zurich, Department of Earth Sciences, Zurich, Switzerland

Worldwide, there is a shift from hazard to risk communication in order to increase societies' earthquake risk awareness and, consequently, their willingness to take protective actions. So far, little research has been conducted on how to design user-centred seismic risk products, which would allow societies to take informed decisions. Only if well designed and tailored to the end users' needs, these products have the potential to increase societies' risk awareness and, in turn, their resilience towards earthquakes.

We thus applied a transdisciplinary approach by co-designing with experts from different disciplines multiple versions of rapid impact assessments, earthquake risk scenarios, and seismic risk maps, which we then tested with the Swiss public and professional stakeholders of the society (e.g., authorities, civil protection). To this end, we conducted several workshops with professional stakeholders in 2021 and two surveys with the Swiss public in 2022 and 2023. The surveys both contained a between-subjects experiment, which allowed us to assess which version of the products is correctly understood, best perceived, and triggers people to take protective actions.

At the conference, we will present the results of those studies and provide evidence-based recommendations on how to design user-centred rapid impact assessments, earthquake risk scenarios, and seismic risk maps. This should support institutions responsible for public communication to add risk products to their communication strategy to effectively inform the society about seismic risk and, consequently, increase their risk awareness and intention to take protective actions.

The project "Bimbim's Team: A Journey to the Planets" was awarded by Europlanet with the main goal to awaken children's curiosity for planetary sciences. Science outreach to children is a major challenge for professionals in any field, especially because of the complexity involved. Initiating children into scientific subjects is not a trivial task. In his project, we tackle the challenge of reaching as many children as possible, combining science and art in an innovative strategy. "Bimbim's team" are puppets theater characters which have the power to fascinate children and transmit science in an unconventional way. Short movies were produced with three stories about the planets: general overview of all solar system planets, Earth and Mars.The videos come with illustrations and animations to better express the scientific content. They were recorded in three languages (Portuguese, English and French) in hopes of reaching an international scale. We expectthat these stories will also call the attention of schools and parents to bring science closer to their children.Another outcome of the project is the involvement of female scientists and the possibility to attract more scientists, especially the minority groups.

OGGM-Edu (https://edu.oggm.org) is an educational platform about glaciers, with the main goal to provide tools and materials for instructors who want to teach about glaciers at secondary schools, in workshops or at universities. Interactive web applications and open access images provide materials for entry-level classes with no experience in physics or programming. Jupyter notebooks at various levels of complexity offer guidance to run and develop simple modeling experiments in the python programming language. OGGM-Edu follows a decentralized open source model: we encourage our users to mix and remix our templates, and offer technical help to develop new classes, run the notebooks on a dedicated cloud service, or translate our materials to various languages. With this contribution, we are looking to connect with educators and scientists in all fields of geosciences interested in online teaching resources.

Earthquake education and training program at the school level in India

DOI: 10.57757/IUGG23-3477 - LINK

Brijesh Kumar Bansal[1]
[1]*Professor, Civil Engineering Department- Indian Institute of Technology Delhi, New Delhi, India*

India has experienced many large earthquakes since historical times, causing large-scale damage and the loss of many lives. More than 2/3rd of the country's total area is exposed to varying degrees of earthquake hazard. The ongoing efforts to advance earthquake science and research experiments have significantly improved our knowledge in recent years. However, we are still far from predicting them. Although some short-term forecasts have been successful, they are generally of limited practical use for earthquake disaster management. To achieve the ultimate goal of mitigating the earthquake hazard, it is essential to focus on systematic R&D efforts. At the same time, earthquake education, training, and knowledge dissemination are critical to minimizing the impact of an earthquake. In India, these aspects are being addressed through specific modules and programmes on a smaller scale. The School Earthquake Laboratory Program is one such module, initiated about two decades ago with a view to introduce basic earthquake education at the secondary school level, inculcate the culture of measurements and interactive learning, and create awareness amongst the students and public at large. The programme was initially implemented in the northwest and northeast Himalayan regions and extended to a few other regions later. The paper briefly presents a summary of efforts made so far and further steps required in this direction.

Teaching on Disaster-Risk to diverse undergraduate careers: merging Science and socio-humanistic perspectives within a situated context and from vocational interests

DOI: 10.57757/IUGG23-3104 - LINK

Natalia Pardo[1], *Diego Valencia*[2], *Aida Barreto-Moreno*[3]
[1]*Universidad de Los Andes, Geociencias, Bogotá, Colombia*
[2]*Independent Consultant, Independent Consultant, Bogotá, Colombia*
[3]*Universidad de Los Andes, Conecta-TE- Centro de Innovación en Tecnología y Educación- Vicerrectoría Académica, Bogotá, Colombia*

In Colombia, classified as a High Risk country in the INFORM Index for risk management developed by the European Commission, Geosciences contents at primary school levels are practically absent, and there are extremely few courses on Natural Hazards and Disaster Risk Reduction at undergraduate level. This fundamental gap results in a generalized lack of knowledge in Earth Systems, Socio-Geo-ecological systems and DRR frameworks, and ultimately limits local capacities in decision-making.

In order to reduce the lack of knowledge at undergraduate level, we re-designed the general course “Natural Hazards and Disasters” at Universidad de Los Andes to a student-centered virtual modality, open to all undergraduate programs of the university. At the end of the course, students from any background are expected to be able to analyze and explain the factors that condition natural hazards, and discuss the vision of disasters as social constructions. The course seeks to sensitize students about the role that we all have, from the different disciplines, both individually and collectively, to reduce diverse vulnerabilities, taking into account specific cultural contexts in Colombia. Students are grouped into disciplinary and multidisciplinary teams to address a case study and analyze it from each vulnerability perspective, according to their careers. The resulting study-case is later used to produce a podcast, which they discuss in a final forum.

Regular evaluation of the course in the last three years attests for improvement of developing abilities, targeting learning goals, rise awareness on Disaster Risk Reduction and motivate proposals on Nature-based and Community-based solutions.

"School catchment" as educational and scientific base for the Sendai Framework, Nexus and 2030 Agenda

DOI: 10.57757/IUGG23-2063 - LINK

Masato Kobiyama[1], Alessandro Gustavo Franck[1], Michele Moraes Carvalho[1], Pedro Luis Borges Chaffe[2], Claudia Weber Corseuil[3]
[1]Universidade Federal do Rio Grande do Sul, Instituto de Pesquisas Hidráulicas, Porto Alegre, Brazil
[2]Universidade Federal de Santa Catarina, Departamento de Engenharia Sanitária e Ambiental, Florianopolis, Brazil
[3]Universidade Federal de Santa Catarina, Departamento de Energia e Sustentabilidade, Araranguá, Brazil

The Sendai Framework, Nexus and 2030 Agenda should be supported by scientists and managers, but their real strategies need to be implemented at the citizen level. In this work, we illustrate the "school catchment" concept as a tool for practical actions based on citizen science and a better understanding of hydrological processes. As a case study, we established the Mampituba river "school catchment" (1940 km^2) in southern Brazil. The minimum requirement for a "school catchment" is the installation of flow- and rainfall-gauging stations to support science learning, discovery, and education at any level by engaging local citizens. We have conducted detailed hydrological monitoring and field survey especially at the upper region of the catchment where sediment-related disasters occur frequently. Besides publishing scientific papers, upon request, we have reported and explained the results to Geopark managers, city officials, mountain guides, and general residents. Such education activities have helped them deepen their understanding of the local hydro-environment. The citizen science promoted within this "school catchment" is making residents more aware of their environments, with a clear increase in interest in topics such as water- and sediment-related disasters, water-energy-food security and ecotourism. Implementing "school catchments" is one way of empowering local communities to find their appropriate behaviors towards sustainable development.

A short documentary "The Grand Tour of the 21st century. Naples between art and technology " is presented here on the presentation of innovative technological results, obtained in a context of green energy resources exploitation (GeoGrid project, POR Campania, Italy, ERDF 2014-2020). The documentary was developed with an innovative artistic language that uses the poetic, participatory and performative modality belonging to documentary. This project stems by the fact that scientists are called upon to make an effort to involve and share crucial issues of research, allowing even non-experts to appreciate the results achieved in their work. On the other hand since art and science have always influenced each other, and both artistic experimentation and scientific dissemination share the need to involve the public in what is happening around us, we firmly believe that a mix of the two languages can become a powerful tool for scientific dissemination.

"Geoscience Connections" is a project to connect the eight IUGG Associations through interviews with early-career scientists (ECS), secretary generals and presidents of each association. The main objective of this project is to transfer scientific knowledge to the general public by connecting a variety of scientific subjects from all IUGG associations. Science outreach movies have a great potential to attract the attention of the public, especially through social media. The project is interdisciplinary, diverse, international and inclusive.Short movies were produced especially with ECS to emphasize the importance of the great variety of topics related to IUGG and to encourage young students to pursue careers related to geodesy and geophysics. The interviews with the IUGG secretary generals and presidents will be filmed during the IUGG Assembly, where most of them will be present. The documentary containing these interviews will be published at the IUGG Social Media Channels until December, 2023. In this talk we will show how the interviews were designed and some examples of short movies with ECS.

In a world where all types of information are available online, science and its outreach also needs to expand. Content creation has become an important aspect of science communication and IAGA scientists are playing a major role in it. IAGA is one of the associations under IUGG which promotes the work of Earth and space scientists studying the magnetic and electrical properties of planets, interplanetary bodies, the Sun and their different phenomena. An outcome of the last IUGG meeting in 2019 was the formation of a dedicated IAGA social media working group to provide an easily accessible platform and an online community for IAGA members; to bridge the gap between scientists and the general public; to increase awareness of the varied work of IAGA; and to promote the work of early career researchers (ECRs) and under-represented groups in IAGA.

This abstract covers an overview of the work undertaken by this working group and content shared on our many different social media platforms - Twitter, Instagram, Facebook, LinkedIn, YouTube, and a blog. The blog posts cover a range of topics including PhD stories on academic life, updates from the community, and historical information. On our other platforms, we share our blog as well as job opportunities, upcoming conferences, workshops, outreach opportunities, new publications, and videos covering the work of IAGA. We hope to attract other members to the group by describing the idea behind our content creation and in turn take ideas from the community to improve our reach.

Connecting the Latin America hydrology community around the 23 Unsolved Problems in Hydrology

DOI: 10.57757/IUGG23-4616 - LINK

Pedro Luiz Borges Chaffe[1], *Rodrigo Cauduro Dias de Paiva*[2], *Cristóvão Vicente Scapulatempo Fernandes*[3], *UPH Latin America Team*[4]
[1]*Federal University of Santa Catarina, Sanitary and Environmental Engineering, Florianopolis, Brazil*
[2]*Universidade Federal do Rio Grande do Sul - UFRGS, Instituto de Pesquisas Hidráulicas, Porto Alegre, Brazil*
[3]*Universidade Federal do Parana - UFPR, Departamento de Hidráulica e Saneamento, Curitiba, Brazil*
[4]*UPH Latin America team, UPH Latin America team, UPH Latin America team, Brazil*

The 23 Unsolved Problems in Hydrology (23UPH) have been recently proposed to guide research efforts and invigorate the field. While this is a great example of community level effort to generate and consolidate important scientific questions, it is only natural that there are remaining biases regarding subfields of the discipline and non-representativeness of participants due to traveling limitations. Here, we present a practical study case of how enhanced digitization allowed our community to gather and synthesize recent research related to the 23 UPH from the Latin American perspective. This synthesis at the Latin American scale recognizes a community with shared water resources, cultures, and needs and offers to the broad international hydrological community a complementary set of unique regional processes and problems. The Latin American initiative was announced through mailing lists in August 2021, it attracted responses from several countries beyond Latin America. The first hybrid meeting in November 2021 counted with 27 in-person and 66 remote attendees. The aim was to form decentralized groups who would be able to: (1) synthesize past and current research for each of the 7 major UPH themes and (2) adapt and propose new UPH focused on Latin American peculiarities. Each subgroup had 2-4 leaders who were responsible to engage other specialists and propose virtual working session during 2022 which were later reported to the larger group. The community has finished the synthesis phase and is currently promoting a workshop to finish proposed questions from Latin America.

Scientists for Ocean Literacy - Empowering scientists as ocean advocates in the UN Decade of Ocean Science for Sustainable Development

DOI: 10.57757/IUGG23-2401 - LINK

Dina Eparkhina[1], Elisa Banchi[2], Donata Canu[2], Michael Rea[3], Maria C. Uyarra[4]
[1]European Global Ocean Observing System, EuroGOOS, Brussels, Belgium
[2]OGS, Istituto Nazionale di Oceanografia e Geofisica Sperimentale, Sgonico, Italy
[3]Michael Rea Media, Consultancy, Stirling, United Kingdom
[4]AZTI, Marine Research- Basque Research and Technology Alliance BRTA, Pasaia, Spain

Science alone cannot provide the solutions to the challenges we face - we need wider society to actively contribute. This has pushed forward the need for more ocean literacy. The Scientists for Ocean Literacy project of the UN Decade of Ocean Science for Sustainable Development 2021-2030 aims to empower scientists to actively engage with society and foster sustainable behaviour. The project expands the horizon of science communication towards a multi-stakeholder and multi-disciplinary dialogue, while building on the existing best practices of the European oceanographic and meteorological agencies.

Ocean literacy raises awareness about our connection with the ocean and promotes co-creation of solutions to environmental degradation. Scientists should be working hand in hand with other professionals, specialists, and educators in developing impactful ocean literacy activities. Furthermore, this would produce a fertile ground for co-creation among disciplines and sectors. Ocean literacy must be recognized as an important aspect of the work of research institutions and supported in scientific careers (Eparkhina et al, EuroGOOS, 2021).

Successfully implemented at pan-European level and with partners from the Atlantic, Mediterranean, and the Arctic regions, the EuroGOOS ocean literacy work has created new synergies and supported the efforts of UNESCO-IOC. A new addition to the Scientists for Ocean Literacy project is the establishment of the DOORS Ocean Literacy Network in 2023. The Network brings together academia, universities, NGOs, and communicators to promote the understanding of the scientific project results and foster ocean culture among the Black Sea citizens of all ages.

Science alone cannot provide the solutions to the challenges we face - we need wider society to actively contribute. This has pushed forward the need for more ocean literacy. The Scientists for Ocean Literacy project of the UN Decade of Ocean Science for Sustainable Development 2021-2030 aims to empower scientists to actively engage with society and foster sustainable behaviour. The project expands the horizon of science communication towards a multi-stakeholder and multi-disciplinary dialogue, while building on the existing best practices of the European oceanographic and meteorological agencies.

The Global Geodetic Observing System (GGOS) of the International Association of Geodesy (IAG) is a collaborative contribution of the global geodesy community to the observation and monitoring of the Earth System. Geodetic observation techniques and analysis infrastructures, as well as high-quality geodetic products, provide the basis for advances in Earth and planetary system sciences and for various applications.

One main objective of GGOS is to support activities and initiatives to communicate the value of Geodesy to science and society, as well as contribute to understand and solve complex issues facing the global geodetic community.

Towards this objective, GGOS has established and maintains a website **ggos.org**, which serves as a **point of entry to Geodesy** to facilitate discoverability and usability of geodetic data and products. This includes user-friendly and illustrative descriptions about geodetic observation techniques and results. GGOS has also recently produced short **videos to explain the value of Geodesy** to non-geodesists. The new "Discover GGOS and Geodesy" video is available in multiple languages (youtube.com/@iag-ggos).

Presently, GGOS is working on the implementation of a comprehensive geodetic portal, the **GGOS Portal** (ggos.org/portal), which should realize in future a comprehensive and descriptive source of geodetic information with detailed metadata. With this, GGOS engages with diverse user communities to increase awareness of Geodesy and the ever-expanding utility of Geodesy in everyday applications.

Observing the surface meteorology of Antarctica has been a valued contribution in our understanding of weather and climate behavior. With over forty years of automatic weather stations (AWS) across the continent, the electronic systems used to capture these observations has been evolving from in-house developed systems to commercial-off-the-shelf systems. Experiences in having the best available observations at an affordable price lead to seeking a new solution to meet as many needs of the future as possible while broadening participation. Over the last six years, effort has been put into the development of a new electronics core for acquiring weather and climate observations. This report will review the development and outcomes of the Polar Climate and Weather Station (PCWS) project. Students at a two-year technical college in concert with an established university broadened participation and exposure of Antarctica, Antarctic meteorology, and electronics to those who would otherwise not have had the opportunity. In addition to the advances, the challenges endured by this project will also be reviewed such as the unexpected pandemic and supply chain issues that followed hampering the project. The results of this effort have provided the basis for a future observing system for the benefit of all.

AMIGOS stations: Ice-ocean-atmosphere multi-sensor systems

DOI: 10.57757/IUGG23-3731 - LINK

Ted Scambos[1]
[1]*University of Colorado, ESOC / CIRES, Boulder, USA*

The Automated Meteorology - Ice - Geophysics - Ocean observing Systems are a series of multi-sensor stations that have been employed for in situ data gathering in support of polar research since 2009, with multiple installations on the Antarctic Peninsula, the Nansen Ice Shelf, and on Thwaites Glacier's eastern ice shelf. The station series have been optimized for weather data collection and near-surface glaciology (AMIGOS-I) and later augmented with sensors for measurements related to ice-ocean interaction and internal ice sheet temperature profiling (AMIGOS-II and -III). The stations are powered by a solar + battery system, and provide real-time data through an Iridium uplink. The stations include cameras, weather instruments, thermistors, and GPS sensors, with later versions including ocean instruments (CTDs and doppler current meters) and a Distributed Temperature Sensing (DTS) fiber optic system. We present an overview of the instrument, past data from earlier installations, and a summary of the data sets and results from the two AMIGOS-III units installed on the Thwaites Glacier ice shelf.

In polar regions, and specifically in continental Antarctica, the local surface mass and energy balances can be largely controlled by snow transport in form of drifting and blowing snow particles, and sublimation both from the snow or ice surface and from the airborne snow particles. Adverse conditions in such extreme environments make continuous and reliable measurements of snow drift and sublimation a challenge, especially during the period of polar night and in absence of maintenance. Additionally, existing state-of-the-art snow mass and moisture flux measurement systems have relatively large power requirements, often resulting in spurious values or data gaps due to insufficient power supply from the autonomous wind and solar based power systems. In this contribution, we present observations of drifting snow events and latent heat fluxes obtained from collocated installations of classical eddy covariance instrumentation, optical snow particle counters, and acoustic particle flux devices deployed in Queen Maud Land, East Antarctica. We investigate the coherence of the optical and low-power acoustic snow drift measurements and compare them to numerical simulations of mass fluxes at the sensor sites. Furthermore, to mitigate the problems of potential power failure, low-power, fast-response humidity sensors are tested in laboratory and field settings to obtain latent heat flux estimates at largely reduced power consumption in comparison to eddy covariance measurements using infra-red gas analysers. Promising or successful novel systems may be a viable alternative for recording continuous time series of sublimation, in particular in the polar night season, and at significantly lower cost.

Co-existence of ice and liquid clouds plays an important role in the cloud life cycle, as well as in precipitation formation and radiative balance. According to satellite observations, coastal regions show the most important proportion of supercooled liquid water (SLW) content in mixed-phase clouds (20-60%), while in the interior this proportion decreases significantly, up to less than 10% in the high Antarctic Plateau (Listowski, et al., 2019). This study is based on two field campaigns on King George Island, northern Antarctic Peninsula, at Escudero station (Portuguese Polar Program projects TULIP/APMAR, February 2022) and King Sejong station (APMAR2 project, February 2023). We present the results of the measurements of SLW content using a new instrument, the universal water content (UWC) sensor, capable to measure both the total and supercooled liquid water content in clouds, by using two vibrating wires sensible to the liquid droplets. We combine the UWC measurements with vertical profiles of tropospheric clouds using a mini-pulse lidar (data provided via MPLnet network) and a vertically-pointing micro rain radar (MRR-2 at Escudero, and a higher vertical resolution MRR-Pro at King Sejong), radiosonde measurements and ERA5 reanalysis data to characterize the tropospheric thermodynamic structure, the melting layer and the precipitation phase transitions. During preliminary case studies, ERA5 specific liquid cloud content vertical profiles showed an agreement with the UWC sensor in the detection of liquid water layers below 2 km altitude, however ERA5 still presents problems to represent the presence of liquid layer clouds at higher altitudes.

In this era of global warming, the climate of the Antarctic continent is extensively studied with climate models, as even a small loss of its polar cap may have a big impact on global sea level rise. However, the meteorological observations needed to evaluate and calibrate models remain scarce, especially in the atmospheric column, in the winter season and away from any inhabited station.

For this purpose, the AWACA (Atmospheric WAter Cycle over Antarctica) project aims to deploy 3 autonomous OPUs (automated Observation Platform Units) sheltering radars and lidars working at various wavelengths along a transect from coastal Terre Adélie to Concordia station, 1100km from the coast to 3200m on the Plateau. These instruments will perform condensed water measurements throughout the lower tropospheric column to characterize clouds and precipitation. Water vapor and snowflakes isotopes measurements will also be made by a spectrometer.

The OPUs will operate during 3 years, being visited only once a year. They will be isolated from any station and therefore self-powered.

A description of the OPUs' design, and the challenges associated with their stand-alone deployment in a harsh and remote environment and the various measurements they will perform will be presented.

For over 60 years the International Commission on Polar Meteorology has been a part of the fabric of the international community, as illustrated in its active participation in IUGG and IAMAS meetings over the years and support for the Workshop on Antarctic Weather and Climate and Antarctic Gravity Wave Instruments Network. This presentation will assess the state of the Commission today with recent updates to it statutes and specifically with a look toward future activities. One of our primary targets for the future is to be more inclusive. This includes widening membership across a wider range of countries and engaging early career scientists. Elements include a balance in the commissions' science endorsement and sessions at biennial meetings across topics centered on the Arctic, the Antarctic, and the Third Pole of the Himalayan Mountains. Support for young scientists and students will be a cornerstone for the ICPM moving forward, along with recognition of early and mid-career efforts of polar meteorologists. These opportunities are in various stages of development, and there are or will be challenges along the way.

Solar thermal tides in the Earth atmosphere play an important role in the dynamics, energetics and transport from the surface to the thermosphere-ionosphere region. Tidal dynamics and its variability impact the global and regional coupling between atmospheric layers. Paper will discuss main drivers and metrics of observed tidal variability in the Mesosphere and Lower Thermosphere (MLT) evaluating capability of whole atmosphere model predictions constrained by meteorological analyses below the stratopause to reproduce it. The observed influence of the data-constrained lower atmosphere on the MLT dynamics is well captured by simulations that are capable to predict the global and regional tidal variability deduced from the space-borne and ground-based measurements of temperature and winds. The model-model and model-data differences in the representation of tides and their effects will be highlighted and discussed. Along with the scale-aware formulations of dynamics-physics coupling in models to adequately constrain the diurnal cycles, daily mean prevailing flows, and wave-wave interactions the rapid (~1-hr cadence) analysis of MLT data will likely improve realism of tidal dynamics in the whole atmosphere predictions.

How should storm surge barrier maintenance strategies be changed in light of inter-annual tidal cycles and sea-level rise?

DOI: 10.57757/IUGG23-0730 - LINK

Sunke Trace-Kleeberg[1], *Ivan Haigh*[1], *Mark Walraven*[2], *Susan Gournenec*[3]

Sea-level rise, changes in storminess and population growth are increasing the risks of coastal flooding. The impacts are amplified in coastal cities due to the high concentration of inhabitants, infrastructure and services. Storm surge barriers can provide flood protection in these low-lying areas with long exposed coastlines. Maintenance is vital to ensure these complex and unique structures remain reliable and comply with legal protection standards. To ensure safe working conditions, water level thresholds above which maintenance work must stop are defined. This study evaluates the changes in past and future water levels exceeding the maintenance threshold to inform management, maintenance and operation strategies of storm surge barriers. The Maeslant barrier in the Netherlands is used as a case study. Results show that 13% of maintenance threshold exceedances occurred during the maintenance season. The effect of sea-level rise and natural inter-annual tidal cycles on future threshold exceedances is also assessed. Findings reveal that the maintenance window will shift earlier in the year and narrow until exceedances occur regularly all year-round. As sea-levels rise, tides play an increasingly dominant role in maintenance threshold exceedances, which in turn will significantly influence maintenance work. This analysis highlights that maintenance strategies at the Maeslant barrier need to be adapted for the barrier to remain operational until its design life of 2100. This analysis can be applied to other existing barriers to assess future intervention points and for barriers in the design phase to verify the implications of design decisions on planned maintenance

JP01a - Tides (IAPSO, IAHS, IAGA, IASPEI, IAG)

The accurate digitization of historical sea level records

DOI: 10.57757/IUGG23-1209 - LINK

Patrick Mcloughlin[1], Gerard McCarthy[1], Glenn Nolan[2], Rosemarie Lawlor[3], Kieran Hickey[4]
[1]Maynooth University, Geography, Maynooth, Ireland
[2]The Marine Institute, Oceanography, Galway, Ireland
[3]Met Éireann, Meteorology, Dublin, Ireland
[4]University College Cork, Geography, Cork, Ireland

Knowledge of regional sea level variations is pivotal to understanding coastal vulnerability. Fundamental to understanding these is the availability of sea level data. In Ireland, existing long sea-level records are rare and are in the north and east of Ireland. Paper marigrams do exist in different locations but are not currently digitized.

Techniques of marigram record digitization are in flux with a number of different techniques in practice. While issues such as distortions in scanned marigrams may be briefly mentioned in literature, what is often not discussed in detail are the issues that arise when digitizing. Such issues as bends, skews, or variations in line thickness in the paper marigram can offset sea level values by a significant amount.

Here we use the case study of Dún Laoghaire (near Dublin) from 1925–1933. We digitize the original marigram trace plus a matrix of known values to assess for any offsets. By comparing the original digitized data and the adjusted data, we can improve our accuracy to the 1 cm level to accurately recover sea levels.

The technique uses freely available software and can be flexibly applied to a range of data thus offering the opportunity to unlock the data held within these sea level archives.

Tidal turbulence in deep Mariana Trench waters?

DOI: 10.57757/IUGG23-0343 - LINK

Hans Van Haren[1]
[1]*NIOZ, -, Den Burg, Netherlands*

To study potential turbulent water motions near the deepest point on Earth in the Challenger Deep of the Mariana Trench, a 588-m long string equipped with specially designed sensitive temperature sensors was moored for nearly three years in 10.9 km water depth. Detailed analysis of one year of good data distinguishes ubiquitous 100-m tall internal waves and hundreds of meters slanted convection turbulent spurs due to internal waves breaking from above. The spurs can occur on a tidal periodicity. Furthermore, internal tidal wave breaking including 100-m tall turbulent overturns reaching the trench-floor is associated with warm water push from above. Once, such tidal wave breaking at the trench-floor occurred precisely during the passing of a tropical storm, which thus interacts directly with deep-trench motions possibly via barotropic sealevel variations. The different turbulence types prevent the hadal waters from being still, which is an important necessity for deep-trench life.

To study potential turbulent water motions near the deepest point on Earth in the Challenger Deep of the Mariana Trench, a 588-m long string equipped with specially designed sensitive temperature sensors was moored for nearly three years in 10.9 km water depth. Detailed analysis of one year of good data distinguishes ubiquitous 100-m tall internal waves and hundreds of meters slanted convection turbulent spurs due to internal waves breaking from above. The spurs can occur on a tidal periodicity. Furthermore, internal tidal wave breaking including 100-m tall turbulent overturns reaching the trench-floor is associated with warm water push from above. Once, such tidal wave breaking at the trench-floor occurred precisely during the passing of a tropical storm, which thus interacts directly with deep-trench motions possibly via barotropic sealevel variations. Intensified internal tides in Explorer and Dangeard Canyons (Celtic Sea shelf edge) observed by a deep ocean glider

DOI: 10.57757/IUGG23-0731 - LINK

Rob Hall[1], *Veerle Huvenne*[2]

[2]*National Oceanography Centre, Ocean BioGeosciences, Southampton, United Kingdom*

Explorer and Dangeard Canyons are named limbs of the large, dendritic Whittard Canyon system that incises the Celtic Sea continental slope. The system is known to feature large (order 80-m amplitude) semidiurnal internal tides, assumed to be generated at the shelf break to the southwest and focused into some limbs of the canyon by its steep, converging bathymetry. Interestingly, other limbs of the same system are much less tidally energetic. These large, but spatially heterogeneous internal tides are thought to have a variety of environmental impacts, from benthic faunal distribution to triggering turbidity currents.

In summer 2022, a University of Washington DeepGlider was deployed in and around Whittard Canyon for 45 days. After correcting for the internal spring-neap cycle, the largest semidiurnal internal tides (order 120-m amplitude) were observed at the mouths of Explorer and Dangeard Canyons and in both limbs the vertical oscillation of isopycnals progressed up-canyon (at 0.6-1.9 m s^{-1} in Explorer and 2.0 m s^{-1} in Dangeard). The associated available potential energy was highest in the lower half of the water column and decreased up the limbs. Finally, a 13-hour yo-yo CTD/LADCP station at the mouth of Explorer Canyon, competed during a coincident habitat mapping and benthic ecosystem survey (JC237), showed the up-canyon energy flux to be 6.7 kW m^{-1}. This evidence suggests very high levels of internal tide dissipation and resulting turbulent mixing within these two canyon limbs, which are likely to have considerable impact on local benthic ecosystems, sedimentological processes, and biogeochemical cycling.

Tidal loading stress in the Bay of Fundy and induced seismicity: A re-assessment

DOI: 10.57757/IUGG23-5002 - LINK

Pierre-Michel Rouleau[1]
[1]*Memorial University of Newfoundland, School of Science & the Environment / Physics, Corner Brook, Canada*

Loading of the Earth's surface by the large marine tides in the Bay of Fundy produces a periodic stress field that is an order of magnitude larger that the global-scale, body-tide stress field. Structurally, the Bay is underlain by rock formations, akin to fluid-filled, fractured media. The locally-distributed stress is conducive to the migration of excess pore-pressure into unstable faults. Recent studies on correlations between the tidal stress tensor and focal mechanisms inferred from earthquakes in tectonically active areas have underscored the role of ocean tide loading; this prompts the question whether tidally-induced excess pore-pressure can trigger earthquakes in the Bay of Fundy, even though the area is tectonically passive. Only Beaumont and Quinlan (1977) have addressed this question; however, over the nearly 50 years since, much advances have been achieved in every aspects of the oceanographic and geophysical dynamics of the Bay of Fundy, in parallel with work elsewhere on precisely mapping the displacement field of loaded coastal regions via GNSS data. In this re-assessment, I examine the loading contribution of the predominant tidal constituents, M_2 in particular, about which the Bay of Fundy (and Gulf of Maine) marine system resonates. In assessing the consequences of the regional tidal loading, attention is paid to the permeable nature of the system's water-rock interface. Moreover, any perturbations of the system's resonant frequency are examined, particularly in relation to the increase of the amplitude of the M_2 marine tides in the Bay/Gulf system observed over the past century.

Secular changes in ocean tides have been documented at some coastal tide gauges. These are often very localized (from river dredging, changes in river discharge, harbor modifications, etc.), but in some cases a network of gauges has observed coherent changes, suggesting the possibility of real, but small, wide-scale changes in the ocean tide. The three-decade time series of satellite altimetry may be sufficiently long and sufficiently accurate to address the problem over the open ocean; recent work by Bij de Vaate et al. is encouraging. Satellite altimetry from the Topex/Poseidon, Jason, and Sentinel-6 series of satellites is here used to map linear rates in the M2 tide. Large-scale coherent signals are detected across much of the ocean, at about 0.1 mm/year, and even larger in a few locations, but the likelihood of significant systematic errors is high. As a complementary approach, we also use a high-resolution ocean general circulation model, run over the same time interval, and forced by realistic changes in ocean stratification and sea-level rise; the stratification changes are by far the more important. As with altimetry, the likelihood of systematic modeling errors is also high, but the two approaches yield a picture of M2 trends that are surprisingly consistent in places, especially in the Indian Ocean and parts of the Pacific. Further improvements are expected as stratification is better delineated and as certain errors in altimetry are suppressed. Tidally coherent errors in satellite orbits and in several corrections will be discussed, with possibility of improvement in several.

Analysis of the tidal range changes across the United States

DOI: 10.57757/IUGG23-1967 - LINK

Kayla Washington[1], *Sönke Dangendorf*[1]
[1]*Tulane University, River Coastal Science and Engineering, New Orleans, USA*

Tides are a crucial factor in the development and characteristics of coastal zones, as well as human activity in these zones. They (i) regulate navigation into and out of ports, (ii) set national and international boundary lines, (iii) are an important factor in the vertical zoning of tidal ecosystems, and (iv) affect the severity and frequency of coastal flooding. As a result, understanding and predicting how tides have changed in the past and how they will change in the future is of utmost practical and scientific importance. Nineteen years ago, the last comprehensive assessment of mean tidal range (MTR) changes across the United States was completed by Flick et al. (2003). As part of the NASA Sea Level Change Team, we are currently updating and extending the assessment temporally to present day and spatially to 120 NOAA tide gauge records, each with 19 or more years of data. We assess the inter-annual to decadal variability, long-term trends, and spatial characteristics of the MTR. Large heterogeneous variability caused by complex coastlines, including numerous estuaries and barrier islands, is found in the tide gauge records. In an attempt to identify coherent large-scale oceanic changes in MTR, we first build coastal indices by grouping time-series with similar variability. Subsequently, these coastal indices are then used to separate more localized changes in individual MTR time-series. In this presentation, we will discuss a variety of case study examples providing an overview of how MTR has been changing spatially and temporally since the late 19th century.

The lunar nodal cycle, causing by moon's declination variations over the period of 18.61 years, results in changes in the amplitude and phase lags of global tidal constituents. However, the observed range in tidal amplitude is at present not yet well understood, and it is crucial for coastal hazard planning and chart datum. The impact of the nodal tide including its plausibly varying amplitudes and phase changes on the highest astronomical tide along the Northwest Pacific coast in North American could be important as a scientific basis for future coastal disaster planning. Additionally, there is no standard procedure of computing the lowest 18.61-year astronomical tides. Hence, we analyzed the contributions of various factors for calculating the lowest astronomical tide, including time spans, sampling frequencies, number of tidal constituents, and nodal tide correction, and establish a standard procedure which was adopted in Taiwan. Finally, we use a modified two-step harmonic analysis procedure to re-evaluate the seasonality and slope variability of the major constitutes (M_2, S_2, K_2, and O_1) along the Pacific Northwest coast in North Ametrica, and analyze the difference between the observed nodal amplitudes and the values predicted by equilibrium tidal theory.

The evolution of paleo tides has important implications for several branches of geoscientific research. For example, the presumably boosted generation of internal tides under glacial conditions is linked to increased tidal mixing, the intensity of the overturning circulation (e.g., Wilmes et al., 2019), and thus paleoclimate. Another application is the interpretation of Sea Level Index Points, influenced by the dynamic tidal levels, for reconstructing paleo sea level. A curious aspect, first predicted by Griffiths et al. (2008), is the emergence of a megatidal regime in the Arctic, with possible links to Heinrich Events (e.g., Velay-Vitow et al. 2020). While several studies reproduced the phenomenon, its extent, and sensitivity could be better constrained. Many ocean tide models operate with open boundary conditions in the Arctic, for which reason they suppress the free formation of the described tidal regime. Thus, it must be determined if this localized Arctic phenomenon induces significant feedback on tidal dynamics in the North Atlantic.

This contribution focuses on the emergence and robustness of the 'Arctic Megatide'. We present sensitivity experiments performed with a truly-global, data-unconstrained ocean tide model. The simulations establish the reproducibility of the phenomenon but predict high sensitivity to the representation of Self-Attraction and Loading (SAL), along with paleo bathymetric features. The ensemble is augmented with hybrid simulations, where the Arctic bathymetry is kept at a non-resonant state. The model differences indicate that the Arctic mega tide increases tidal mixing in the North Atlantic by 20%, with possible implications for ocean circulation.

Polar ocean tides revisited

DOI: 10.57757/IUGG23-2136 - LINK

Ole Andersen[1], *Stine Kildegaard Rose*[1]
[1]*DTU Space, Geodesy and Earth Observation, Kongens Lyngby, Denmark*

Polar oceans have generally been harder to determine from satellite altimetry because the regions outside the 66 parallel has traditionally only been surveyed satellites in sun-sun-synchronous orbits. With Cryosat-2 this has changed. However, the satellite poses a number of challenges to tidal analysis because of its long ground-track repeat period (368 days) and its diverse measurement modes, low-rate mode (LRM) over the ocean and synthetic aperture radar interferometric mode (SARin) over ice surfaces and parts of the ocean.

The SAMOSA+ physical retracker was developed to process the Cryosat-2 data across measurement modes and hereby enables the determination of the sea state bias. This way it provides more stable sea level estimates compared with traditional empirical retrackers used in the Polar Ocean. Nearly 10 years of Cryosat-2 data have been analyzed for residual ocean tides to the FES2014 ocean tide model in the Arctic Ocean and Antarctic Ocean using the response formalism. We use data from the near monthly repeat pattern of C2 as this has a favorable alias period for most major constituents. Using this information, the long wavelength corrections to the major astronomical constituents M2, S2, K2, N2, K1, O1, P1, and Q1 tides have been mapped for both the ocean and floating ice shelves domains. In addition, several smaller third, fourth and sixth diurnal tides have been determined. Some of these small compound/over tides does show small but consistent signal across regions like the Weddell sea (South Atlantic) and in the Baffin Bay between Greenland and Canada.

The "Estimating the Circulation and Climate of the Ocean" (ECCO) Consortium has a 20-year legacy of supporting fundamental climate research through the sustained production of innovative, global multi-decadal geophysical ocean state estimates. ECCO estimates are free-running solutions to state-of-the-art numerical general circulation models that are constrained with diverse, heterogenous, and sparse satellite and in-situ measurements in a least-squares sense.

In recent years the ECCO project has sought to better represent the drivers of global and regional sea level rise, including the contributions from ocean-driven melting of the Greenland and Antarctic Ice Sheets. This talk describes some of the challenges and benefits of expanding the scope of ECCO's original "ocean-only" state estimation system to include useful representations of ocean/cryosphere interaction in general and ocean/ice-sheet interaction in particular.

Recent observations show that the Antarctic ice sheet is losing mass at an accelerating pace and that this is projected to accelerate in the coming decades, contributing significantly to sea level rise. Ice sheet contributions to sea level rise remains one of the largest sources of uncertainty to future projections. However, so far ice sheets are not included in the majority of climate models used in CMIP5/CMIP6 to make sea level projections. Therefore, to accurately simulate future climate and sea level rise, ice sheet models need to be included in Earth System Models.

Here, ocean temperatures from EC-Earth with CMIP6 forcing are used to calculate basal melt forcing for BISICLES. Ocean temperatures are averaged over five oceanic sectors of Antarctica and three different depth ranges. Then, a quadratic basal melt parameterisation calibrated on sea level contribution derived from observation-based changes in grounding line ice discharge is applied as forcing for BISICLES. Based on this methodology, freshwater feedback was then coupled asynchronously into EC-Earth at one-year intervals. We find that the choice of calibration and ocean temperature depth range significantly impacts the basal melt calculation and additionally show initial results from the freshwater feedback coupling.

Buoyancy-driven flow of the Antarctic slope undercurrent and heat transport toward Amundsen Sea ice shelves

DOI: 10.57757/IUGG23-3035 - LINK

Yidongfang Si[1], Andrew Stewart[1], Alessandro Silvano[2], Alberto Naveira Garabato[2]

[2]University of Southampton, Ocean and Earth Science, Southampton, United Kingdom

Elevated ice shelf melt rates in the Amundsen Sea have been attributed to transport of warm Circumpolar Deep Water onto the continental shelf via bathymetric troughs. These inflows are supplied by an eastward, subsurface slope current that opposes the westward momentum input from local winds and tides, referred to as the Antarctic slope undercurrent. Previous studies have linked variations in the melt rates of the Amundsen Sea ice shelves to wind fluctuations. Yet the mechanism via which the undercurrent forms, and thus what controls the mean shoreward heat transport, remains unclear. In this study we investigate the dynamics of the undercurrent using a high-resolution ocean-sea ice process model coupled to a static ice shelf. We explore the sensitivities of the undercurrent strength, shoreward heat transport, and ice shelf melt rates to winds, tides, diapycnal mixing, and geometry. We find that the undercurrent forms with realistic strength provided that there is a trough allowing access to the continental shelf and ice shelf cavity, and that there is a cross-slope buoyancy gradient. The vorticity balance within the CDW layer reveals that the bathymetric steering of the undercurrent toward the ice shelf is related to diapycnal upwelling that occurs as CDW melts the ice. These findings imply that the mean flow of the Antarctic slope undercurrent is primarily established by buoyancy forcing on the continental shelf, and motivate a focus on processes that influence cross-shelf/slope buoyancy gradients to better understand future changes in shoreward heat transport.

Warm ocean waters drive rapid ice-shelf melting in the Amundsen Sea. The ocean heat transport toward the ice shelves is associated with the Amundsen Undercurrent, a near-bottom current that flows eastward along the shelf break and transports warm waters onto the continental shelf via troughs. Here we use a regional ice-ocean model to show that, on decadal time scales, the undercurrent's variability is baroclinic (depth-dependent). Decadal ocean surface cooling in the tropical Pacific results in cyclonic wind anomalies over the Amundsen Sea. These wind anomalies drive a westward perturbation of the shelf-break surface flow and an eastward anomaly (strengthening) of the undercurrent, leading to increased ice-shelf melting. This contrasts with shorter time scales, for which surface current and undercurrent covary, a barotropic (depth-independent) behavior previously assumed to apply at all time scales. This suggests that interior ocean processes mediate the decadal ice-shelf response in the Amundsen Sea to climate forcing.

Water mass transformation (WMT) around the Antarctic margin controls Antarctica Bottom Water formation and the abyssal limb of the global meridional overturning circulation, besides mediating ocean-ice shelf exchange, ice sheet stability and its contribution to sea level rise. However, the mechanisms controlling the rate of WMT in the Antarctic shelf are poorly understood due to the lack of observations and the inability of climate models to simulate those mechanisms, particularly beneath the floating ice shelves. We used a circum-Antarctic ocean-ice shelf model to assess the contribution of surface fluxes, mixing, and ocean-ice shelf interaction to the WMT on the continental shelf. The salt budget dominates the WMT rates, with the basal melt of ice shelves driving buoyancy gain at lighter density classes and salt input at coastal polynyas driving buoyancy loss at heavier densities. We found a considerable sensitivity of the WMT rates to model horizontal resolution, tides and topography within the Filchner-Ronne, East and West Antarctica ice shelf cavities. In the Filchner-Ronne Ice Shelf, an anticyclonic circulation in front of the Ronne Depression regulates the rates of basal melting/refreezing and WMT and is substantially affected by tides and model resolution. Model resolution is also found to affect the Antarctic Slope Current in both East and West Antarctica, impacting the on-shelf heat delivery, basal melt and WMT. These results highlight the importance of resolving tides and small-scale features of the flow and topography to adequately represent water mass transformations on the shelf that directly influence the abyssal global overturning circulation.

Increased ocean-driven melting of Greenland's marine terminating glaciers is identified as a trigger of glacier retreat and dynamic ice loss from the ice sheet over the last few decades. The increasing melt rates, in turn, have been loosely attributed to a warming of the North Atlantic's subpolar gyre during a negative phase of the North Atlantic Oscillation (NAO). Limited data records from the fjords, however, mean that this hypothesis is largely untested. Here we use a 12 year record of properties from Sermilik Fjord, SE Greenland, and the nearby shelf, combined with historical ocean and atmosphere, and remote sensing data, to show that property changes inside the fjord are not simply related to the heat content of the North Atlantic's subpolar gyre or the NAO phase. Instead, we show that fjord properties are directly related to properties on the nearby continental shelf which, in turn, vary as a result of the regional wind-stress and export from the Arctic Ocean. The implication of these findings for reconstructing the variability of melt rates at the glaciers' margins back in time will be discussed.

Meltwater from the Greenland Ice Sheet has the potential to freshen the surface of the Labrador Sea and limit deep convection. Typically, meltwater is added to ocean models at the surface, neglecting the observed mixing of meltwater within fjords. We investigate how a more realistic representation of meltwater amplifies the transport of freshwater across the southwest Greenland shelf break. Results from four coupled ocean/sea-ice simulations forced with atmospheric reanalysis are compared for the years 1992-1993. We compare eddy permitting and mesoscale eddy resolving (horizontal resolutions of approx. 5km and 3km in the study region, respectively) simulations with no meltwater to examine the importance of mesoscale processes in off shelf transport. Two different meltwater forcing schemes are implemented in the mesoscale eddy resolving configuration: meltwater added to the surface layer and meltwater vertically distributed over the upper 200m. When meltwater is added, there is an increase in off shelf freshwater transport (S_{ref}=34.7) compared to the no-meltwater case (total transport of 45.2 ~mSv). Transport off the shelf increases by 12mSv in the surface meltwater case and by 23.1mSv in the vertically distributed meltwater case. In the mesoscale eddy resolving simulations, when meltwater is vertically distributed, there is enhanced baroclinic conversion at the shelf break compared to the simulation with no meltwater. This suggests that meltwater from the Greenland Ice Sheet could have a disproportionate impact on freshwater transport into the Labrador Sea by modifying cross shelf exchange.

In north Greenland, which holds more than 2.7 m of sea level equivalent, the ice flows through ice shelves, as in Antarctica. These floating platforms are the most vulnerable parts of the ice sheets as the advection of warm, salty ocean waters increases basal melting, which can trigger an increase in ice flow into the ocean. Here we study the recent dynamic and geometric changes of all present and former ice shelves along the north coast of Greenland. We document the evolution of the surface elevation using data from the GIMP project, from NASA's instruments (ICESat-1/2, ATM, LVIS, GLISTIN-A) and generate DEMs using ASTER imagery between 2000-present. We also monitor changes in surface ice velocity and grounding zone evolution using a combination of optical and radar data. We use the elevation time series to monitor the temporal evolution of the ice shelves volumes and combine them with the surface flow velocity to calculate basal melt rates in a Lagrangian framework at unprecedented level of resolution. Finally, we compare our observations with nearby CTD measurements, the TOPAZ4b reanalysis of Arctic ocean physics provided by Copernicus Marine Service and model outputs from the Modèle Atmosphérique Régoinal. We show that basal melting, grounding line retreat and fracturing are rapidly increasing and is followed by an increase in ice discharge into the ocean. These observations demonstrate that significant changes are occuring in a region that has long been considered stable, which may have dramatic consequences for the ice sheet contribution to sea level rise.

Calving of the Greenland Ice Sheet since 1985

DOI: 10.57757/IUGG23-2109 - LINK

[1]Jet Propulsion Laboratory- California Institute of Technology, n/a, Pasadena- CA, USA
[2]Joint Institute for Regional Earth System Science & Engineering- University of California Los Angeles, na, Pasadena- CA, USA

The Greenland Ice Sheet has undergone rapid changes in recent decades, as the ice has grown thinner and outlet glaciers have retreated bit-by-bit. Calving-front retreat often represents a response to environmental forcing, but at the same time, the slow etching away of ice can weaken the ice sheet and induce further glacial change. To better understand the causes and effects of recent changes in Greenland, we combine satellite observations of glacier terminus positions with a simple flow model to create a continuous, ice-sheet-wide history of Greenland's areal extents since 1985. With nearly four decades of monthly ice outlines, we explore the complex relationships between secular change and seasonal cycles of calving in Greenland, and we report on the mass changes associated with the ongoing advance and retreat of the ice sheet.

This work was performed at the California Institute of Technology's Jet Propulsion Laboratory under a contract with the National Aeronautics and Space Administration's Cryosphere Science Program.

The ocean influences on mass loss at tidewater glaciers are poorly understood, leading to uncertainty in sea level rise projections. Subglacial discharge plumes drive mass loss via submarine melting and may also facilitate mass loss by modulating calving rates. However, current theories underpredict submarine melt rates at terminus regions that are far from discharge plumes, suggesting that they may miss key ocean processes. A new set of observations from autonomously deployed moorings less than 100 m from the terminus of LeConte Glacier, Alaska, and a high-resolution numerical model, reveal that the near-glacier ocean is filled with energetic internal waves. We find that the internal wave kinetic energy and frequency are correlated with subglacial discharge fluxes on weekly to seasonal timescales. The waves radiate away from the discharge plume and could enhance ice-ocean boundary layer fluxes of heat and salt along the terminus. Accounting for waves within current submarine melt rate parameterizations increases predicted melt rates by up to 70%. Because the dynamical ingredients - a buoyant plume rising through a stratified ocean - are common to many tidewater glacier systems, such internal waves are likely to be widespread.

Broad spatial and temporal scales modulating ice/ocean interactions, an observational perspective

DOI: 10.57757/IUGG23-0655 - LINK

Pierre Dutrieux[1]
[1]*British Antarctic Survey, Polar Oceans, Cambridge, United Kingdom*

In Antarctica and Greenland, interactions between Oceans and Ice sheets are crucial to the regulation of the global overturning circulation, the current acceleration of ice flow into the ocean and the associated global sea-level rise. Over recent decades, satellite, airborne and in situ ocean and ice observations have demonstrated with increasing temporal and spatial resolution that these interactions are complex and occur on a broad ranges of multidimensional scales. Using an observational lens limited to the past 30 years during which capabilities for direct observations have grown exponentially, I will present an overview of the complexity of the coupled system and the feedbacks involved, covering boundary layer, meso- and large-scale processes in the ocean, and the dynamical and geometric response of the ice at tens of meters to hundreds of kilometers scales. The advent of an array of remote and autonomous in situ technologies provide exciting perspectives for future fruitful explorations.

Interannual variation of modified Circumpolar Deep Water volume in the Dotson-Getz Trough, West Antarctica

DOI: 10.57757/IUGG23-0761 - LINK

Tae-Wan Kim[1], Heewon Yang[1], Yeonggi Kim[1], Jaeill Yoo[1], Jisoo Park[1]
[1]Korea Polar Research Institute, Division of Polar Ocean Sciences, Incheon, Korea Republic of

In recent decades, wide-spread thinning of ice shelves in the Amundsen Sea has been recorded driven by basal melting. Relatively warm modified Circumpolar Deep Water (mCDW) flows onto the continental shelf and fills the Dotson-Getz Trough (DGT) and reaches the base of the Dotson Ice Shelf (DIS). Long-term hydrographic data (2007–2018) for the DGT were obtained during seven oceanographic surveys to study the interannual variation in mCDW volume and properties in the DGT and their causes. Although the mCDW volume showed relatively weak interannual variations at the entrance of the DGT, these variations intensified in front of the DIS. There, the mCDW volume was ~8 × 10^3 km^3 in 2007, rapidly decreased to 4.7 × 10^3 km^3 in 2014 before rebounding to 7.3 × 10^3 km^3 in 2018. Such interannual variability appears to result from local Ekman pumping along the DGT, with the dominant south-southeast wind modulating the amplitude of Ekman upwelling along the eastern boundary of the Amundsen Sea polynya during the austral summers of the surveyed years. We note a strong correlation between the wind variability and the longitudinal location of the Amundsen Sea Low.

[2]University of Gothenberg, Department of Marine Sciences, Gothenberg, Sweden

Ice shelves terminating towards the Amundsen Sea are losing mass rapidly, exporting an increasing amount of meltwater into the ocean. Investigation into the fate of the glacial meltwater in the Amundsen Sea is therefore pressing for predicting the future climate response to the ice shelf processes. However, observations near ice shelves often lack continuity in either time or space, limiting our knowledge of the meltwater pathway. In summer 2022, we deployed six ocean gliders in front of the Dotson Ice Shelf (DIS), obtaining two ship CTD transects and 573 glider profiles, yielding more than ten fine-resolution (median horizontal sampling interval: 650 m) glider transects along the DIS within three weeks, allowing us to compare the full picture along DIS over short time scales (median sampling interval: 4.5 days). Glider transects reveal that the meltwater content is higher (about 20 g/kg) in the west (outflow) and lower in the east (inflow), with a meltwater-poor layer centred at about 350 m sandwiched by two meltwater-rich layers (above about 250 m and centred at about 450 m). We find particularly meltwater-poor cores within the meltwater-poor layer, potentially indicating eddies. Isopycnals diverge near the meltwater outflow core and shoal below about 600 m at the inflow region, indicating geostrophic flow out of and into the cavity respectively. We calculate the volume transport of meltwater exported from the ice shelf cavity and assess its variability during the three weeks.

Graph analysis for subglacial hydrology and sediment flux to the ocean

DOI: 10.57757/IUGG23-1515 - LINK

Alan Aitken[1]
[1]*University of Western Australia, School of Earth Sciences, Perth, Australia*

A better knowledge of sediment flux to the ocean has many implications for understanding past and future cryosphere evolution including understanding potential impacts on ice shelf stability and ocean circulation, understanding the record of past cryosphere events from sediment records and understanding impacts on nutrient supply and CO_2 drawdown. Physical model studies of subglacial sediment transport are relatively few, and due to computational expense, these often do not explore the broader model space for the glacial scenario of interest. The lack of a comprehensive quantitative knowledge of the subglacial sediment transport system limits our ability to understand sedimentary records of ice sheet change, and to express the potential impacts of future cryosphere change on the ocean. I present here a graph analysis approach to enable broad exploration of model space to understand hydrological change and for quantitative estimates of water and sediment fluxes through the system and to the ocean. The analysis is based on the outputs of physical models, including an ice sheet model output and a subglacial hydrology model output. The analysis defines catchment-scale graphs of the subglacial hydrology network, from which subgraphs are defined optimised to the problem at hand. Such representations greatly reduce the model size and allow efficient development of an ensemble result. These subgraphs may be defined from prior information, or ad-hoc during run-time based on stochastic, probabilistic or adaptive algorithms. I demonstrate the approach for a synthetic example and show examples from catchment-scale model studies in Greenland and Antarctica.

Hydraulic suppression of basal glacier melt in sill fjords

DOI: 10.57757/IUGG23-3027 - LINK

Johan Nilsson[1]
[1]*Stockholm University, Department of Meteorology, Stockholm, Sweden*

We examine how hydraulically-controlled exchange flows in silled fjords affect the relationship between basal glacier melt and features of warm intermediate Atlantic Water (AW) outside the fjords. Using theory and an ocean-circulation model, we show that an exchange flow can be forced to transit into a hydraulic regime if the AW interface height decreases, the AW temperature increases, or the production of glacially modified water is boosted by subglacial discharge. In the hydraulic regime, the heat transport across the sill becomes a rate limiting factor for the basal melt, which is suppressed. An interplay between processes near the ice--ocean boundary and the hydraulically-controlled exchange flow determines the melt dynamics, and the sensitivity of the basal melt to changes of the AW temperature is reduced. The model results are discussed in relation to observations from Ryder, Petermann, and 79°N glaciers in North Greenland. We also outline how hydraulic suppression of basal melt can be represented in ice sheet modelling.

We examine how hydraulically-controlled exchange flows in silled fjords affect the relationship between basal glacier melt and features of warm intermediate Atlantic Water (AW) outside the fjords. Using theory and an ocean-circulation model, we show that an exchange flow can be forced to transit into a hydraulic regime if the AW interface height decreases, the AW temperature increases, or the production of glacially modified water is boosted by subglacial discharge. In the hydraulic regime, the heat transport across the sill becomes a rate limiting factor for the basal melt, which is suppressed. An interplay between processes near the ice--ocean boundary and the hydraulically-controlled exchange flow determines the melt dynamics, and the sensitivity of the basal melt to changes of the AW temperature is reduced. The model results are discussed in relation to observations from Ryder, Petermann, and 79°N glaciers in North Greenland. We also outline how hydraulic suppression of basal melt can be represented in ice sheet modelling.

We report on observations from instruments deployed on a pair of moorings sited ~5 km apart, beneath Ronne Ice Shelf, Antarctica. Measurements of temperature, salinity and current velocities for the period from early 2015 to mid-2019 demonstrate strong variability at timescales from tidal to interannual. Here we focus on features that are a few days in length that we interpret as vortices streaming past the site. The intensity of the vortices is enhanced towards the ice-shelf base; they are in geostrophic equilibrium, have a radius (12 km), substantially larger than the estimated internal radius of deformation (~1500 m) and have a relative vorticity that is 30 to 40% of the local planetary vorticity. The velocity of the features, determined by correlating observations from instruments on the two moorings, is the same as that of the ambient water flow. The time series of basal melt rates, measured using a collocated downward-looking radar, shows the melt rate signal to be dominated by an approximate spring-neap variability, but with a significant response to the eddying flow. Although tidal activity clearly affects basal melt rates, as illustrated by the strong ~14-day variation, the net effect of the vortices is less obvious. Here we argue that the cyclonic and anticyclonic vortices ventilate the thermocline via Ekman pumping, thus increasing melting. Such eddy features are clearly a significant component of sub-ice shelf ocean variability, at least in the study area.

Warming of deep Atlantic Water in recent decades has resulted in extensive retreat of marine terminating glaciers in Northwest Greenland, increasing their discharge, contributing significantly to sea level rise. We use data and numerical models to consider whether the pathways of deep Atlantic Water, through the complex system of canyons of Melville Bay, increased the vulnerability of glaciers over the observed ocean warming period. New observations of salinity and temperature of the ocean water and bathymetry from NASA's Ocean Melting Greenland mission, as well as Mankoff's discharge estimates are combined with FESOM ocean model results. We find that the pathways of Atlantic Water are crucial for understanding the increase in discharge of certain glaciers over the ocean warming period. More specifically, the vulnerability of a marine terminating glacier in Northwest Greenland to Atlantic Water depends on its latitudinal position, the location of the fjordal channel entrance along the Southern or Northern canyon head and whether the fjordal channel is deep enough to be a pathway for Baffin Bay Intermediate Water. The Upernavik N and C glaciers, which are in the most vulnerable position, contributed 10% to the total discharge change of Northwest Greenland. In addition, the glaciers that exhibited the largest normalised discharge change showed correspondence between their discharge estimates and the observed changes in fjord geometry during the retreat of the glacier calving front. Warming of deep Atlantic Water impacted the normalised discharge estimates, but the sensitivity to the fjord geometry also controlled large parts of the observed trends.

Antarctic glaciers are losing ice rapidly to the ocean through basal melting of ice shelves/tongues. To better predicate future sea level rise, it is urgent to detect the rapid basal melting of ice shelves/tongues as well as ocean's role in this process. In this study, basal melting of Drygalski Ice Tongue (DIT), the seaward extension of David Glacier in Northern Victoria Land, East Antarctica has been detected using a surface deployed Autonomous Phase-sensitive Radio-Echo-Sounder (ApRES). The ocean water changes adjacent to DIT front has been revealed using an ocean mooring. ApRES observation suggests a rapid basal melting > 10 m/a close to DIT front in February and mooring data shows a synchronous ocean warming in austral summer, indicating Antarctica Surface Water intrusion to the base of DIT. The mooring data has been used to simulate the basal melting of DIT front, which coincides with ApRES measurements. We conclude that rapid basal melting close to the tongue front was likely triggered by intrusion of Antarctica Surface Water in austral summer. Glacier-ocean interactions, such as glacier basal melting, can be detected from spaceborne, terrestrial and oceanic observations and are important processes to predict future sea level changes. To better understand the driving forces of glacier changes, multi-disciplinary observation and numerical modeling are required.

Antarctica's ice shelves are a highly critical component for the interlinkage between ice sheet and ocean. Their shape and evolution play an important role for the strength of ice mass loss, e.g. by amplification or weakening of the buttressing effect. Ocean tides are the most important direct forces acting on the ice shelves, inducing vertical and horizontal motion and deformation. In our study we investigate the effect of ocean tides on the Ekström Ice Shelf. The northward flow of the ice is mainly modulated by the tidal constituents at the ter-diurnal and quarter-diurnal bands, whereas the dominant vertical tides have a diurnal and semi-diurnal periodicity and amplitudes up to ten times larger than the ter- and quarter-diurnal tides. The causes of the higher frequency tidal modulations are still poorly understood. The area of the largest effect of the higher frequency tides is assumed to be the grounding zone of the ice streams feeding the ice shelf.

Here we present first results of geophysical experiments at the grounding zone of the Ekström Ice Shelf conducted in the field seasons 2021/2022 and 2022/2023. In 2021/2022 we setup GNSS and seismic stations to record vertical and horizontal motion of the ice as well as seismic events in order to gain insights into ice dynamics and ground properties. In season 2022/2023 GNSS and seismic station were dismantled, and the experiments were complemented by magnetotelluric measurements to image the sub-ice ocean-land transition and the crustal structure beneath the ice stream.

Under The UN Decade for Ocean Science, UNESCO/IOC has established the UN Ocean Decade Tsunami Program (ODTP). The purpose of the program is to establish a global framework from which significant gains in both operational tsunami science (instrumentation, analysis, forecasting, etc) and preparedness capacities can be realized. To guide this effort a Scientific Committee was established to, in part, identify aspirational goals in both of these areas with the intent of fundamentally advancing the state of the Global Tsunami Warning and Mitigation System over the course of the Decade. In this paper, these specific goals related to tsunami detection, measurement, and forecasting will be outlined along with the types of instrumentation and analysis strategies being considered to achieve them. As a primary objective of the ODTP is to elevate the capacities of all at-risk IOC member States, the ODTP has prioritized strategies that encourage the participation of all at-risk states, in a way that can be seamlessly combined to develop a global tsunami sensing and forecasting network far more advanced and capable that could otherwise be achieved with individual, independent actions.

Tsunami Digital Twin – A new paradigm for tsunami disaster resilience

DOI: 10.57757/IUGG23-2090 - LINK

Shunichi Koshimura[1], *Erick Mas*[1], *Bruno Adriano*[1], *Akihiro Musa*[2]
[1]*Tohoku University, International Research Institute of Disaster Science, Sendai, Japan*
[2]*Tohoku University, Cyberscience Center, Sendai, Japan*

The digital twin is now recognized as digital copies of the physical world's objects stored in digital(cyber) space and utilized to simulate the sequences and consequences of target phenomena. By incorporating the physical world's data into the digital twin, users can fully view the target through real-time feedback.

Given the importance of the digital twin, the authors propose "Tsunami Digital Twin (TDT)" as a new paradigm in tsunami science and engineering to enhance tsunami disaster resilience.

The components of TDT are the transformation from "Data" to "Information" by integrating sensing, monitoring, and simulation; "Interpretation" of data and information; "Inference" by using available data and information to draw conclusions and consequences and decide policies and responses for social resilience. The fusion of these components is the key to gaining knowledge and insight for optimal solutions in the physical world. The components to be covered are the following six research themes that will be presented in the tsunami session.

Theme 1: Real-time tsunami inundation modeling and forecast capability.

Theme 2: Dynamic exposure estimation and guidance to mobile devices and connected vehicles.

Theme 3: Application of machine learning to enhance real-time tsunami inundation forecast capabilities.

Theme 4: Machine learning-based damage/loss estimation methods.

Theme 5: Remote sensing data analysis for mapping.

Theme 6: Social sensing of cascading disaster processes in the tsunami-affected area.

In June 2021, UNESCO IOC approved the Ocean Decade Tsunami Programme (ODTP) in response to the call to action by the UN Ocean Decade of Ocean Science for Sustainable Development (2021-2030). The ODTP has two overarching goals: (1) develop the warning system's capability to issue actionable and timely forecasts for tsunamis from all identified sources for all communities at risk, and (2) 100% of communities at risk are prepared and resilient to tsunamis by 2030. In 2022, a Scientific Committee for ODTP was established to develop a 10-Year Research, Development and Implementation Plan to reach these two objectives. This presentation will focus on three of the four areas of the plan:

-Enhance tsunami risk assessments and research on technologies, so the countries know their expected vulnerability and threat (tsunami characteristics), and can identify and prioritize the at-risk communities.

-Ensure all National Tsunami Warning Centres have access to data, tools and communication platforms, protocols and training to timely and effectively warn coastal and maritime communities threatened by tsunamis and other coastal hazards that are integrated into a multi-hazard framework.

-Emphasize the importance of building tsunami resilient communities that are prepared and ready to respond through the UNESCO IOC Tsunami Ready Recognition Programme.

Tsunami Ready is a global, voluntary community-based effort approved in 2022. It has 12 indicators categorized into Assessment, Preparedness and Response, and thus addresses all of the three aforementioned areas of the Plan. The objectives will be achieved through involvement of stakeholders at all levels and attention on capacity development and governance.

Spatial and temporal coverage of a cargo-ship GNSS network to detect tsunamis

DOI: 10.57757/IUGG23-3624 - LINK

Bruce Thomas[1], James Foster[1], Tasnîme Louartani[2], Jean Roger[3]

Recent tsunamis demonstrate the urgent need for more densely spaced observations and direct measurements from the oceans. Most of the existing observing capacity is located on land or close to the shore, and often sparse (seismic network, land-based GNSS, tide-gauges and DART array), limiting our ability to predict, detect and respond to tsunamis. We propose a network of ships with GNSS systems as a way to fill this geodetic observation gap in the ocean by tracking changes in sea-surface height, and detecting even small, ~10 cm amplitude tsunamis of different origins. One year of navigation data from the commercial shipping fleet is used to generate statistical coverage maps of large ships for different epochs in the Pacific region which are overlapped with regions source of tsunamis and impacted by tsunamis. Some first results describe what a cargo-ship network might experience in terms of tsunami travel time and tsunami predicted amplitudes based on several tsunami models calculated over the Pacific. They clearly demonstrate that commercial shipping lines provide an excellent temporal and spatial coverage of the ocean globally. A focus on different regions indicates that the highest density of ships is near coastlines, and testing different tsunami origins helps understand more precisely how this network could improve regional early warning. By exploring the geographic relationship between tsunami sources, travel times and amplitudes with the ships locations, the discussion seeks to determine the ability of a defined ship network to provide effective warnings for the communities at risk and improve hazard mitigations.

In June 2022 the Intergovernmental Oceanographic Commission (IOC) of UNESCO established the Tsunami Ready Recognition Programme. It is modelled after the US TsunamiReady® Program established in 2001. To receive Tsunami Ready recognition, each community must meet 12 indicators that cover Assessment, Preparedness, and Response. The recognition is renewable every four years. The Tsunami Information Centres in each region (ITIC in the Pacific, CTIC in the Caribbean, IOTIC in the Indian Ocean and NEAMTIC in the Mediterranean and Northeast Atlantic) facilitate the implementation of this Programme. To date, more than 30 communities in 20 countries in the Pacific and Caribbean, and 40 globally have been recognized.

ITIC and its Caribbean Office (previously known as the Caribbean Tsunami Warning Program) have been supporting the program in its different phases since 2012. In 2014, Anguilla, a UK Territory in the Caribbean, was the first to be recognized. Currently, with funding from USAID, ITIC, in coordination with CTIC for the Caribbean, is leading TR projects in several SIDS in the Caribbean and Pacific. It is also providing support through capacity development and sharing of best practices worldwide. Additionally, ITIC hosts the website for the Programme (tsunamiready.org). By conducting this work ITIC and CTIC and the countries, communities and other stakeholders will be contributing to the IOC Ocean Decade Tsunami Programme and specifically the goal of 100% of communities at risk are prepared and resilient to tsunamis by 2030. An overview on the implementation process, deliverables and challenges will be presented.

Providing data, data products, software, and services for tsunami risk

DOI: 10.57757/IUGG23-3952 - LINK

Fatemeh Jalayer[1], *Hossein Ebrahimian*[2], *Konstantinos Trevlopoulos*[2]
[1]*University College London, Institute for Risk and Disaster Reduction, London, Italy*
[2]*University of Naples Federico II, Structures for Engineering and Architecture, Naples, Italy*

Excellent science is enabled and enriched through making the relevant scientific research tools and results directly accessible to the scientific communities and the civil societies. The European Tsunami Risk Service (ETRiS) aims to collect, harmonize and make available tsunami risk related data (e.g., impact, damage, consequences), data products (e.g., fragility and vulnerability curves), software, and services in a way that they are findable, accessible, interoperable, and reusable by a broad user base. ETRiS is part of the candidate Thematic Core Service for tsunami (http://tsunamidata.org) and is integrated into the Data Portal of the European Plate Observing System (EPOS, https://www.ics-c.epos-eu.org).

This web platform (https://eurotsunamirisk.org) provides data products and services required for probabilistic tsunami risk analysis (PTRA) in a multi-risk context. Here are some features:

- Maps: visualizing data products and data sets
- Data Products: damage scales, fragility curves, consequence models, vulnerability curves
- Tsunami Impact and Consequence Datasets: selected raw/processed datasets of impact and damage incurred by tsunami
- Tsunami Risk Modeller's Toolkit: software and tools for tsunami risk analysis, stand-alone software and tools for post-processing raw data, model testing and validation
- E-Learning: Online teaching material, Jupiter notebooks, docker applications for probabilistic analysis and uncertainty characterization and propagation, fragility and vulnerability modelling, model testing and selection
- User support and organization of user testing and feedback workshops.

We herein present this service and its features and solicit input and collaborations for enriching it and widening its scope.

This work is supported by Horizon Europe Project Geo-INQUIRE. Geo-INQUIRE is funded by the European Commission under project no. 101058518 within the HORIZON-INFRA-2021-SERV-01 call.

Excellent science is enabled and enriched through making the relevant scientific research tools and results directly accessible to the scientific communities and the civil societies. The

European Tsunami Risk Service (ETRiS) aims to collect, harmonize and make available tsunami risk related data (e.g., impact, damage, consequences), data products (e.g., fragility and vulnerability curves), software, and services in a way that they are findable, accessible, interoperable, and reusable by a broad user base. ETRiS is part of the candidate Thematic Core Service for tsunami (http://tsunamidata.org) and is integrated into the Data Portal of the European Plate Observing System (EPOS, https://www.ics-c.epos-eu.org).

This web platform (https://eurotsunamirisk.org) provides data products and services required for probabilistic tsunami risk analysis (PTRA) in a multi-risk context. Here are some features:

- Maps: visualizing data products and data sets
- Data Products: damage scales, fragility curves, consequence models, vulnerability curves
- Tsunami Impact and Consequence Datasets: selected raw/processed datasets of impact and damage incurred by tsunami
- Tsunami Risk Modeller's Toolkit: software and tools for tsunami risk analysis, stand-alone software and tools for post-processing raw data, model testing and validation
- E-Learning: Online teaching material, Jupiter notebooks, docker applications for probabilistic analysis and uncertainty characterization and propagation, fragility and vulnerability modelling, model testing and selection
- User support and organization of user testing and feedback workshops.

We herein present this service and its features and solicit input and collaborations for enriching it and widening its scope.

Probabilistic Tsunami Hazard and Risk Analysis (PTHA/PTRA) has its roots in the corresponding probabilistic approaches in the seismic sciences. However, there are several substantial differences in the cascading source and effect modeling chain, necessitating for complex workflows, involving still larger gaps in data and knowledge, and requiring different approaches in dealing with uncertainties.

The European Cooperation in Science and Technology (COST) Action AGITHAR (Accelerating Global Science in Probabilistic Hazard and Risk Analysis) has run for four years and has since then gathered parts of the scientific community around PTHA/PTRA and made some substantial progress in communicating and unifying the underlying concepts. Additionally, the effort has allowed the European tsunami community to coordinate a number of new research efforts and infrastrucutral developments, which are of benefit for the global science in PTHA/PTRA.

In this presentation we will outline the results of AGITHAR's major deliverables, a compilation of research gaps in PTHA/PTRA and uncertainty communication, findings in interdisciplinary tsunami research cooperation, and a collection of current practices in PTHA/PTRA. Ideas and opportunities of sustaining AGITHAR's output into the future will be given.

Probabilistic tsunami risk assessment from historical impact files: Mediterranean and connected seas

DOI: 10.57757/IUGG23-4034 - LINK

Gerassimos Papadopoulos[1], *Ioanna Triantafyllou*[2], *Andrzej Kijko*[3]

Probabilistic tsunami risk is assessed using a procedure that allows including mixed data from the instrumental part of tsunami catalogs, and data from the highly incomplete and uncertain pre-instrumental part. Such a model was used successfully for hazard assessment of earthquakes (Kijko et al., 2016) and tsunamis (Smit et al., 2019), considering seismic magnitude and tsunami height as metrics of the respective hazards. We applied this technique using catalogs for the basins of the Mediterranean and connected seas. Wave impact (destructiveness) is expressed in terms of tsunami intensity, K, i.e., a risk metric on the Papadopoulos-Imamura 12-degree scale. Risk level is assessed in terms of probabilities of exceedance and return periods of certain intensity levels in specific time frames. Tests and sensitivity analysis showed that using complete data sets generally provided more realistic results than using entire data sets. Our results indicated that the risk level depended on the seismicity level and not on the size of the investigated basin. The highest tsunami risk level was found in the eastern Mediterranean, with a significantly lower risk in the western Mediterranean. In the Marmara Sea, the tsunami risk was low, and the lowest was in the Black Sea. The risk in the Corinth Gulf in Central Greece was comparable to that of WM. The return period of damaging tsunamis was 22 years in the entire Mediterranean basin and from 31 to 1 660 years in the various sub-basins.

Role of tsunami-tide interactions in evaluating tsunami hazard for Anchorage and Upper Cook Inlet, Alaska

DOI: 10.57757/IUGG23-2129 - [LINK]

Elena Suleimani[1], *Dmitry Nicolsky*[1], *Michael West*[1]
[1]*University of Alaska Fairbanks, Geophysical Institute, Fairbanks, USA*

The historic tsunami events have led to a common misconception that the Upper Cook Inlet (UCI) is completely immune to tsunami impacts. A coordinated effort is now underway to evaluate tsunami hazards in the area, as a part of the Alaska tsunami inundation mapping program.

Tsunamis were not reported in Anchorage during the Great Alaska earthquake. The 1964 rupture did not produce a substantial amount of slip in the presently creeping Kenai segment of the plate interface, which resulted in a relatively small amount of energy entering Cook Inlet. Another potential reason for the unreported tsunami was the timing of the arrival of the wave: after midnight at low tide.

Tsunami inundation models used in hazard assessment studies usually employ static-tide runs with the Mean High Water vertical datum, because dynamically coupled tsunami-tide models are hard to implement. However, UCI is a shallow water body with extreme tidal ranges of up to 10 meters, which makes tsunami-tide interactions crucial for accurate hazard assessment. We perform numerical modeling of the 1964 tsunami in UCI by dynamically coupling the tsunami model with tides, and suggest that a 3-meter high tsunami did occur, but was unnoticed in Anchorage due to its arrival on low tide that was 5 meters below Mean Sea Level. Our further modeling shows that the inundation zone, corresponding to the tsunami calculated on a high static tide, is larger than that computed with dynamically coupled tide, therefore our tsunami inundation maps do not underestimate potential hazard due to static-tide modeling.

Deep learning of tsunami building damage from multimodal physical parameters for real-time damage assessment

DOI: 10.57757/IUGG23-2256 - LINK

Ruben Vescovo[1], *Erick Mas*[1], *Bruno Adriano*[1], *Shunichi Koshimura*[1]

Tsunami building damage estimates are critical to post-disaster supply logistics and disaster management. Likewise, accurate damage estimates in a digital twin framework (Koshimura et al., 2023) enable more effective responses to disaster emergencies. However, meaningful results from an eventual disaster digital twin would be contingent on real-time inputs, at best. Hence, any practical implementation of a model that performs tsunami building damage estimates precludes reliance on post-disaster data, such as current damage detection models. By embedding physical representations of both the inundated environment and the tsunami, we propose to circumvent the limitations of optical imagery-based deep learning models. We aim to curtail the reliance on post-event data during evaluation, limit the constraints associated with the observation angle, and learn multi-level damage representations based on spatial and geophysical context. Our purpose is to learn these representations by training on physical parameters rather than optical imagery. Thus, we adapt deep learning architectures, initially developed for computer vision tasks, to take in a larger input tensor. Then, we extend and combine remotely sensed data, such as digital elevation models, land use, and cadastral maps. These extra layers embed the physical and spatial context relevant to tsunami inundation in the input. Finally, we test our modified architecture and benchmark the results against a random forest baseline.

Typically, disaster response using remote sensing technology requires pre and post-disaster datasets. Unfortunately, pre-disaster data is not always available, and a lack thereof may lead to unreliable results in building damage predictions. Augmenting pre- and post-disaster data can artificially increase the training samples in machine learning (ML) models. In this regard, SAR simulators can provide synthetic data for augmentation purposes.

Here, we introduce a general framework for applying SAR simulators to building damage estimation. We used a SAR simulator, RaySAR, and optimized surface parameters, reflection, and a 3D model of the Onagawa Nuclear Power Plant, where the 2011 Tohoku tsunami hit, to assess the reliability of the SAR simulator compared to an actual SAR image. In addition, we constructed 3D models of damaged buildings with multiple damage statuses of the European Macroseismic Scale (EMS-98) to evaluate the suitability of the simulator for representing earthquake and tsunami damage. We strive to improve the original simulator using a more capable rendering algorithm, path tracing, and incorporation of Graphics Processing Units (GPUs) to achieve higher realism in diffuse reflections and shorter computation times. The results are evaluated using similarity measures in the spatial and frequency domains, contrasting simulated with authentic SAR imagery.

Preliminary results show that in simulated SAR imagery, damaged and undamaged buildings show distinguishable signatures. We believe that our simulator overcomes the limitations of the diffuse reflection model employed in RaySAR. Conclusively, the proposed framework seems promising for improving damage mapping in the context of future digital twin implementations.

Probabilistic Tsunami Forecasting (PTF) combines early estimates of earthquake parameters with ensembles of urgent tsunami propagation simulations through the Tsunami-HySEA model. In the present implementation, the PTF is initialised by the earthquake information, but not updated further with new data. In the recently started Horizon Europe project DT-GEO work has started upgrading it into a Digital Twin providing a time dependent update of the model when new data becomes available. This enables a close to real time synthesis of data products and numerical models, continuously updating the model forecast as new data are continuously assimilated. In DT-GEO, an extended set of data sources, including improved earthquake solutions, sea level tsunami data, and GNSS, will be integrated. Secondly, the Digital Twin will implement a modularised inclusion of improved wave and source physics through dispersion, non-hydrostatic tsunami generation, inundation, improved earthquake physics, and cascading earthquake triggered landslide tsunamis. The model will be tested at site demonstrators, in the Mediterranean Sea for eastern Sicily and Samos, and in the Pacific Ocean for Chile and Japan. The presentation will explain how the PTF as it works today, followed by an outline of the design of the components in the Digital Twin. The presentation will finally describe initial improvements and plans for further development, including long term plans such as potential integration into Destination Earth and service provision within EPOS-ERIC. This work is supported by the European Union's Horizon Europe Research and Innovation Program under grant agreement No 101058129 (DT-GEO, https://dtgeo.eu/).

Developing a deep learning super-resolution framework for tsunami inundation forecasting

DOI: 10.57757/IUGG23-2187 - LINK

Bruno Adriano[1], Shunichi Koshimura[1]
[1]Tohoku University, International Research Institute of Disaster Science, Sendai, Japan

Real-time forecast of tsunami inundation in a high-resolution domain, e.g., meter or sub-meter resolution, is essential for efficient evacuation procedures and damage assessments. Current approaches to real-time tsunami forecast are based on two conventional approaches; one is high-performance computing (HPC) to accelerate numerical tsunami calculations, and the other is building a large database of tsunami scenarios for specific areas of interest. However, these approaches have three significant drawbacks. First, HPCs are not primarily available in developing countries, especially for disaster management purposes. Second, the tsunami database must be constantly updated for accurate prediction because urban environments constantly change. Third, both approaches focus primarily on estimating coastal tsunami height or, at best, inundation depth at moderate resolution (e.g., greater than 10 m). We propose a novel deep learning-based system to address the above drawbacks by integrating advanced deep neural network algorithms and high-resolution numerical tsunami simulations. We developed an advanced deep neural network that analyzes pre-computed tsunami scenarios. The pre-computed scenarios include pairs of high-resolution inland inundations and corresponding coarse offshore tsunami heights and inundations. The network learns to estimate the high-resolution inundation based on corresponding patterns in a coarse tsunami dataset. The network can generate tsunami inundation for extensive areas at less than 10 m resolution, achieving 80% accuracy for scenarios outside the pre-computed dataset. Moreover, our network requires only a coarse offshore tsunami height as input, which allows easy application on lightweight personal computers.

Multi-area applicability of machine learning-based immediate tsunami prediction

DOI: 10.57757/IUGG23-2299 - LINK

Shiho Honda[1], *Kota Gunji*[1], *Taro Arikawa*[1]
[1]*Chuo University, Civil and Environmental Engineering, Bunyo-ku- Tokyo, Japan*

Machine learning is one of the methods employed for the immediate prediction of tsunami occurrence. There have been few studies on error evaluation focusing on the arrival time of the tsunami inundation. In this study, we used machine learning to predict the tsunami arrival times for two areas and evaluated the errors. Tsunamis were calculated for several thousand cases for three different earthquake sizes using the tsunami simulator Q-Wave and assuming a Nankai Trough earthquake. Using these data, we trained a neural network to predict tsunami arrival time on the basis of the initial water level. As the amount of training data increased, the error decreased and the model with the most training data was used to predict the tsunami arrival times for two areas. The errors tended to be particularly large in coastal areas where tsunamis often reach. In some cases, the error was larger in Area B than in Area A, even though the amount of data for Area B was double that of Area A. These errors may be ascribed to variations in the arrival time of tsunamis in the training data due to topographical characteristics. For a magnitude 9.0 earthquake, the standard deviation of the tsunami arrival time in Area B is approximately 1.5 times that of Area A. Therefore, in addition to increasing the number of output variables and the accuracy of tsunami simulation, a more detailed consideration of the effect of area-specific characteristics on the error is needed in the future.

Coastal Tsunami Prediction in Tohoku Region, Japan, Using S-net Observations based on Artificial Neural Network

DOI: 10.57757/IUGG23-2222 - LINK

Yuchen Wang[1], Kentaro Imai[1], Keisuke Ariyoshi[1], Takuya Miyashita[2], Narumi Takahashi[1]

Research Institute for Marine Geodynamics, Yokohama, Japan
[2]Kyoto University, Disaster Prevention Research Institute, Uji, Japan

Seafloor observation network for earthquakes and tsunamis along the Japan Trench (S-net) was installed offshore Japan. It provides observations for tsunami early warning. Coastal tsunami prediction using offshore tsunami observations contains two main types: tsunami inversion (Tsushima *et al.*, 2009) and tsunami data assimilation (Maeda *et al.*, 2015). The first type must consider the source information, whereas the second type is affected by coseismic deformation. Recently, artificial neural network was introduced to tsunami prediction (Mulia *et al.*, 2020).

We adopted a denoising autoencoder (DAE) model for coastal tsunami prediction. It is a neural network with the encoder-decoder structure trained to denoise or correct corrupted data. We used 1,000 stochastic earthquake models (M7.0–8.8) in Tohoku region, Japan, and calculated synthetic tsunami waveforms at 50 S-net stations and two coastal stations. The DAE model was trained using 800 synthetic scenarios. Then, we tested the model against 200 unseen synthetic scenarios and two real tsunami events: the 2016 Fukushima earthquake and the 2022 Tonga volcanic eruption.

DAE model accurately predicted coastal tsunami waveforms for synthetic events. The maximum amplitude was accurately predicted for the 2016 Fukushima tsunami with a forecast accuracy of over 90%. The entire waveforms were also fairly predicted. However, coastal waveforms were not satisfactorily predicted for the 2022 Tonga volcanic tsunami, likely due to its different generating mechanism (i.e., meteorological tsunami). Our research is the first study to apply artificial neutral network to tsunami prediction using real observations. In the future, we will adopt more tsunami scenarios for model training.

Tsunami forecasting method using time averages of dense ocean bottom pressure data (S-net)

DOI: 10.57757/IUGG23-0638 - LINK

Yuichiro Tanioka[1], *Tatsuto Oishi*[1], *Yusuke Yamanaka*[1]
[1]*Hokkaido University, Faculty of Science, Sapporo, Japan*

A dense cabled observation network, called the seafloor observation network for earthquakes and tsunami along the Japan Trench (S-net), was installed in 2017. Since then, the tsunami forecasting methods using S-net data have been developed vigorously. Especially, tsunami assimilation techniques or waveform inversion techniques to obtain tsunami initial conditions were newly developed. However, the ocean bottom pressure data are always contaminated by non-tsunami components such as sea-bottom acceleration change, ocean acoustic wave or P wave due to the earthquake. Therefore, tsunami components are needed to be separated from those non-tsunami components before those recent tsunami forecasting methods are applied.

In this study, we developed a new tsunami forecasting method using the time average of ocean bottom pressure data (S-net). Therefore, pre-data process to eliminate non-tsunami components form original data is not necessary. To test our method, tsunamis from the various fault models distributed along the plate interface along the Japan Trench were first computed. Then, time averages of computed ocean bottom pressure data at S-net stations were calculated by changing the time average windows. Second, tsunami initial conditions, initial ocean surface deformations, were estimated using interpolation of those time averaged ocean pressure data at S-net stations. Third, forecasted tsunamis were computed from those estimated tsunami initial conditions. Finally, forecasted tsunami waveforms along the coast were compared with the tsunami waveforms computed from the fault model at first. We conclude that this tsunami forecasting method performed well in general with some underestimations of tsunami heights along the coast.

A dense cabled observation network, called the seafloor observation network for earthquakes and tsunami along the Japan Trench (S-net), was installed in 2017. Since then, the tsunami forecasting methods using S-net data have been developed vigorously. Especially, tsunami assimilation techniques or waveform inversion techniques to obtain tsunami initial conditions were newly developed. However, the ocean bottom pressure data are always contaminated by non-tsunami components such as sea-bottom acceleration change, ocean acoustic wave or P wave due to the earthquake. Therefore, tsunami components are needed to be separated from those non-tsunami components before those recent tsunami forecasting methods are applied.

In this study, we developed a new tsunami forecasting method using the time average of ocean bottom pressure data (S-net). Therefore, pre-data process to eliminate non-tsunami components form original data is not necessary. To test our method, tsunamis from the various fault models distributed along the plate interface along the Japan Trench were first computed. Modifying the pre-computed tsunami database for real-time tsunami forecasting after the 2016 off-Fukushima earthquake by an unpredicted mechanism

DOI: 10.57757/IUGG23-0781 - LINK

Yutaka Hayashi[1], Masashi Kiyomoto[2], Go Tange[2], Keishi Noguchi[2], Satoshi Harada[3], Yuji Nishimae[2]

On 22 November 2016, an intraplate normal-fault earthquake with a magnitude (M_{JMA}) of 7.4, with a tension axis in the northwest-southeast direction (hereafter, 2016 off-Fukushima earthquake), occurred east of the Fukushima Prefecture, Japan. However, the tsunami database (TDB), which contains pre-calculated tsunami data used for real-time tsunami forecasting by the Japan Meteorological Agency, had assumed that earthquakes in the Fukushima region were north-south oriented reverse fault type. The earthquake mechanism of the 2016 off-Fukushima earthquake differs from the predictions made in the TDB. Although the incorrect classification of normal and reverse faults did not affect the real-time tsunami prediction, the difference in fault plane strike was the main cause of the underestimated height prediction for Miyagi Prefecture. An efficient scenario arrangement is achieved when the differences in predictions from adjacent scenarios in the TDB are similar. Sensitivity analyses of tsunami height distribution to fault parameters for the 2016 off-Fukushima earthquake revealed the importance of the fault plane strike [1]. Therefore, adding earthquake tsunami scenarios with different fault plane strikes and the same epicentre near the epicentral area is reasonable. We compared the centroid moment tensor solutions for earthquakes with a moment magnitude of 5.5 or more that occurred in the coastal area around Japan between September 1994 and April 2017 with the fault parameters assumed in the TDB. Afterwards, we added scenarios to the TDB for regions where the difference in strike directions was observed to be 30° or more.

The lattice Boltzmann method (LBM) is an alternative computational fluid dynamics to conventional approaches to solve macroscopic equations. Despite various successful applications in many engineering fields, the LBM for tsunami modeling is still under development. In this study, we present the recent advances of the LBM for tsunami modeling and discuss future development. Tsunami involves various scales of fluid dynamics. Therefore, tsunami simulation methods have to be a unified method that covers the whole process from its generation to inundation. To achieve this goal, we present and discuss (i) the three-dimensional (3D) nonstatic pressure free-surface model, (ii) the two-dimensional (2D) shallow water model, and (iii) the hybrid 2D-3D model by the LBM for tsunami modeling. First, we develop the volume of fluid (VOF) based free-surface model using the cumulant model in the 3D LBM. We demonstrate that the cumulant LBM accurately calculates the impact pressure acting on a structure in violent flow fields. Second, we develop a shallow water model by 2D LBM and apply it to simulate the 2011 tsunami off the Pacific coast caused by the Tohoku earthquake. We demonstrate that the 2D LBM reproduce the tsunami propagation and inundation with an accuracy equally as good as that of the finite difference method. Finally, we develop a coupling 2D-3D LBM method and apply it to dam-break flow. We demonstrate that the proposed method connects 2D and 3D models. Then, we conclude that the LBM is valuable for the unified tsunami modeling method and provide the future direction.

Impact of tsunami measurements from dense offshore network on modeling of tsunami source and propagation

DOI: 10.57757/IUGG23-1610 - LINK

Hiroaki Tsushima[1], Yutaka Hayashi[1], Takeyasu Yamamoto[1]
[1]Meteorological Research Institute- Japan Meteorological Agency, Department of Seismology and Tsunami Research, Tsukuba, Japan

We investigated impact of dense seafloor observation network along the Japan trench, S-net, on tsunami generation and propagation modeling. We focused on the 2016 Mw 6.9 off-Fukushima earthquake, Japan, which generated the largest tsunami in this subduction zone after the S-net deployment. We inverted the offshore tsunami waveforms for the accurate tsunami source, and then used it in numerical tsunami simulation to clarify how well the tsunami waveforms recorded at the coastal sea-level stations can be reproduced. The results showed that the simulated tsunami waveforms matched the observations well for 90 min from the tsunami arrival time at each station, whereas the reproducibility in the temporal variation of tsunami energy over the long duration, including the decay process, varied from station to station. Because the discrepancies between the observations and calculations exceed the uncertainties due to the source estimation error, our results suggest the room for improvement in the propagation modeling. Another insight we found thanks to the offshore-data-constrained tsunami source is that the leading parts of the coastal tsunami waveforms might have non-negligible effect from the tsunami nonlinearity although they are often fed into linear tsunami inversion. This study has demonstrated that tsunami data from dense offshore network can contribute not only to accurate reproduction of targeted tsunami event, but also to the performance evaluation of the present source and propagation modeling technologies.

We used offshore and coastal tsunami data provided by NIED, MLIT, GSI and JMA. This work was partially supported by JSPS KAKENHI Grant Numbers JP19H02409 and JP21K04621.

The study of long wave runup is a classical problem in fluid dynamics, in both its linear and nonlinear formulations. On the other hand, little attention has been given to the inverse problem, i.e. the reconstruction of the initial condition from a known runup time history.

According to the piston model of tsunami generation, the problem can be modelled as an initial value problem with assigned initial water surface displacement and zero velocity. In this framework, the solution of the linear problem, i.e. the runup as a function of time, can be written as the convolution of the initial water surface with an Abel kernel. This solution can be analytically and uniquely inverted, obtaining the initial wave surface as a functional of the runup function.

In this work, this solution is applied to analytically generated runup time series and its properties are analyzed. In particular, the robustness of the solution to added noise is verified and the effect of nonlinearity is investigated through the use of a Riemann transform of the coordinates.

Uncertainties in a paleoearthquake modeling

DOI: 10.57757/IUGG23-2557 - LINK

Yusuke Yamanaka[1]
[1]*Hokkaido University, Institute of Seismology and Volcanology, Sapporo, Japan*

For modeling a paleo earthquake-tsunami event, tsunami inundation areas by assumed sources for the paleo earthquake can be estimated along coastal areas where tsunami deposits were identified for the event. An earthquake source scenario among them with the best inundation area for the distribution of tsunami deposits can be determined as a reasonable source scenario of the earthquake. The estimated inundation area, therefore, has an important role in the development of source scenario and, however, strongly reflects numerical effects such as a grid size and types of governing equations. This study targets a tsunami generated by the great earthquake in the 17th-century in Hokkaido, Japan, and discusses how such effects impact the development of the earthquake source scenario.
At a coastal site of eastern Hokkaido, where tsunami deposits for the event were found, we compared tsunami inundation areas simulated under several source scenarios by shallow water and Boussinesq models in different-sized grid systems. Results indicated that tsunami propagation and inundation patterns even from an identical source might be variable greatly owing to the model differences. Existing studies estimated an inundation area expected in the 17th-century tsunami at the site, as well as other sites, and proposed source scenarios of the earthquake by accounting for the results. However, the results of this study suggested that non-identical tsunami propagation and inundation patterns from the identical sources proposed by them could be produced owing to the model differences. Therefore, the source scenarios may include large uncertainties associated with the numerical effects.

Boulders motion under breaking solitary waves

DOI: 10.57757/IUGG23-2007 - LINK

Pin-Tzu Su[1], *Ira Didenkulova*[1], *Atle Jensen*[1]
[1]*University of Oslo, Mathematics and Natural Sciences, Oslo, Norway*

Impact of solitary breaking waves on partly submerged boulders is studied experimentally in a small wave tank. Focus is on the forces and motion of boulder with different size. Furthermore, sand is added which change the friction coefficient. Experiments are conducted at the Hydrodynamics lab at the University of Oslo in a small 3m long and 10 cm wide wave tank, filled with 5 cm water.A block releasing mechanism generates solitary waves with an amplitude normalized by the water depth a/h = 0.47. The dimensions of the block are 15.03 cm, 10 cm and 5.00 cm (length, width, height). Generated solitary waves propagate to a 1:10 beach. Boulders of different size, volume and orientation are placed alternately (one at a time) at different locations on the beach slope (smooth or sandy) with respect to the wave breaking point. The transport of boulders and their motion is studied with respect to the boulder characteristics (volume, size, orientation), inclusion of sand and the initial position of the boulders. The sand on the slope changes bottom friction, and therefore, increases the boulder transport. Overall, the effects of boulders' length (parallel to wave direction) on the displacement of boulders are more evident in this study.

The role of resonance has been long recognized as a relevant aspect in controlling the duration and other inundation metrics of tsunami response. However, whether their site-specific behavior is controlled by the source or the morphology is challenging to be determined owing to several reasons. First, in situ data to carry out the characterization can be only obtained during tsunami events, and it is usually spatially sparse, thereby limiting generalization. Moreover, distinguishing between source and bathymetric control is possible in these cases even though both signals are intermingled, but whether the resulting amplification will be similar for other events is debatable. Alternatively, analytical or numerical methods can identify multiple modes dominated by the bathymetry. However, distinguishing which ones would dominate the actual response remains a challenge because earthquake source characteristics are usually absent.

In this work, we take advantage of using a large number of stochastic earthquake simulations to drive a NLSWE numerical model to identify response trends on a set of different bays in Central Chile. We couple these results with a free oscillation model and historical data to validate some cases. Results show that bays can be classified as being bathymetry-controlled, source-controlled, or a mixture of both, depending on how consistent their response is when magnitudes and rupture distributions are varied. Such characterization could help in understanding site-specific hazards, as a first step to mitigation.

Real-time tsunami estimation in volcanic events remains challenging because modeling the tsunami generation process in real-time is greatly uncertain. In this study, we investigated the performance of a tsunami waveform inversion method that can estimate an initial sea surface deformation useful for real-time estimation in a volcanic-induced tsunami event. As a case study, we focused on the 2018 Anak Krakatau event, which had a tsunami resulting in a large number of casualties in Indonesia.

We assumed a source area located around the collapsed area of Anak Krakatau and assigned point sources with the Gaussian shape as a basis function. Propagation of the point sources was individually solved based on the linear longwave equation to estimate Green's functions at four tide gauge stations where the 2018 tsunami was observed. Based on an inversion analysis using the observed waveforms and Green's functions, we obtained an initial sea surface deformation producing reasonable tsunami waveforms at the tide gauge stations. Our estimated deformation peaked at the southwestern part of the Anak Krakatau volcano, consistent with tsunami generation areas reported by prior studies for this event. Additionally, our inversion analysis successfully reproduced the observed waveforms better than those from an existing study, which conducted a similar analysis to ours.

Early warning systems should be available for volcanic tsunamis. Present tsunami warning systems have been specialized for earthquake-generated tsunamis, and it remains challenging to rapidly evaluate the tsunami potential accompanied by a volcanic eruption and/or volcanic sector collapse. By targeting the volcanic sector collapse of Anak Krakatau in 2018, which generated a large tsunami as a case event, we develop a real-time forecasting method for tsunamis accompanied by such eruptions in Indonesia. The proposed forecasting method is based on the utilization of observation stations near the source area and a pre-computed database. In this study, six virtual observation stations were placed in the vicinity of the volcano. Then, a pre-computed waveforms database was constructed from various collapse scenarios using a numerical simulation of sector collapse and tsunami propagation. In the real application, tsunami forecasting computation will be conducted using the initial conditions which are selected from the best combination of scenarios inside the database through waveforms fitting at six observation stations. The reliability of the method was examined using three hypothetical collapse scenarios of Anak Krakatau assuming three different sliding directions. Based on numerical experiments, the forecasted tsunami along the coast of Java and Sumatra by our method resulted in satisfactory performance. Our results indicate that the combination of a pre-computed database and the existence of observation stations near the source area was able to produce appropriate tsunami forecasting for the coastal area. We conclude that our method has a reasonable predictive skill for volcanic-induced tsunamis in Anak Krakatau.

The destructive tsunami on 22 December 2018 due to the flank collapse of the Anak Krakatau volcano was a bitter reminder of large tsunami risks and of the shortcomings of the existing tsunami warning systems for atypical (non-seismic) sources. In the Mediterranean, several tsunamis were generated by landslides associated with volcanic systems in the past.The volcanic unrest experienced in 2011-2012 on the Santorini volcanic island in the Southern Aegean Sea pointed out the need to identify and quantify tsunami hazard and risk due to possible flank instability which may be triggered as a result of volcanic unrest or nearby seismotectonic activities. Inspired from this need, in this study we examined three possible landslide scenarios in Santorini Island with tsunamigenic potential. The results show that the scenarios considered in our study are able to generate significant local tsunamis impacting Santorini and the nearby islands, as well as producing significant impact along the coasts of the Southern Aegean Sea. While maximum tsunami amplitudes/arrival time ranges are 1.2m/30-90min for locations in the Greek-Turkish coasts in the far field, they are in the order of ≈60m/1-2min for some locations at the Santorini Island. The extreme tsunami amplitudes and short arrival times for locations inside the Santorini Island is a major challenge in terms of tsunami hazard warning and mitigation. As an effort to address this challenge, a discussion on the requirements for local tsunami warning system addressing atypical sources in the context of multi-hazard disaster risk reduction is also provided.

Inspired from this need, in this study we examined three possible landslide scenarios in Santorini Island with tsunamigenic potential. The results show that the scenarios considered in our study are able to generate significant local tsunamis impacting Santorini and the nearby islands, as well as producing significant impact along the coasts of the Southern Aegean Sea. While maximum tsunami amplitudes/arrival time ranges are 1.2m/30-90min for locations in the Greek-Turkish coasts in the far field, they are in the order of ≈60m/1-2min for some locations at the Santorini Island. The extreme tsunami amplitudes and short

arrival times for locations inside the Santorini Island is a major challenge in terms of tsunami hazard warning and mitigation. As an effort to address this challenge, a discussion on the requirements for local tsunami warning system addressing atypical sources in the context of multi-hazard disaster risk reduction is also provided.

Numerical simulation of landslide tsunamis using smoothed particle hydrodynamics

DOI: 10.57757/IUGG23-0459 - LINK

Chiaki Tsurudome[1], Naoto Kihara[1]
[1]Central Research Institute of Electric Power Industry, Meteorology and Fluid Science Division, Abiko, Japan

Tsunamis can be generated by mass movement such as slide, slump, and sector collapse. The recent events of such “landslide tsunami” include Papua New Guinea tsunami in 1998, Sulawesi tsunami and Krakatau tsunami in 2018. In order to estimate how landslide tsunamis affect buildings and infrastructures, it is required to predict and analyse both landslide and tsunami accurately. This work presents the numerical simulation of landslide tsunamis using Smoothed Particle Hydrodynamics (SPH).

SPH is a particle method which is suitable for simulating multi-physics and large deformation problems. DualSPHysics, one of the opensource code of SPH, was used in the numerical simulation. DualSPHysics has the non-Newtonian fluid model and the Discrete Element Method (DEM) coupling, which can be accelerated by GPU. In this work, the non-Newtonian fluid model was applied to underwater landslide cases, and the SPH-DEM coupling was utilised to analyse subaerial landslide tsunamis. The results were compared with the existing experiment data. Landslide motion and tsunamis were successfully simulated in both underwater and subaerial landslide cases. Overall, the time series of water level agreed with the experimental results. Further investigation and future developments will be discussed.

Estimating the scale of submarine landslide tsunamis in the Sea of Japan

DOI: 10.57757/IUGG23-0783 - LINK

Masataka Inui[1], *Yoshinori Shigihara*[1], *Takashi Kumamoto*[2]

The Sea of Japan contains traces of submarine landslide collapses of various sizes, some of which may have caused tsunamis in the past. Many important infrastructure facilities are located in coastal areas of Japan. Therefore, it is very important for disaster prevention to estimate the risk of tsunamis caused by submarine landslides that may occur in the future. The objective of this study is to establish a method for estimating the scale of tsunamis generated along the Sea of Japan coast using trace data from past submarine landslides.

We examined data from about 1,500 submarine landslide sites in the Sea of Japan and were able to extract about 300 sites whose longitudinal profiles clearly had the shape of landslides. Then, using parameters such as water depth, slope angle, landslide width, and volume, the initial tsunami characteristic amplitude, which is the maximum depression of the free surface above the submarine landslide, can be calculated. In this study, the equation of Watts et al. (2005) was used to estimate the scale of tsunamis caused by submarine landslides.

As a result, the tendency of tsunamis caused by submarine landslides varies from region to region. Large-scale tsunamis were found to be concentrated in southwestern Hokkaido, while medium-scale tsunamis were found to be distributed over a wide area. In the presentation, we will also show an example of estimating the return period and magnitude of submarine landslide tsunamis in the Sea of Japan by probabilistic evaluation using the Monte Carlo approach.

On self-induced transparency in weakly nonlinear meteotsunami shoaling

DOI: 10.57757/IUGG23-1220 - LINK

Alex Sheremet[1], *Victor Shrira*[2]
[1]*University of Florida, Civil and Coastal Engineering, Gainesville, USA*
[2]*Keele University, School of Computing and Mathematics, Keele, United Kingdom*

Meteotsunamis are long waves generated by atmospheric perturbations (scales of O(1 -10 km) and O(1 min to 10 min); e.g.Rabinovich and Monserrat 1996, 1998; Sheremet et al. 2016). Their amplitudes over the shelf are small O(1 cm) but may increase by shoaling to O(1 m) at shoreline. Often meteotsunamis evolve into `dispersive shock' (`solibore'). The constituent solitary waves are much smaller scale than the original wave. For the most of the meteotsunami evolution over shelf there is practically no reflection, the dynamics is well described by the KdV with variable coefficients. The reflection occurs in the areas with relatively steep bottom gradients. The magnitude of metotsunami hazard depends on reflection/transmission at such areas. Here we study meteotsunami reflection at the shoreline. The commonly observed generation of solibores implies that a sizeable part of meteotsunami energy is transferred to smaller scale waves, for which reflection is significantly reduced, and conversely, the energy transmitted to the shoreline (meteotsunami hazard) significantly increased. The phenomenon is similar to the self-induced transparency (Kocharovskaya and Khanin, 1986; a process that allows propagation in a normally opaque medium) but with entirely different physics: the large scale, small amplitude wave is reflected, while small scale, finite amplitude waves reach the shore. We investigate the sensitivity of the process to propagation parameters and quantify the reflected/transmitted energy.

3.11 Densho Road Promotion Organization to transfer experiences and lessons

DOI: 10.57757/IUGG23-0374 - LINK

Fumihiko Imamura[1]
[1]*Tohoku University, IRIDeS, Sendai, Japan*

In the areas affected by the 2011 Tohoku Earthquake and tsunami, there are remains of earthquake disasters and traditional facilities scattered over a vast area spanning multiple prefectures in Tohoku, and it is not easy to visit them in a limited amount of time. Therefore, it is necessary to classify and provide information on traditional facilities, install guide maps and signs, and create a network so that visitors can visit and inspect facilities efficiently according to their purpose and time. The 3.11 Densho Road Promotion Organization, a general foundation, was started. In order to learn the lessons of the 2011, we aim to carry out various activities and projects related to disaster prevention by utilizing the network of disaster lore facilities. There are many remains and exhibition facilities for learning the actual situation and lessons of the disaster. Based on its facilities and networks, this promotion organization plays a central role in carrying out various initiatives and projects related to "learning" and "preparation" for disaster prevention, mitigation, and tsunamis. It is very important to convey the damage situation and experience of the great earthquake, the emergency response at the time, and the ongoing recovery and reconstruction activities both domestically and internationally and leave them to future generations.

The importance of passing on lessons from the disaster has been emphasized in the areas affected by the 2011 Tohoku earthquake and tsunami. Since then, efforts have been made to promote the dissemination of disaster learning. However, it is unclear what kind of disaster education/learning is effective in changing behavior for disaster risk reduction and whether the content of effective disaster tourism differs depending on the content disseminated, visitors' interest, awareness of the disaster, preparedness, and the purpose of their visit. In this study, we aim to analyze the effectiveness of disaster learning and which contents of learning and experiences effectively change their actions to reduce disaster risk. We conducted an online survey among visitors (N=1,175) to the disaster-affected areas from the 2011 event to understand the contents of their learning and how their learning experience has influenced their actions to reduce their disaster risk. The main findings are as follows: 1) visiting the interior of the earthquake ruins, seeing the townscape that was cleared before the earthquake, and listening to the stories of locals who experienced the disaster was found to be most effective in promoting learning, regardless of the visitor's disaster preparedness or purpose; 2) informal and interactive interactions with locals who experienced the disaster may be effective for visitors whose purpose is not to learn about the disaster. Finally, two measures are proposed to enhance the effective communication of disaster memories and disaster risk reduction in the future.

Extracting cascading consequences of the 2011 Great East Japan earthquake and tsunami using social sensing data

DOI: 10.57757/IUGG23-2242 - LINK

Xuanyan Dong[1], *Erick Mas*[1], *Bruno Adriano*[1], *Shunichi Koshimura*[1]
[1]*Tohoku University, Department of Civil and Environmental Engineering, Sendai, Japan*

Tsunami is a typical secondary disaster that can cause unpredictable consequences. After a large earthquake strikes, multiple disaster chains occur when one event triggers another, resulting in a wider and more severe impact than the initial strike. Although some studies have been conducted to analyze cascading effects, many potential impacts of cascading disasters remain uninvestigated from a social sensing perspective. In this study, we propose a method for identifying cascading disasters using natural language processing to extract causal relations comprehensively and objectively between events based on tweets and other auxiliary data, such as remote sensing and newspaper data. The applicability of this method is illustrated by employing data extracted from the Twitter official API on the 2011 Great East Japan earthquake and tsunami. Our methodology can be undertaken in four steps: (i) use relevant keywords to acquire data from Twitter API for the analysis period. (ii) clean and visualize the data, then, extract disaster causal knowledge via pattern matching. (iii) compare semantic and syntactic features and classify the casual and noncausal types using machine learning. (iv) create a disaster keywords database and get tsunami cascading event automatically by calculating cosine similarity between each sentence pair.Our method can effectively and automatically extract the broadest possible range of events during the early stages of the disaster by developing a tsunami event's relationship. Furthermore, the feature combinations that are most suitable for tweets can also be compared in this paper.

Tsunami evacuation of connected and autonomous vehicles using flocking control algorithm

DOI: 10.57757/IUGG23-2252 - LINK

Daiki Hachiya[1], Kazuki Wako[2], Erick Mas[3], Shunichi Koshimura[3]

The evacuation during the 2011 Great East Japan Earthquake and Tsunami revealed a high preference for vehicle evacuation in coastal areas. Although evacuation by foot is generally suggested, considering the contribution to evacuating vulnerable people (e.g., the elderly, infants, and disabled), it is essential to plan for safe and reliable evacuation by car. Connected and Autonomous Vehicles (CAVs) have a great potential to improve transportation system efficiency through autonomous driving and communication technologies. Assuming that CAVs will be widely used in the future, it is crucial to examine the impact of autonomous car evacuation on traffic flow (e.g., moving speed, evacuation time, and traffic capacity). In this study, we evaluate the effectiveness of CAVs in tsunami evacuation using the flocking algorithm as the primary control model. We developed a microsimulation of CAVs self-driving along a road with obstacles using agent-based modeling. Then, we quantitatively compared the CAVs model to a human driving control model as a baseline to assess its effectiveness. The results indicated that CAV flocking control performs better than the baseline in a three-lane roadway environment with obstacles. Applying the proposed flocking algorithm method and optimizing navigation-control parameters to various traffic situations, this study contributes towards investigating safe autonomous car evacuation in the future.

Artificial intelligence, specifically deep learning (DL), has been increasingly used in remote sensing technology for rapid disaster assessment. Despite having high accuracy, the approach requires numerous samples to maintain its performance. However, in an emergency response phase, training samples are often unavailable. Moreover, generating ground truth data is laborious and time-consuming, which impedes the fulfillment of damage information for emergency response needs. Given this background, we utilized historical disaster events collected worldwide to recognize damage in new unseen locations. We compared the performance of multiple DL convolutional neural networks (e.g, ResNet34, ResNex, and SwinTransformer). We used the trained model to estimate the damage in the 2011 Tohoku Tsunami to illustrate the usefulness of both historical data and DL models for mapping a new disaster event. Preliminary results show that SwinTransformer outweighs the performance of others CNN-based models. The accuracy of the transformer-based model reaches 85% compared to 82% for both ResNet34 and ResNext. However, when the best performance model is tested on the 2011 Tohoku Tsunami, the performance drops to 23% accuracy. This reduction in accuracy may be attributed to the difference in sensing conditions and data distribution between the global and the Tohoku datasets.

Tsunami seismology: Historical review and future direction

DOI: 10.57757/IUGG23-0171 - LINK

Kenji Satake[1]
[1]*the University of Tokyo, Earthquake Research Institute, Tokyo, Japan*

Most tsunamis are generated by submarine earthquakes, and tsunami data are used to study earthquake sources. Tsunami waveform inversion was first proposed in the 1980s and has been applied to many earthquakes in the world. Tsunami speed is slower than typical rupture velocity of earthquake source, while seismic wave velocity is faster. This difference makes the tsunami waveform inversion more robust for spatial distribution, while the seismic inversion is more robust for temporal resolution. Global deployment of deep ocean bottom pressure gauges provides valuable data for tsunami waveform inversion, because they are free from coastal nonlinear effects. The effects of elastic earth on trans-oceanic tsunami propagation can now be accounted for.

Tsunami data are also useful for historical and prehistorical earthquakes. Coastal tsunami heights or inundation limits can be estimated from damage descriptions in historical documents, often without information on temporal evolution of tsunami. For paleo-tsunamis, tsunami heights and inland extent can be estimated from the distribution of tsunami deposits. Thickness and grain size distribution of tsunami deposits are also sensitive to the tsunami source parameters, hence can be used to study earthquake sources, through sediment transport modeling. While nonlinear effects must be considered, these methods are also valuable tools to study earthquakes in the past.

Eastern Indonesia suffers from significant tsunami hazards due to its complex tectonic setting characterized by several subduction zones, numerous active volcanoes, as well as submarine landslides. Following the two destructive tsunamis in Indonesia in 2018 in Palu and Sunda Strait, it has been urgent to address large tsunami hazards in this unique tsunamigenic zone. This presentation outlines the outcomes of an international collaborative project on "Building Earthquake and Tsunami Resilience in East Indonesia", supported by the Royal Society (UK) for the period 2019-2023. The project brought together research teams from UK and Indonesia, working together towards safer communities from tsunamis and earthquakes. The project mapped and studied seismogenic and tsunamigenic zones in East Indonesia, modelled scenarios of potential future tsunamis, and developed community resilience to tsunamis. A marine seismic survey was conducted in August 2022 to obtain seismic and bathymetric data from the region. The project also studied several recent earthquakes and tsunamis in the region, including the 14th November 2019 Molucca Sea tsunami following an Mw 7.2 earthquake, the 16th of June 2021 tsunami following an Mw 5.9 earthquake, and the 2018 Palu earthquake and tsunamis. It is believed that this project has generated a large database for earthquake and tsunami resilience studies in East Indonesia, and will inspire future research works. This research is funded by The Royal Society (the United Kingdom), grant number CHL/R1/180173 and Lloyd's Tercentenary Research Foundation, the Lighthill Risk Network, and the Lloyd's Register Foundation.

[4]The University of Tokyo, Earthquake Research Institute, Tokyo, Japan

Two large earthquakes occurred in the Alaska-Aleutian subduction zone in July 2020 (*M*w 7.8) and July 2021 (*M*w 8.2), generating tsunamis characterized by considerably longer periods than that typically expected from their moment magnitudes. The 2020 earthquake resulted in approximately 40–90 min tsunami periods (Mulia et al., 2022, GRL; Heidarzadeh and Mulia, 2021, Ocean Eng.). Similarly, the 2021 event exhibited long-period tsunamis of >50 min (Mulia et al., 2022, SRL). For comparison, the April 2014 Illapel, Chile, earthquake (*M*w 8.2) and the November 2016 Kaikoura, New Zealand, earthquake (*M*w 7.8) produced tsunamis with dominant periods ranging from 15 to 21 min (Heidarzadeh et al., 2019, Ocean Eng.).

To reveal the underlying cause for such anomalous occurrences, we conducted an inversion analysis using tsunami and geodetic data. Our inversion results indicated the up-dip extent of both earthquakes confined at a depth of ~20 km of the plate interface, which corresponds to the shelf break on the surface. Therefore, the coseismic surface displacement predominantly took place at shallow water depths of ~200 m within the broad continental shelf extending ~120 km offshore. Consequently, it is responsible for the long-period tsunami waves as the water depth is inversely proportional to the period. This geophysical setting is uniquely attributed to the Alaska-Aleutian subduction zone, which is rarely found in other major subduction systems. References: https://doi.org/10.1029/2021GL094937; https://doi.org/10.1785/0220210359; https://doi.org/10.1016/j.oceaneng.2021.109243.

On January 9, 2014 a M=5.1 earthquake occurred on the north shore of Cuba. The event was dip-slip on a WNW-ESE fault. The location is the site of offshore islands, oriented WNW-ESE, with a total length of 200 km. This suggests that larger seismic events are possible. The earthquakes are 90 miles (144 km) from the south shore of Florida. We modeled potential tsunamis from a fault oriented WNW-ESE and dipping 90 degrees. To represent shaking from a M=7.5 earthquake we used a length of 100 km, width 10 km, and slip 1.85 m. The modeling was performed using a numerical program (Nicolsky et al., 2011) at UAFGI. Results show heights of 3-8 cm at Key West, Everglades (ENP), Marco Island and Miami. Maximum heights of 0.4 m are observed near source. Travel times for initial wave are: ENP 15 min; Key West 28 min; Miami 30 min; Marco Island 240 min. The peak occurs 10-50 min later. We also modeled slip with reversed polarity (some aftershocks showed reverse slip); the models gave the same heights and times but reversed polarity. This is because the grid for bathymetry is coarse (3x3.7 km pixel size) so detailed interaction with the shore is not well represented. We modeled a larger event by increasing the slip. This resulted in a M=7.8 hypothetical event, with higher amplitudes but similar time histories. These results suggest that South Florida would experience only a modest hazard from tsunamis generated by earthquakes on the north shore of Cuba.

[3]International Research Institute of Disaster Science, Tohoku University, Sendai, Japan

Sandy tsunami deposits from the 1611 Keicho Oshu earthquake are distributed in peat at a depth of 50cm-1m in Atsuma, eastern Iburi, Hokkaido. The elevation at the time of the event was 3-4.5m, and it slopes gently inland. The thickness of the sediments is more than 50 cm at the thickest point, and it became thinner inland and invisible at about 500 m from the coastline ca. 200 years ago. Also, the mean grain size of the tsunami deposits becomes as fine as 3.5φ near the distribution limit. The size of the tsunami suggested by the properties of these deposits is about 5m in height, which is smaller than that in the tsunami scenario by the Cabinet Office (about 9m at the coast). Neighboring Tomakomai and Mukawa also show that the inland extent of the tsunami indicated by geological traces is significantly shorter than that drawn in the hazardmap. In these areas, no other possible tsunami traces could be discerned even on X-ray CT images during the past 2500 years, though known tephras (Ta-b; 1667 CE, Us-b; 1663 CE, B-Tm; 10th Century CE, Ta-c3; ca. 2000yr BP, Ta-c2; ca. 2500yr BP) were well-preserved. The new information about the 1611 tsunami in Atsuma, together with the research results in Tomakomai and Mukawa, provides important constraints for the size and recurrence interval of tsunamis in the northern part of the Japan Trench and is useful for the evaluation of source models of earthquakes and the damage estimation.

A major submarine volcanic eruption occurred on 15 January 2022 in the vicinity of the Tonga-Kermadec Islands in the Tropical Pacific Ocean. The eruption produced tsunami waves that were recorded throughout the World Ocean, including the Caribbean, Mediterranean and Black seas. The event attracted considerable scientific attention. Several thousand sea level and atmospheric pressure records have been examined, as well as numerous other geophysical data. A unique feature of the tsunami waves measured by coastal tide gauges and open-ocean bottom pressure recorders was the dual forcing mechanism that sent both oceanic waves –induced directly by the eruption and radiating outward from the source at the longwave speed of ~200 m/s – and atmospheric Lamb waves that circled the globe several times at the speed of sound of ~315 m/s. This dual source resulted in marked tsunami waves with heights of 2.0-2.5 m on the Pacific coasts of Chile, the US , New Zealand, Japan and the Aleutian Islands. The "atmospheric" waves arrived first, but the direct oceanic waves were much higher. In the Atlantic and Mediterranean, the waves were mostly of atmospheric origin (except on the coast of Argentina). Numerical models of the event show generally good agreement with observation. Global maps also reveal regional "hot spots", where the tsunami heights were greatest. On the Atlantic Coast of the US, arrival of the Tonga tsunami coincided with hurricane generated waves to produce a hazardous double jeopeordy wave event.

Modeling tsunami generation by moving pressure systems: Case studies and implications

DOI: 10.57757/IUGG23-4803 - LINK

Vasily V. Titov[1]
[1]*NOAA/PMEL, NOAA Center for Tsunami Research, Seattle, USA*

On January 15, 2022, the Hunga-Tonga Hunga-Ha'apai volcano generated unexpectedly strong tsunami that was recorded all over the Pacific Ocean and in other ocean basins, including the Caribbean and Mediterranean seas. Mounting evidence quickly pointed toward an unorthodox tsunami generation mechanism – forcing by propagating pressure anomalies from acoustic gravity waves (a.k.a atmospheric Lamb waves) originated from the volcanic blast.

The Lamb wave forcing of tsunami is similar to the formation of meteotsunamis from weather systems and to the gravity waves formation from other large atmospheric explosions like meteorite impacts, including the role of Proudman resonance to amplify the wave in certain directions. Those generation mechanisms have been studied before; however, the January 15, 2022 Tonga tsunami is the first event that proved the existence of air-pressure coupling mechanism for tsunami generation during the blast events. It also provided ample data for the model verification and testing for pressure-generated tsunamis. As the result, the ongoing modeling efforts to simulate the 2022 Tonga tsunami plays an important role in quantifying the hazard and possible mitigation measures for tsunamis generated by moving pressure disturbance.

Tsunami models simulating moving pressure generation mechanisms for volcanos, meteotsunamis, asteroid impacts are presented. Commonalities, differences and effectiveness of these sources for tsunami generation are considered. Potential hazard mitigation measures are discussed.

Genesis of the 2022 Tonga volcanic tsunami

DOI: 10.57757/IUGG23-1328 - LINK

Y Tony Song[1]
[1]*NASA Jet Propilsion Laboratory, Earth Science, Pasadena, USA*

The 2022 Tonga volcanic eruption generated a surprisingly large air-pressure wave (lamb wave) and a locally damaging tsunami. The tsunami generation is still puzzling because both the air wave and submarine explosion drove changes in sea level. Here we have derived observational evidence from satellite altimetry (a rarity for a volcanic tsunami), assisted by a combined atmospheric and oceanic tsunami model, to shed light on its genesis. We found that three satellites had captured the sea level signal of the tsunami: the AltiKa satellite observed the near-field tsunami, 29 minutes after the eruption, while the Sentinel-6 Michael Freilich and Jason-3 satellites in tandem 30 seconds apart captured the tsunami through the volcano center and encountered the tsunami wave at about 54°S about 5 hours after the eruption. We proposed a mass-conserving tsunamigenic mechanism, which couples the volcanic ejecta to ocean waters filling in the erupted crater, to reconcile the satellite observations with other in-situ measurements. We concluded that the erupted air-waves had increased the tsunami's destructive power through the inverted barometer effect during their overlapping period in the near field, and orchestrated the far-field disturbance in the Pacific Ocean and beyond. Our study also demonstrated an altimetry procedure to isolate tsunamis from ocean dynamic features and a data-based approach to quantify volcanic tsunami source for early warnings.

Oceans Graduate School and The UWA Oceans Institute, Perth, Australia

An eruption of the Hunga Tonga-hunga Ha'apai Volcanic Eruption on 15 January 2012 caused tsunami waves, observed globally in tide gage records. In this study we investigate the origin of tsunami waves through the analysis of tide gauge records and numerical simulations in the Indo-Pacific region. The atmospheric pressure wave (Lamb wave) due the eruption was recorded in meteorological stations across Australia. The moving pressure jump was recorded as a ~6.5-hPa jump at the Norfolk Island; ~3.5 hPa at Broken Hill, NSW and Perth and was estimated to be travelling at ~340 ms^{-1}. In the deep ocean this allows for Proudman resonance between the ocean and atmosphere generating a meteotsunami propagating westward across the Indian Ocean. Tide gauges located across the whole Indian Ocean basin recorded the meteotsunami generated by the pressure jump. There were two distinct signal on the tide gauge records. The first signal was recorded in advance of the predicted volcanic tsunami along the east coast of Australia and was due to the meteotsunami. The arrival of the second signal corresponded to tsunami wave generated by the displacement of the volcano travelling as a 'free' wave. These findings were confirmed by numerical simulations using an ocean circulation model that incorporated a moving atmospheric pressure jump travelling at a speed of ~ 340 ms^{-1}. The long ocean waves were amplified due to Proudman resonance in the deep ocean, where the water was deeper than 5000 m. The model predicted of the meteotsunami corresponded well with observations.

Hazardous tsunamis are generally generated by megathrust earthquakes in subduction zones, like the 2004 Mw 9.1 Sumatra-Andaman earthquake and the 2011 Mw 9.0 Tohoku earthquake. However, recent severe tsunami impacts from atypical sources gain remarkable attention from scientists in related fields. The 2020 Samos normal-faulting earthquake of Mw 6.9 produced an unexpected maximum tsunami runup of up to 3.8 m. The 2022 Hunga Tonga–Hunga Ha'apai volcanic eruption generated unusual tsunami through the air-sea coupling of atmospheric acoustic-gravity waves and ocean surface, which is widely observed in the global oceans. Here, we present the tsunami source characteristics and hydrodynamic behaviours of the two aforementioned atypical cases to investigate the intensifying factor for both tsunami events. We adopt an integrated approach, including source inversion and tsunami modelling, together with spectral and statistical analyses of tsunami waveforms. We find the 2020 Samos tsunami is exacerbated by not only the favorable source conditions for tsunami generation but also the near-source bathymetric morphology. For the 2022 Tonga volcanic tsunami event, we identify four distinct tsunami wave components which are associated with their complex generation mechanisms ranging from air–sea couplings to seafloor crustal deformation during the volcanic eruption. The unexpected tsunami hazards from the atypical sources highlight the significance of various unusual mechanisms for tsunami generation and some favored conditions in intensifying tsunami behaviours. Both tsunami events call for technical improvement for traditional seismic warning system.

Probing the Greenland ice sheet by teleseismic P-wave coda autocorrelation

DOI: 10.57757/IUGG23-1399 - LINK

Thanh-Son Pham[1], Ammu Sanjayan[2], Hrvoje Tkalčić[1]

[2]University of Kerala, Department of Geology, Thiruvananthapuram- Kerala, India

Seismic body waves from distant earthquakes travel steeply to a seismic station and carry rich information about subsurface structures. In an ice sheet environment, the sharp seismic discontinuity at the ice-bedrock interface effectively reflects the energy that is bounced from the free surface. Thus, the ice sheet acts as a waveguide to trap a large portion of incident seismic energy, resulting in repetitive ground motions recorded by over-ice seismometers. The weak self-similar signals can be amplified by cross-correlating the earthquake seismograms with themselves (i.e., autocorrelation) before stacking over multiple events. Here, we apply this autocorrelation technique to the records of P-wave arrivals and following reverberations (i.e., the P-wave coda) of stations deployed over the central region of the Greenland ice sheet (GrIS), the second-largest ice sheet on Earth. Firstly, we estimate the thickness and P- over S- wave speed ratio of the ice sheet beneath several recording sites and find good agreement with independent estimates primarily based on airborne radio-echo-sounding data.

Furthermore, we observe seasonal fluctuation in amplitudes of P-wave coda autocorrelograms, with stronger reflection peaks in summers and weaker in winters. We use numerical experiments to decipher the mechanism underlying temporal variation. Our findings could shed light on the working mechanisms of the GrIS and similar environments, including future missions to icy planets and satellites.

Seismic signals are powerful to characterize ice and subsurface structures, and we image shallow ice structure near the West Antarctic Ice Sheet (WAIS) Divide with active and passive seismic data and the Thwaites Glacier eastern shear margin with passive data. The eastern shear margin has a planned active-seismic survey in the 23/24 field season. Passively recorded seismic ambient noise can be used to extract wave propagations between receivers and provide complementary information to the active seismic data. High-frequency energy is high in active-seismic data, but surface waves are often more prominent in ambient noise records due to their source mechanisms. We use a surface-wave dispersion analysis, an analysis of horizontal-versus-vertical (H/V) ratio, wave-equation-based seismic imaging, and reflection migration for imaging firn-air, firn and shallow ice layers. We identify the leaky modes following the direct waves by examining their behaviors of energy decay and particle motion. The leaky modes are guided P waves and contain P-wave velocity information and exist possibly due to the sharp velocity contrasts at the firn layer. Together with normal modes, we use a joint inversion of leaky and normal modes for P- and S-wave velocity estimation in the near-surface. Because seismic ambient noise always exists, we also use them for time-lapse analysis of the ice structure for understanding its dynamics.

The eastern shear margin has a planned active-seismic survey in the 23/24 field season. Passively recorded seismic ambient noise can be used to extract wave propagations between receivers and provide complementary information to the active seismic data. High-frequency energy is high in active-seismic data, but surface waves are often more prominent in ambient noise records due to their source mechanisms. We use a surface-wave dispersion analysis, an analysis of horizontal-versus-vertical (H/V) ratio, wave-equation-based seismic imaging, and reflection migration for imaging firn-air, firn and shallow ice layers. We identify the leaky modes following the direct waves by examining their behaviors of energy decay and particle motion. The leaky modes are guided P waves and contain P-wave velocity information and exist possibly due to the sharp velocity contrasts at the firn layer. Together with normal modes, we use a joint inversion of leaky and normal modes for P- and S-wave velocity estimation in the near-surface. Because

seismic ambient noise always exists, we also use them for time-lapse analysis of the ice structure for understanding its dynamics.

We present a probabilistic approach to the inversion of surface wave dispersion data from glacial environments. This is intended to (i) assess non-linearity and non-uniqueness, and (ii) properly quantify resolution and trade-offs. For this, we use seismic data from Distributed Acoustic Sensing (DAS) experiments deployed on the Vatnajökull ice sheet located on Grímsvötn volcano in Iceland, and the Northeast Greenland Ice Stream (NEGIS).

Our method is based on a regularisation-free Bayesian inference approach, implemented using a Hamiltonian Monte Carlo (HMC) algorithm. Exploiting derivative information for efficient sampling of high-dimensional model spaces, HMC approximates the posterior probability densities of all model parameters. Applied specifically to multi-mode surface wave dispersion measurements, HMC yields probabilistic models of 1-D anisotropic stratified media parameterised in terms of the P-wave velocities Vpv and Vph, the S-wave velocities Vsv and Vsh, the anisotropy parameter η, and density ρ.

The benefits of this approach, not only from a glaciological perspective, include regularisation-free estimates of firn and ice properties, models that are not a priori biased by the exclusion of all parameters except S-wave speed, and some level of direct access to the vertical density profile.

Near-terminus areas of glaciers generate a rich spectrum of complex seismicity. Both ballistic and scattered coda waves of seismic events (e.g. surface and basal icequakes, iceberg detachment) carry information about elastic wave propagation within the glacier and, therefore, the mechanical properties of the ice. In this study, we utilize a temporary array deployment to obtain insights into cryoseismicity and ice structure of the Hans glacier at Hornsund, Svalbard.

We use direct and scattered wave fields from tens of thousands of icequake records to reconstruct the impulse response between seismometer pairs within the array and to infer Rayleigh wave velocities. The dynamic ice deformation around the array results in good azimuthal coverage. We demonstrate, that misfits between azimuthally bin-averaged zero-lags of cross-correlations and a theoretical sinusoidal dependence of apparent velocity can be used to measure an azimuthal anisotropy of the glacial ice, 3.5% in our case. We suggest that the anisotropy is a result of stress regime and crevassing. The study thus shows how passive seismic records can be used to characterize terminus regions near the ice-ocean boundary. In future experiments, this may help elucidate how ice dynamics precondition iceberg calving, one of the central processes of ice mass loss and eustatic sea level rise.

We present new results from a multiyear effort to record environmental signals in the Beaufort Sea using distributed acoustic sensing (DAS). We collected seafloor DAS data on a 36-km long segment of telecom dark fiber for eight one-week intervals in 2021 and 2022. The eight data collects comprise two samplings of each Arctic "season" (ice bound, ice free, and partial ice coverage during freezing and breakup). We recorded icequakes, floating sea-ice collisions, ice grounding events, ice flexural-gravity waves excited by winds, currents, and hovercrafts, ocean gravity waves, earth microseisms, and submarine soil/permafrost resonance. We have used these signals to characterize both sea ice extent and sea-ice thickness in the Beaufort Sea. Sea ice-extent is determined by clustering ambient noise data in 30-minute windows using a convolutional neural network. The presence or absence of ocean gravity waves is the dominant factor in the ice/no-ice clustering. Sea ice thickness is estimated from the inversion of ice flexural-gravity wave dispersion curves. This novel application has the added benefit of simultaneously inverting for snow thickness on the ice sheet, a confounding factor in other remote sensing methods. Ocean gravity wave parameters will also be presented. Comparison with wave buoys purposefully deployed above the fiber indicates that DAS can capture low-frequency waves with high spatial resolution during both open water and partially ice-covered periods. *SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525*

Seismic emissions and frostquakes: mechanisms of thermal stress release during seasonal freezing and melting of soft soils in subarctic areas

DOI: 10.57757/IUGG23-1517 - LINK

Nikita Afonin[1], Elena Kozlovskaya[1], Jarkko Okkonen[1], Emma-Riikka Kokko[1], Kari Moisio[1]
[1]University of Oulu, Oulu Mining School, Oulu, Finland

In this study the analysis of continuous seismic data is used to investigate the processes related to seismic events generated through the release of accumulated thermal stresses in the upper water-saturated soils during freezing and melting. Under certain conditions, the stresses are released as a swarm of small-scale magnitude impulses, called cryoseismic emission, which have no or very little effect on the infrastructures. In some cases, however, this stress release can result in seismic events called frostquakes. Such events can be of relatively large magnitude, and they are capable to produce cracks on the ground surface and damage infrastructures such as buildings and roads. To understand what combinations of weather and ground conditions results in these different stress release mechanisms, we installed two seismic arrays with co-located soil stations in two geographically different sites in Northern Finland characterized by different weather, geological and hydrogeological conditions. The first site is located in the municipality of Sodankylä at the latitude of 67.36 deg. and the second one in the city of Oulu at the latitude of 65.04 deg. Based on local inhabitants 'eyewitness' reports of ground shaking and unusual 'seismic noise' near the Oulu site on 06.01.2023, we identified several frostquakes in seismic records. The analysis of continuous seismic records allowed us to recognise two different stress release mechanisms: frostquakes and cryoseismic emission. Our results support the conclusion that stress release by different mechanisms is defined mainly by certain meteorological and groundwater conditions.

Seismogenic glacier sliding

DOI: 10.57757/IUGG23-0584 - LINK

Fabian Walter[1]
[1]*Swiss Federal Institute for Forest- Snow and Landscape Research WSL, Torrents and Mass Movements, Birmensdorf, Switzerland*

Already some of the earliest cryoseismological studies aimed at detecting signals describing glacier sliding. However, for decades the existence of widespread stick-slip icequakes was debated as most microseismic monitoring networks failed to provide clear evidence for seismogenesis below the surface crevassing zone. In recent years, studies have shown that stick-slip signals accompany rapid sliding of polar ice streams as well as relatively slow motion of mountain glaciers.

Here I review recent observations of stick-slip sliding monitored with seismic instruments. Sustained series of stick-slip ruptures seem to be a common manifestation of surging motion and these tremor-like signals lasting up to several hours have counterparts in volcanic and tectonic environments. I discuss under which conditions such seismogenic stick-slip sliding seems to emerge in a noisy glacier environment and why it is easily missed with local seismic networks. Simplified slider-block models show how stick-slip tremor accompanies water-enhanced sliding episodes assuming that glacier sliding can be described by rate-and-state friction. This friction rheology explains the complex dynamics of tectonic boundaries including earthquake rupture and triggering. Accordingly, first applications of finite fault models support the idea of rate weakening bed patches acting as seismic sources embedded within a surrounding rate strengthening ice-bed interface.

Together with stick-slip icequakes, other passive seismic observations hint towards a pervasive hydraulic control on basal sliding and fracturing. A better understanding of seismic sources and wave propagation related to glacier ice could therefore be key in addressing critical knowledge gaps in subglacial processes.

Glacier flow instabilities are mainly caused by changes at the ice-bed interface, where basal slip and sediment deformation drive basal glacier movement. Understanding basal processes and their response to external forcing remains difficult due to limited access to the glacier bed. In this study, we examine variations in subsurface and subglacial mechanical conditions of Kongsvegen glacier (Svalbard). This glacier shows strong indications of an imminent new rapid flow event. To investigate the potential causes of such an acceleration, we combine conventional measurements such as surface velocity (20 GNSS along the flow line) and basal water pressure (two boreholes) with seismic measurements (14 seismometers along the flow line and 6 seismometers in boreholes) and a unique measurement of basal drag applied to the sediments. We use our seismic measurements to study (1) subglacial hydrological conditions and (2) changes in ice structure using seismic interferometry.
At seasonal time scales, we observe an inverse relationship between basal drag and surface runoff. At shorter time scales, the basal drag is initially very sensitive to meltwater input, but this sensitivity gradually decreases and almost disappears as the season progresses. The response of the glacier to meltwater inflow often reflects transient flow behaviour. In winter, we observe a doubling of the basal drag compared to the previous winter. These changes are concomitant with changes in seismic velocity suggesting a downward propagation of the surge. Using our multi-instrument approach, we discuss the different behaviours observed during two years of recordings to highlight the mechanisms of glacier destabilisation.

Rapidly-rising jökulhlaups, or glacial lake outburst floods, are a phenomenon with a high potential for damage. The initiation and propagation processes of a rapidly-rising jökulhlaup are still not fully understood. Seismic monitoring can contribute to an improved process understanding, but comprehensive long-term seismic monitoring campaigns capturing the dynamics of a rapidly-rising jökulhlaup are rare. In 2012, we installed a seismic network at the marginal, ice-dammed lake of the A.P. Olsen Ice Cap in NE-Greenland. Episodic outbursts from the lake cause flood waves in the Zackenberg river, characterized by a rapid discharge increase within a few hours. We deployed industrial geophones (4.5 Hz) for the five on-ice stations. Two stations were designed as mini-arrays with three vertical sensors, and the remaining ones were equipped with three-component sensors. All sensors were sunk about 3 m into the ice. Our 6 months long seismic dataset comprises the whole fill-and-drain cycle of the ice-dammed lake in 2012 and includes one of the most destructive floods recorded so far for the Zackenberg river. Seismic event detection reveals periods of high seismicity during enhanced surface melting prior to the outburst flood. During the outburst itself the number of detected events dropped due to the elevated seismic tremor level. Based on waveform characteristics and event localization we detected potential basal events. We will present and discuss the temporal and spatial evolution of basal events throughout the entire fill-and-drain cycle of the jökulhlaup.

Jökulhlaups (also known as GLOF, glacier lake outburst floods) that travel subglacially are only detectable indirectly, via observation of the glacier's surface deformation (GNSS, InSAR) or the seismic signals they generate.
At Iceland's Vatnajökull glacier, floods from Grímsvötn travel more than 40km below the ice before feeding into the glacial river.
To study the propagation and the physics of the jökulhlaups, temporal seismic arrays were installed close to the terminus, i.e. west, southwest and south of Vatnajökull. Frequency-wavenumber-analysis (fk-analysis) and match field processing (MFP) are two seismic methods able to locate the generated tremor along the propagation path. We present insights into Grímsvötn floods between 2014-2016 and October 2022. We discuss the properties of the 3-component seismic data and their location with respect to hydrometric and GNSS observations. Ultimately, these understandings may contribute to improve the early warning of subglacial floods.

What have we learned about the earthquake deformation cycle from advances in geodetic monitoring?

DOI: 10.57757/IUGG23-1599 - LINK

Tim Wright[1]
[1]*University of Leeds, COMET- School of Earth and Environment, Leeds, United Kingdom*

Over the last 20 years, measuring Earth's deformation with satellite geodesy has developed from a niche research activity into a robust and reliable operational suite of monitoring tools. We now have thousands of continuously recording GNSS stations and a suite of satellites acquiring data suitable for routine InSAR analysis. In this presentation, I will review what we have learned from these data sets about the earthquake deformation cycle and discuss the areas where further research is needed. Before satellite geodesy, coseismic deformation had been measured for just a handful of earthquakes. We have now mapped the deformation fields from hundreds of events, and InSAR, in particular, has been particularly powerful, revealing a diverse array of behaviour in the brittle crust. Following earthquakes, we have now built up long time series of post-seismic observations for many events. The combination of spatial and temporal information that satellite geodesy provides is being used to disentangle the mechanisms responsible for postseismic stress adjustments, in turn giving us unique insights into the rheology of the crust and mantle. Once initial rapid postseismic transients have decayed, long-term geodetic observations from InSAR and GNSS are now mapping strain accumulation patterns over vast regions, and these are beginning to be used to help better inform seismic hazard models. We are also increasingly seeing a variety of transient behaviours that don't fit into the classic co- post- inter-seismic framework. I will end the presentation by discussing these and the potential for new discoveries over the coming decade.

Probing the locking status of the Xianshuihe fault with geodetic observations and a viscoelastic deformation model

DOI: 10.57757/IUGG23-2485 - LINK

Xiong Xiong[1], *Faqi Diao*[1], *Yage Zhu*[1]
[1]*China University of Geoscience at Wuhan, School of Geophysics and Geomatics, Wuhan, China*

The slip rate and locking status of active faults are important for regional seismic hazard assessments. Up to now, elastic models have been routinely used in probing the fault locking status with geodetic observations. The viscoelastic deformation, however, was suggested to be of significance for estimating the fault locking status. In this study, we examined the effect of viscoelastic deformation for mapping the fault locking by applying both elastic and viscoelastic deformation models on the Xianshuihe fault, a major seismogenic fault in southwestern China. In the past 500 years, the Xianshuihe fault has experienced 19 earthquakes with M>6, making it a cause for common concern of seismic hazard among both scientific and societal communities. We constructed viscoelastic deformation models based on GPS velocities near the Xianshuihe fault to invert the fault locking status of this fault. Our results suggest that elastic models result in overestimates of both the fault locking depth and moment accumulation rate, while viscoelastic deformation models yield more reliable results. Relying on the obtained fault locking distribution, we identify four potential asperities along the Xianshuihe fault. And, a clear spatial correlation between the asperities and historical ruptures was observed, suggesting that the fault locking may control the rupture extent of strong earthquakes on this fault. Moreover, we found that the 2022 M6.8 Luding earthquake only ruptured a part of an identified asperity. And the seismic moment accumulated on the unruptured segment is roughly equivalent to an Mw6.8 earthquake, underscoring the potential seismic hazard there.

And the seismic moment accumulated on the unruptured segment is roughly equivalent to an Mw6.8 earthquake, underscoring the potential seismic hazard there.

The borderland between China and Myanmar is characterized by complex tectonics and heavy seismic hazard, but its present-day crustal deformation pattern is still contentious. We have processed all the data of regional GNSS networks from 1998 to 2020 for this region and further derived strain rate fields. The results show that Myanmar arc moves towards the Qinghai Tibet Plateau in the NNE direction at a velocity of ~30mm/yr. The shear strain accumulation in this zone is prominent, with east-west compression at outer flank of the arc, and nearly south-north compression at its interior. The Sagaing fault is characterized by heterogeneous kinematics with higher principal strain rate and shear strain rate.Sichuan Yunnan block is rotating remarkably clockwise around the eastern Himalayan syntaxis. The Xiaojiang fault zone is experiencing sinistral strike slip. The central segment of Honghe fault has a lower strike slip rate, while the north and south segments have a relatively higher shear rate. The Dayingjiang fault in southwestern Yunnan shows east-west extension and sinistral strike slip. The Longling-Ruili fault is characterized by dextral strike slip and extension. The NE trending Nantinghe fault, Menglian fault and Jinghong-Daluo fault have lower shear rates, dominated by left-lateral strike- slip. The Lancang fault and Wuliangshan faults are characterized by a dextral strike slip, while the northwest trending Longling-Lancang fault zone shows dextral strike slip and tension. The study is significant to earthquake disaster assessment and understanding of the regional geodynamics of this region.

Crustal strain rate field around Izu collision zone, Japan, inferred from GNSS and InSAR data

DOI: 10.57757/IUGG23-0045 - LINK

Ryosuke Doke[1]
[1]*Hot Springs Research Institute of Kanagawa Prefecture, Research Section, Odawara, Japan*

The Izu collision zone, characterized by the collision between the Izu-Bonin arc and the Honshu arc, is located in the northernmost part of the Philippine Sea Plate. Numerous large earthquakes have occurred throughout history, particularly in the northeastern margin of the zone (Ishibashi, 2004, Earth Planets and Space). From our previous analysis result using GNSS, a shear deformation zone, whose width is about 20 km in EW, exists in the northeastern part of the Izu Peninsula (Doke et al., 2020, Geological Society of London, Special Publications). However, GNSS station density is still insufficient to understand this complex tectonic field.

In this study, we performed GNSS and InSAR analysis to estimate the crustal strain rate field in and around the Izu collision zone. To calculate the high-resolved strain field, we combined E-W components obtained from the 2.5-D analysis result of InSAR time series analysis of ALOS-2/PALSAR-2 data and N-S components of GNSS velocity data that were spatially interpolated.

The estimated crustal strain rate field, whose output resolution is 100 m, shows not a homogeneous deformation zone but the existence of some patch-like deformation concentrated zones. Some of the deformation zones may be related to the volcanic activities in this region (Hakone and Higashi-Izu volcanoes). The other deformation zones spatially correspond well with the branch faults of the active Kita-Izu fault zone, which is the source fault of the 1930 Kita-Izu earthquake (M7.0). Therefore, this result shows the strain concentrations and possibilities of earthquake occurrences on these branch faults.

The Maghrebian Atlas Mountains in North Africa results from the Nubia – Eurasia (Nu-Eu) plate convergence in the western Mediterranean. In this study, we examine the correlation between the thrust belt and adjacent Sahara Platform domains in the light of new GPS and seismotectonic results. We also test the Quaternary tectonics and seismotectonic activity from the GPS velocities and determine 3 – 6 mm/yr oblique convergence with transpression and block rotations. The diffuse Nu-Eu plate boundary originally limited to the North Africa coastline extends further south to include the Maghrebides tectonic blocks and southern Sahara Atlas suture zone, the Rif and Tell Atlas, Middle Atlas, High Plateau, and High and Sahara Atlas. The kinematics and late Quaternary strain distribution show westward anticlockwise rotations with an average 3°/Myr from NNW-SSW to WNW-ESE. The transpressive tectonic system is also conducted by large East-West trending right-lateral shear zones inducing clockwise rotation on regional tectonic blocks consistent with paleomagnetic results along the Tell Atlas. The crustal deformation is documented along the tectonic blocks of the Atlas Mountains and Sahara Platform pointing out large earthquakes and the displacement field with strain partitioning largely controlled by the Nu-Eu plate motions.

Crustal deformation is analyzed assuming an elastic medium in most cases. However, inelastic deformation plays an important role in various crustal processes such as tectonic stress accumulation and long-term topographic formation. We have been trying to isolate inelastic deformation signals from geodetic observation data. The M9.0 2011 Tohoku earthquake has brought a unique opportunity in this regard. The postseismic deformation pattern was reversed from the interseismic one. However, along the concentrated contraction zone along the Japan Sea coast, we identified persistent localized contraction before and after the Tohoku earthquake, which is considered to be an inelastic contribution. The identified inelastic strain rate is consistent with the geologically estimated value, indicating a contribution of inelastic processes to long-term deformation. Associated with the Tohoku earthquake, crustal deformation of the Japan island arc has been time-dependent. Since the strain components change in time satisfying the stress equilibrium, time-dependent strain rate data allows us to estimate the heterogeneous distribution of elastic properties and inelastic contribution. Also, we can assume that the observed strain can be considered a sum of elastic and inelastic strains. By assuming the plane stress condition, elastic deformation of the crust can be predicted with an appropriate boundary condition. Then the residuals can be considered inelastic contributions. We will present an overview of these approaches and their applications to GNSS data in Japan to demonstrate how the exploration works, together with their tectonic implications.

An extensive seismic swarm, as well as transient deformation, have continued since the end of November 2020 in the Noto Peninsula, central Japan, which is a non-volcanic/geothermal area far from the major plate boundaries. We present the transient deformation clarified from a combined analysis of multiple GNSS observation networks, seismicity, and their interpretation. We analyzed data at 30 continuous GNSS stations operated by SoftBank Corp., the Geospatial Information Authority of Japan (GSI), and universities. The total displacement pattern for two years shows horizontal inflation and uplift up to ~70 mm around the source of the earthquake swarm. In the first three months, the opening of the low-angle tensile crack is estimated with a volumetric increase of ~1.4 x 10^7 m^3 at a depth of ~16 km. In the next 15 months, the observed deformation is well reproduced by shear-tensile sources, which suggests an aseismic reverse-type slip and expansion of a southeast-dipping fault zone at a depth of 14-16 km. The estimated shear-tensile sources locate at the downdip of the clusters of the earthquake swarm. We interpreted our deformation model and earthquake sequence as follows. Upwelling fluid sub-horizontally spread in a southeast-dipping fault zone. And they migrated up-dip along the fault zone and caused sub-meter aseismic slip below the seismogenic depth. The aseismic slip further triggered intensive earthquakes above the seismogenic depth.

Acknowledgments: We are grateful to SoftBank Corp., ALES Corp., and GSI for providing us with GNSS observation data. This work was supported by JSPS KAKENHI Grant Number JP22K19949.

Throughout the earthquake cycle at fault zones, Earth's crust undergoes deformations. GNSS coordinate time series reveals tectonic motion, seismic displacements, and periodic signatures. Additional motion patterns are usually summarized as transient tectonic signals, i.e., unexpected accelerations with respect to standard trajectory models. As the number of permanent stations increases and as time series grow, we are increasingly able to recognize transient tectonic signals. Since some of these suspected tectonic transients have subtle magnitudes or sometimes unusual spatiotemporal features, we need to develop methods for determining which transients are artifacts and which are of a tectonic origin.

Here, we investigate the impact of certain GNSS processing choices and how they affect the appearance of transients in the GNSS displacement time series solutions. In our study, we choose data from Cascadia, a region for which the occurrence of transients in the GNSS time series is well known. To control our database, we processed data based on network solutions from 150 carefully selected GNSS stations for the time between 2015 and 2020. Then, we have an opportunity to discriminate between tectonic transients and processing artifacts in the GNSS displacement time series. We will discuss the detected transients against selected GNSS-related indicators (data quality, observation residuals, troposphere delays, etc.) to identify potential GNSS artifacts aliasing into the transient signals.

Slow slip events on la Venta-Chacalapa fault system, Mexico

DOI: 10.57757/IUGG23-1146 - LINK

Vladimir Kostoglodov[1], Victor Cruz-Atienza[1], Ekaterina Kazachkina[1], Jose Antonio Santiago[1], Jorge Real[1]
[1]UNAM, Seismology, Mexico City, Mexico

La Venta-Chacalapa creeping fault system (LVC) is the ~650 km long northern boundary of the Xolapa sliver, which is located along the Pacific coast of Guerrero and Oaxaca states of Mexico. The LVC splits the North America tectonic plate (NA) and the Xolapa sliver, which is slowly moving SE with respect to (wrt) the NA with an average secular rate of ~5 mm/year as a consequence of the oblique subduction between the Cocos and NA plates.
Long-term GPS observations unveil transient episodes of crustal slow slip events (cSSE) on the LVC. These cSSE are concomitant with large subduction thrust slow slip events (tSSE) which had been occurring in Guerrero every 3.5-4 years before 2017, and about of ~1 year after 2017 on the plate interface between the Cocos and NA plates. The tSSEs apparently reduce the normal stress and the friction on the LVC, thereby activating the cSSEs.
The SE component of Xolapa displacements on the LVC during the cSSEs had developed with a time delay (~3 month) wrt the trench normal displacement component. After the great Mw8.2, 2017, Chiapas earthquake the frequency of tSSEs have increased while the time lag has almost vanished. Very short time lags were also detected on the LVC in Oaxaca where the frequency of tSSE is of 1-2 years.
Our observations of cSSEs on the LVC are in general consistent with the 'Rate and State Friction' theoretical and experimental results (e.g., Boettcher and Maron, 2004).

This research was supported by DGAPA, UNAM grant IG100921.

Department of Geology and Geoenvironment, Athens, Greece

We present a comprehensive analysis of geodetic data, including InSAR imagery and GNSS observations, to assess the pattern of ground motions of the Paliki peninsula in western Cephalonia, Greece. Paliki is prone to frequent, strong earthquakes, due to its close proximity to the right-lateral Cephalonia Transform Fault (CTF), a 140 km long strike-slip fault that accommodates the relative motion between the Apulian and Aegean lithospheric plates. Our analysis covers the period from 2016 to 2022 and leverages the LiCSBAS, an open-source package, for InSAR time series analysis with the N-SBAS method. We combined the InSAR results with the GNSS observations. The results indicate that active faults on the Paliki peninsula are oriented approximately N-S and exhibit slip rates between 2-5 mm/yr in the line-of-sight direction. The horizontal component of movement is dominant, providing initial evidence of right-lateral strike-slip faulting on the peninsula. The InSAR data also indicate possible post-seismic motion along the fault plane that ruptured on the 3 February 2014 M5.9 earthquake in the northwest part of the peninsula. Moreover, we have identified other possible active structures, including both strike-slip and thrust faults, confirmed by field geological data. The coastal town of Lixouri undergoes uplift, as evidenced by positive line-of-sight displacement values in both imaging geometries. Velocity cross-sections reveal several discontinuities, possibly bounded by active faults and/or crustal flexure. The integration of geodetic data with seismological and field geological data provides a valuable tool for the monitoring of interseismic behaviour of active faults.

[2]Escuela Politecnica Nacional, Instituto Geofisico, Quito, Ecuador

The La Plata subduction segment in Central Ecuador is a 50x50 km2, shallow isolated asperity hosting regular Slow Slip Events (SSEs) and seismic swarms. Here, we combine 20 years of seismological and geodetic data to document the history of slip deficit accumulation and its release. Inter-SSEs slip deficit geodetic model reveals that the plate interface appears to be fully locked from the trench down to 15 km depth over a length of 70 km along trench. Analysis of survey-mode GNSS data reveals that a large SSE with equivalent magnitude of Mw 7.2 ruptured the full locked area in 2005. This SSE was synchronous to a large seismic swarm that lasted ~2.5 months, included several M~6 earthquakes, and accounting for 10-15% of the total moment release. Two large SSEs with magnitude of Mw 6.8-6.9 then occurred in 2016 and 2021, rupturing the shallowest part of the locked area. Kinematic slip inversions reveal thatthe 2016 & 2021 SSEs propagated from north to south. Aside the large SSEs, several smaller (Mw 6-6.3) and shorter SSEs occurred in 2010, 2013, 2017 and 2019, involving partial ruptures of the locked patch. All occurred synchronously to seismic swarm. This history allows to provide the evolution of moment accumulation and release through time. It shows that the behavior of the asperity is neither time-predictable nor slip-predictable.

Observation of seafloor strain caused by shallow SSE and VLFE fault in the Nankai Trough by seafloor fiber optic strainmeters.

DOI: 10.57757/IUGG23-2395 - LINK

Eiichiro Araki[1], Takashi Yokobiki[1], Satoru Baba[1], Yojiro Yamamoto[1], Mark Zumberge[2], Shuhei Nishida[1], Yuya Machida[1], Hiroyuki Matsumoto[1]
[1]Japan Agency for Marine-Earth Science and Technology, Institute of Marine Geodynamics, Yokosuka, Japan

Slow slip occurs repeatedly in the shallow part of the plate subduction boundary region in the Nankai Trough (Araki et al., 2017). To investigate its activity in wider area, we developed and installed a seafloor fiber-optic strainmeter connected to a submarine cable observation network (DONET) in west of the previous observation network in the borehole in 2019. In January-February, 2022, the seafloor fiber-optic strainmeter observed slow transient extension of about 0.7 μstrain over 3 weeks. Very low-frequency earthquakes (VLFEs) were observed in the vicinity during this period. The fiber-optic strainmeter was able to observe slow step-like changes for many of the VLFEs that occurred near the strainmeter. We observed strain change about 20 n strain for a VLFE of Mw 4.4. The observed strain change polarity and transitions were consistent with those expected from the focal mechanisms of the VLFEs, suggesting the possibility to investigate slip processes of each individual VLFE by seafloor fiber strain record.

The strain changes by the local VLFEs were insufficient to account for the total slow 3-week strain change observed by the fiber optic strainmeter. Therefore, we propose that shallow slow slip occurred in the areas where the VLFEs were observed, and that the slow slip may have loaded individual VLFE faults into a burst-like cluster of VLFEs.

We further expanded our strainmeter observations by adding two strainmeters in array and in different direction in November 2022, where we anticipate more robust and detailed fault slip analysis will be performed in the next similar slip occurrence.

Slow slip occurs repeatedly in the shallow part of the plate subduction boundary region in the Nankai Trough (Araki et al., 2017). To investigate its activity in wider area, we developed and installed a seafloor fiber-optic strainmeter connected to a submarine cable observation network (DONET) in west of the previous observation network in the borehole in 2019. In January-February, 2022, the seafloor fiber-optic strainmeter observed slow transient extension of about 0.7 μstrain over 3 weeks. Very low-frequency earthquakes (VLFEs) were observed in the vicinity during this period. The fiber-optic strainmeter was able to observe slow step-like changes for many of the VLFEs that occurred near the strainmeter. We observed strain change about 20 n strain for a VLFE of Mw 4.4. The observed strain change polarity and transitions were consistent with those expected from the focal mechanisms of the VLFEs, suggesting the possibility to investigate slip processes of each individual VLFE by seafloor fiber strain record.

The strain changes by the local VLFEs were insufficient to account for the total slow 3-week strain change observed by the fiber optic strainmeter. Therefore, we propose that shallow slow slip occurred in the areas where the VLFEs were observed, and that the slow slip may have loaded individual VLFE faults into a burst-like cluster of VLFEs.

We further expanded our strainmeter observations by adding two strainmeters in array and in different direction in November 2022, where we anticipate more robust and detailed fault slip analysis will be performed in the next similar slip occurrence.

High-rate positioning from Global Navigation Satellite Systems (GNSS) observations involves the acquisition of signals at a higher rate (> 1 Hz) than conventional positioning (< 0.7 Hz). This increased measurement frequency has opened possibilities for a wide range of applications, such as measuring seismic waves and monitoring tsunamis, volcanoes, and landslides. The development of low-cost GNSS receivers has made high-rate positioning more accessible and affordable for a wide range of applications. However, the performance of these low-cost GNSS receivers for high-rate measurement applications still needs to be thoroughly evaluated and analyzed to ensure their reliability and accuracy. To investigate the reliability and accuracy of low-cost GNSS receivers for high-rate positioning, we collect 6-day continuous data at 1-Hz, 2-Hz, 5-Hz, and 10-Hz frequencies from a heterogeneous network of stations equipped with geodetic, survey-grade, and navigation antennas. These stations comprise of dual (u-blox ZF9P) and single frequency (u-blox M8T) low-cost GNSS receivers. In this study, we evaluate these sets of high-rate data by comparing signal-to-noise ratio (SNR), cycle slip, dilution of precision, multipath, and precise point positioning. In addition, we assess the effects of the ultra-rapid and final precise orbit product on the PPP solutions.

This work presents an analysis of dynamic displacements observed on GNSS stations in the Aegean region, induced by the two earthquakes with magnitude 7.8 and 7.5, in Southern Turkey on 06/02/2023. For this reason, GNSS data of 1Hz observation rate from continuously operating stations located across the Aegean Sea and the mainland of Greece was processed using Precise Point Positioning method. Position time-series were analyzed to estimate the amplitude of the displacement, the direction in which the maximum displacement is observed and the time of occurrence. Furthermore, emphasis is given on comparing the characteristics of the displacements observed between the two events and examine a possible correlation with the corresponding faults' geometry for each separate event. An additional evaluation of the kinematic behavior of permanent GNSS stations located in proximity of the Hellenic subduction zone with the African plate, the latter sharing a tectonic boundary with both the Arabian and Anatolian plates was conducted. The results of this work discuss the effects that strong earthquakes can have at distances over 1000 km and along active tectonic boundaries, implying the larger-scale impact of such geohazards.

Anthropogenic earthquakes are rarely monitored with high-rate GNSS. Nevertheless, the progress in the GNSS processing techniques allows recording the mining tremors of smaller amplitudes, i.e., magnitudes about 4, with high-rate GNSS as well as complementary sensors to the seismic instruments. Although high-rate GNSS recording frequency and sensitivity are lower than seismic sensors, high-rate GNSS can capture the waveforms appropriately.

Here we demonstrate that if the GNSS observations are carefully filtered, we can retrieve the small signal of ground vibrations of the low-magnitude shallow anthropogenic earthquakes with the accuracy of very few millimetres for displacements and 1-2 cm/s for velocities. We analysed five mining tremors with magnitudes of 3.4-4.0 and presented the results from high-rate GNSS position changes calculated parallel with the PPP and variometric approach. We obtained satisfying correlations with seismological data in correlation, peak values comparison and earthquake first epoch determination.

Moreover, we show that high-rate GNSS can be a supplementary tool for seismic moment tensor inversion for small magnitude shallow anthropogenic earthquakes and might be crucial in case of a lack of seismic data, complementing unfavourable focal coverage. The obtained full, deviatoric, and double-couple solutions are similar, which shows that GNSS data may be added for moment tensor inversion in place of seismometers if needed without significant loss of the solution quality.

Finally, considering the high-rate GNSS positioning noise level, we demonstrate the capacity to resolve the dynamic displacements from high-rate GNSS at the epicentral distance of about 7-8 km.

A magnetotelluric (MT) regional investigation is underway in Southeastern Brazil as part of a comprehensive Multiphysics project (sponsored by Petronas Brasil) which integrates multiple geophysical datasets aiming to understand the deep structure and tectonic processes connecting onshore orogenic belts and the offshore extended margin that resulted in the formation of the petroliferous Campos basin. The megastructures of the São Francisco Craton (SFC), the Ribeira Fold Belt (RFB) and the basement of Campos basin have been surveyed by a total of 100 broadband and long period MT stations recording at periodicities of 10^{-3} to 10^{5} s, with spacing varying from 25 to 45 km and distributed in a 400 km x 350 km sided NW-SE oriented array. The MT time series were processed using robust methods followed by dimensionality analyses using the phase tensor scheme which pointed to a predominantly three-dimensional character of the study area. The first 3D resistivity models have been derived from non-linear regularized inversion using the full impedance tensor data. The 3D model shows good data fit depicting prominent geoelectric signatures in the suture zone between the CSF and the RFB. There are noticeable variations between the crust and the lithospheric mantle, and good opportunities for the understanding the compartmentalization of the internal domains of the RFB consistent with surface geology. The work is in progress, and the next steps will include recording new MT stations to extend the study area and the integration of results with both onshore and offshore geothermal, gravimetric and magnetic datasets.

How the lithospheric structure of the coast-parallel orogenic belts in SE Brazil is related to the petroliferous offshore rifted margin is not well understood. We present a three-dimensional magnetotelluric (MT) resistivity model of the Southeastern Brazilian onshore-offshore margin from 174 long period and broadband amphibious MT soundings distributed in NW-SE profiles crossing orthogonally the regional coast-parallel Serra da Mantiqueira and Serra do Mar mountain belts. Dimensionality analysis from phase tensor (PT) along the two main profiles outline the character of the subsurface: i) Onshore, there is a marked three-dimensional behavior with spatially changes over Brasília (BrB) and Ribeira (ROB) Orogenic belts and the PT minimum phase varies over the periods suggesting segmentation in the crust and between the crust and mantle.; ii) Offshore, PT ellipses are mostly 1-D in nature for shorter periods with high minimum phases corresponding to thick conductive sediments in the Santos basin and low minimum phases marking the resistive basement. We undertook 3D inversion of the data incorporating topography/bathymetry. 3-D MT resistivity model shows a highly heterogeneous crust beneath the BrB and a major sub-lithospheric suture zone beneath ROB. Crustal conductivity anomalies distinguish a wide antiformal structure below the BrB and a megasynform structure below the ROB, which provide evidence for both compressional and extensional tectonic regimes beneath the Southeast Brazil.

An array using *76* long period magnetotelluric (LMT) stations with 70 km spacing was deployed covering central and northeast sector of Parnaiba basin and the west edge of the Borborema Province in northeast Brazil. The data were processed including the remote reference technique to improve the estimated transfer functions – Full impedance tensor (Z) and Tipper (T) data spanning from 10s to over 10,000 s. 3D MT inversion tests using ModEM code were carried out using best practice procedures and good misfits have been achieved e.g., nRMS ~ 2.2 for joint inversion of Z and T, and nRMS < 2 for separated inversion of these transfer functions. The preferred resistivity model reveals remarkable large-scale deep conductive structures in the area. The electrical signature of the major suture zone - Transbrazilian lineament (TBL) - is not uniform from north to south, and sometimes is not well demarcated, as also observed in previous MT works. The new model suggests a lithosphere-asthenosphere boundary ~150 km in agreement with other studies, however intriguing prominent and wider deep conductor shallowing in the central part of the model where high heat flux is also observed suggests a mantle-crust control of this lineament and the shape of the block. Parnaíba block has a lateral discontinuity in all E-W profiles, going from North to South, that match the proposed limits between domains Grajaú and Teresina domains, the latter showing thinning in the N profiles and dipping E-W in S profiles.

The southern Indian shield region (SISR) is dominated by several tectonic blocks separated by a complex set of faults and shear zones. The resistivity structure of the lithosphere beneath the SISR is investigated by using 65 magnetotelluric stations. The NW-SE trending, 800 km long profile with an inter-site spacing of about 25 km covers a part of the Deccan volcanic province (DVP), western Dharwar craton (WDC), and southern granulite terrain (SGT). The raw data consists of broadband time-series records within the period range of 0.01 to about 3,000s. Firstly, 2-D modeling was carried out to get the geo-electrical map of the sub-surface. SISR is a geologically complex unit, and in this type of region, sometimes 2-D modeling does not give significant details of off-profile prominent features. So, 3-D MT inversion was carried out with the diagonal (Zxx, Zyy) and off-diagonal (Zxy, Zyx) elements. Conductive features obtained in 2-D models are spatially correlated with features in the 3-D model. The features mapped in the 3-D resistivity model can be interpreted in terms of the deep seated faults, rifts, and shear zones. This study observes the southward subduction polarity between the western Dharwar craton and southern granulite terrain. The lithospheric thickness increases from DVP to SGT. The present study results are well correlated with the geological features mapped in the area.

The electrical properties of rocks are sensitive indicators for CO2 migration processes. Due to their sensitivity to the pore fluids, electric and electromagnetic geophysical methods bear a great potential for monitoring underground CO2 storage reservoirs and for early-warning leakage detection. However, CO2 is a reactive gas which massively interacts with other pore fluids as well as the solid rock matrix. Therefore, classic petrophysical relationships do not necessarily apply.

With laboratory studies we investigate the impact of CO2 on the complex electrical conductivity of water-bearing rocks with and without a reactive mineral matrix under geologically relevant pressure and temperature conditions. By combining the rock physics findings with site-specific 3D time-lapse simulation studies, we can develop optimized electromagnetic monitoring setups with respect to coverage and resolution.

The presented results provide insight into the reactive processes in rocks subject to CO2 and can be used to correct for chemical interactions during the interpretation of electrical measurements in terms of saturation. Our experimental and numerical results have implications for leakage detection methods and monitoring the evolution of mineral dissolution and/or precipitation processes at the grain-water interface during underground CO2 storage. Additionally, the results also advance our understanding of geogenic CO2-rich geosystems, such as volcanic terrains with gas emissions or low-temperature CO2 discharges.

The Koillismaa-Näränkävaara complex in North-eastern Finland is currently studied with a variety of geophysical and geochemical investigations to better understand its geological history and assess its mineral potential. The area is characterized by an East-West oriented deeply seated ultramafic intrusion within the granitoid bedrock which has been indicated by gravity and magnetic anomalies as well as 2D inversion of sparse magnetotelluric (MT) data. It was successfully drilled at a depth of 1.5 km by the Koillismaa Deep Hole. The aim of this study is to better delineate the geological structure around the Koillismaa Deep Hole area. We collected 70 MT sites along an approximately 40 km long profile across the intrusion. In addition, we also tested our newly acquired EM transmitter and collected a densely sampled controlled source AMT (CSAMT) profile across the Koillismaa Deep Hole at the centre of the MT profile.

Data analysis of the MT data shows prominent geoelectrical strike direction perpendicular to the intrusion. However, it also shows a change of strike direction with depth by 20°. We will discuss possible causes of observed anisotropy and show inversion results of the MT data and compare it with latest results from our CSAMT survey. Our EM results will be further compared to other existing geophysical data such as borehole logs, gravity, and magnetic modelling as well as petrophysical measurements of the drill core.

[2]*Institute of Geophysics and Meteorology, University of Cologne, Cologne, Germany*

Electrical conductivity variations provide unique constraints on chemistry, mineralogy, and physical structure of the crust and mantle. As a physical property, conductivity is highly sensitive to the presence of fluids and volatiles (i.e., hydrogen). Here, we present a new 3-D electrical conductivity model (MECMUS) derived by inverting data from more than 1300 USArray MT stations covering 90% of the contiguous United States on a quasi-regular 70-km grid. The use of a novel multi-scale imaging approach and locally refined meshes allows us to consistently incorporate a large range of spatial scales and image 3-D electrical conductivity distribution from the surface down to mantle transition zone. We find conductivity variations that correlate with known continental structures such as due to the active tectonic processes within the western United States as well as the presence of deep roots beneath cratons. We further interpret conductivity variations in terms of the upper mantle water content by coupling electrical conductivity with constrains on mantle thermo-chemical structure derived from the analysis of seismic data (in the form of P-to-s and S-to-p receiver functions). Further, we explore the links between electrical conductors and lithospheric controls on occurrence of critical mineral deposits.

Here, we present a new 3-D electrical conductivity model (MECMUS) derived by inverting data from more than 1300 USArray MT stations covering 90% of the contiguous United States on a quasi-regular 70-km grid. The use of a novel multi-scale imaging approach and locally refined meshes allows us to consistently incorporate a large range of spatial scales and image 3-D electrical conductivity distribution from the surface down to mantle transition zone. We find conductivity variations that correlate with known continental structures such as due to the active tectonic processes within the western United States as well as the presence of deep roots beneath cratons. We further interpret conductivity variations in terms of the upper mantle water content by coupling electrical conductivity with constrains on mantle thermo-chemical structure derived from the analysis of seismic data (in the form of P-to-s and S-to-p receiver functions). Further, we explore the links between electrical conductors and lithospheric controls on occurrence of critical mineral deposits.

A high resolution magnetotelluric investigation was conducted in the Sehqanat oil field, SW of Iran, in 2020 (Phase II) to map geoelectrical structure of the region from surface down to several kilometers. The Sehqanat oil field is located in sedimentary Zagros zone comprising ranges of the biggest oil fields in Iran. The most interesting target in this survey was geological contact between Gachsaran (Cap Rock) and Asmari (Reservoir) formation. According to the electrical logs information, large resistivity contrast exists at the boundary of two mentioned formations. The Gachsaran formation is formed by tens to hundreds meter of evaporites which is highly conductive (ca. 1-10 ohm-m) and the Asmari formation, in contrary, comprising of dense carbonates with more electrical resistivity range (more than 100 ohm-m). The broadband magnetotelluric data were collected in a 3-D pattern at more than 600 stations along five parallel southwest-northeast profiles crossing the main geological trend of the study area. Velocity information extracted from seismic data acquired in the region used to make initial model for magnetotelluric modeling. In order to image a comprehensive subsurface resistivity map throughout the Sehqanat oil field, three-dimensional inversion was performed on the magnetotelluric data as well as two-dimensional routine. The 2-D inversion results depicted the main resistivity structures while the 3-D inverted model shows significantly more details and consistency.

Subduction of the Neotethys Ocean resulted in collisions of continental plates, with formation of Cenozoic orogens. The different shapes and structures of various segments of these young orogens, such the Zagros Collisional Zone, suppose a complex interplay of shallow and deep structures, producing different degrees and styles of deformation. As part of the PRIN 2017 project, we analyze several types of recently acquired data (e.g., seismic tomography models of the crust and upper mantle, Moho depth, seismicity distribution, and surface topography). We find that the NW and central Zagros is characterized by a zone of thickened crust of variable width and overlain by topography that exhibits large height variations over small distances, in the central part of the collisional zone. These variations are accompanied by sharp lateral changes in the number of seismic events and velocities/temperatures at depths of ~100 km.

We attribute these observations to relamination processes (i.e., the detachment of Arabian crust from the subducting lithospheric mantle and its underthrusting beneath the crust of the overriding plate), which are controlled by the variable geometry and stiffness of the overriding and subducting plates. This hypothesis is tested by performing a series of numerical experiments, using the numerical code I2VIS [1], that simulates relamination processes, occurring during continental collision. The consistency of the results is also verified through forward models of the static gravity field of the modelled structures, which are compared with the present-day observed gravity.

School of Geophysics and Information Technology, Beijing, China

The East Himalayan Syntaxis (EHS) is featured with an abrupt U-turn of all geological boundaries, geomorphic features and river systems at the east end of the Himalayan orogenic belt. The EHS is believed to be the region with strongest Cenozoic uplift and exhumation in Tibetan Plateau. The most significant geomorphology feature in EHS is the over 7000m Gyara Peri (GP) and Namcha Barwa (NB) peaks, which rise abruptly from the <3000m surrounding Yarlung-Tsangpo canyon. Since the late Pliocene, the central Namcha Barwa area has experienced fast uplift and has developed a series of high-angle fault networks that are focused around EHS. Magnetotelluric array measurements were used to map the 3D electrical structure beneath the EHS in order to better understand the reasons beneath the rapid growth of regional elevation. The inversion model reveals crustal high conductivity anomalies around the NB region, which may be related to the decompression melts caused by the rapid uplift of the region. On the other hand, the crustal structure directly beneath NB is imaged as highly resistive NNE directed anomaly. This feature is consistent with previous regional resistivity model and the velocity structure discovered by magnetotelluric and surface wave results. The resistive "wedge" may reflect the northward intrusion of deep materials into the crust of the Lhasa block, which further induces the uplift of regional structure. With the gradual intrusion of the wedge, the uplift may gradually expands to the northeast, forming the long and narrow surface compound anticline responses.

The time-dependent thermal trigger for intracontinental rifting and break-up of continents

DOI: 10.57757/IUGG23-3811 - LINK

Yuriy Maystrenko[1], *Trond Slagstad*[1]
[1]*Geological Survey of Norway NGU, Geophysics, Trondheim, Norway*

Ocean closure and collisional orogeny frequently enrich the lithospheric mantle in radioactive elements (uranium, thorium, potassium) due to the subduction of continent-derived sediments and continental crust. According to thermal modeling, increased content of radioactive elements within the anomalous lithospheric mantle causes a time-dependent rise of temperature, providing favorable conditions for intracontinental rifting more than 50-100 million years after the closure of the ocean. In addition, the obtained results indicate that in a global-scale mantle convection system, there is a clear tendency for the mantle upwellings to move towards the thermally anomalous upper-mantle block over time. Concentrating convectional upwellings under the anomalously hot lithosphere can cause extensional stresses that can theoretically trigger the break-up of the already thermally weakened, continental lithosphere. Moreover, our results provide an explanation of why rifting and continental break-up occur along or in close vicinity to the suture zones not immediately after the orogenic event but with a delay in time, dependent on the concentration of heat-producing elements in the anomalous mantle block and the size of this block. Thus, the presence of structural/compositional inhomogeneities within the anomalous lithosphere plays a rather secondary role, affecting mostly the geometrical configuration of the rifts. Therefore, a newly discovered, time-dependent process of weakening the continental lithosphere can be responsible for intracontinental rifting and the subsequent continental break-up and is controlled by the enhanced content of radioactive elements within the anomalous lithospheric mantle of the suture zones.

Our study area is located in the Central High Atlas (Morocco), which is the largest intraplate mountain chain in North Africa. It consists of a series of basins developed during the Triassic and Jurassic subsequently inverted during the Cenozoic as consequence of the convergence between African and European plates. The area features NE-SW and ENE-WSW trending folds that interfere with smaller-scale oblique and perpendicular folds. Previous studies have shown that Jurassic rocks of the Central High Atlas are affected by a regional interfolding remagnetization that separates two different tectonic events: the Jurassic extension and the Cenozoic inversion. Remagnetization has been dated as Cretaceous (ca. 100 Ma) and is related with burial.

A high resolution paleomagnetic study (91 sites in about 35 km^2) was carried out on the Anemzi syncline, a paradigmatic structure of the Central High Atlas. By means of Small Circle methods, both the remagnetization direction and the paleobedding (i.e. the bedding attitude at the remagnetization time) were calculated and used restore the 3D structure at 100 Ma times, which represent the structure developed during the extensional stage. Restoration is compared with the present-day structure to better understand the evolution of the Central High Atlas during both the basinal stage and the subsequent inversion and to extract relevant clues about the importance of the inheritance of extensional structures (normal faults, gabbro intrusion, diapirism, etc.) during mountain building.

The role of the Iceland plume in the NE Atlantic continental breakup derived from a data-integrative 3D model

DOI: 10.57757/IUGG23-2778 - LINK

Maria Laura Gomez Dacal[1], Magdalena Scheck-Wenderoth[2], Jan Inge Faleide[3], Judith Bott[2], Mansour Abdelmalak[3], Denis Anikiev[2]

The present-day state of the NE Atlantic lithosphere is the product of a complex geodynamic history that includes the continental breakup between Greenland and Eurasia about 55 million years ago, after multiple phases of extensional deformation and the emplacement of the Iceland plume. Open questions related to the process of continental breakup in this area are which role the Iceland plume played and whether we can image the traces of it in the present-day configuration of the crust and mantle. With the present work we aim to contribute to these questions by means of the integration of available geoscientific observations - including seismic profiles, existing geological maps and models, seismic mantle tomography and, particularly, gravity data - into one consistent three-dimensional model. The final model resolves the main structural characteristics, as well as the density distribution, of the crust and upper mantle of the entire NE Atlantic including its conjugate margins of Greenland and Norway. It allows us to correlate the obtained density anomalies in the crust with proposed surface indicators of the plate's journey over the plume. Besides, mantle density anomalies can be related with the present-day plume location and its interaction with the mid-ocean ridges. The model also indicates major differences in the density configuration between both conjugated margins increasing with the distance to the plume and towards the sheared margin segment. Altogether, our results indicate that the breakup of the continent, with its pre-existing crustal configuration, could have been facilitated by the presence of the plume.

This study aims to find evidence of a residual thermal anomaly along the path of a hotspot beneath the continental lithosphere using gradiometry data.
Considering a simple model of thermal anomaly, we calculated the associated gravity gradients and found that the horizontal component which is highly sensitive to the directional structure of the source has a magnitude of several hundred mEötvös, well above the current detection level of the data.Using GOCE satellite data, we created scale-orientation diagrams in four regions (Africa, Greenland, Australia, and Europe) to determine the direction and spatial scale of the strongest signal. We searched for a signal in the direction of plate movement, with a spatial scale of a few hundred kilometers (scale of the plumes). We then determined the ancient positions of the hotspots over the lithosphere and created maps of Bouguer gravity gradients and topographic gradients, filtered at a spatial scale of a few hundred kilometers and oriented in the direction of the hotspot's path. Interpreting these signals is challenging as it is difficult to separate the residual thermal anomaly from the surface topography and related crustal root , if the topography is aligned with the direction of plate motion and/or correlated with the volcanic chains generated by the plume.
Despite these challenges, the results shows that gradiometry data has the potential to track hotspots in the continental lithosphere for tens of millions years.

East Antarctica is the least understood continent involved in the assembly of Gondwana, a key stage in the global supercontinent cycle. Thick crust stretches from Dronning Maud Land to the Gamburtsev Subglacial Mountains, suggesting that the Kuunga Orogen, formed during the collision of India and East Antarctica during Gondwana assembly, had a significant impact on the Precambrian lithosphere of parts of interior East Antarctica. Geological and geophysical research has revealed key aspects of the collisional East African-Antarctic Orogen and the subduction-related Ross Orogen along the paleo-Pacific margin of Gondwana. However, the paths and architecture of these different orogens in the entirely ice sheet covered and remote interior of East Antarctica have remained more difficult to investigate, making it even more challenging to link subduction and collisional processes leading to Gondwana assembly and growth.

Here we present a new satellite-conformed aeromagnetic anomaly compilation that includes data recently collected between the interior of Dronning Maud Land and South Pole, together with airborne and satellite gravity imaging and seismological and geological constraints that provide tantalising new views into different crustal provinces, cratons and orogens in interior East Antarctica. We propose that a suture zone, partially exposed in the Shackleton Range, may cross the continent linking major fault systems imaged in the Gamburtsev Province and Princess Elisabeth Land. By superimposing our geophysical layers on a new plate tectonic reconstruction, we explore the potential evolution of accretionary and collisional stages in East Antarctica during the assembly of Gondwana from Edicaran to Cambrian times.

The lithosphere of East Antarctica, undoubtedly as complex as its neighbours in Gondwana, presents particular challenges in progressing the understanding of its tectonic nature due to its remote location and the harsh environment for on-ground geophysical instruments. Satellite-based and airborne data gathering has enabled composite maps for subglacial topography and potential field properties to be developed (e.g., Bedmap3, ADMAP2, ADGRAV) while international initiatives (such as 3D-Earth) provide 3D reference models of the crust and upper mantle with improving on-ground constraints for properties such as seismic wavespeed.

In this contribution, we share information on a new facility 'Geophysical Research Instrumentation for AnTarctica' (GRIT) that is enabling new ground-based data to be collected across multiple geophysical techniques (currently seismic, magnetotelluric, GNSS). We present an updated seismic crustal structure for the East Antarctic sector between Mawson and Dumont D'Urvillle stations (including new locations on remote outcrops), in the context of recent satellite-based studies. We also illustrate the relative importance of different observables as 'integrator' datasets for multivariate studies that show exceptional promise in multidisciplinary geoscience research, and how computational approaches can provide quantitative metrics to optimise targets for future field campaigns.

A better understanding of the heterogeneous lithosphere and deeper Earth, and interactions between the solid Earth and ice sheets, is urgently needed for Antarctica as this informs the response of ice sheets to global change. Combining the results of computational approaches and international initiatives for data collection and collation will result in optimised and accelerated research progress in the coming years.

East Antarctica is the keystone to Gondwana and is fundamental to the understanding of continental breakup and the distribution of continents since the Jurassic, with further implications for the formation of today's oceans and ice sheets and evolution of climate. Analysis of multiple geophysical datasets in East Antarctica, including radio-echo sounding, potential fields and seismic datasets have revealed the distribution of sedimentary basins within East Antarctica. Differences in the morphology and orientation of sedimentary basins define lithospheric domains separated by basement-dominated regions. The basement highs are defined by multiscale linear features evident in gravity, bed topography and seismic tomography models. These boundaries, we suggest, indicate the margins of former continental blocks that were assembled in the Precambrian to form East Antarctica. Rheological contrasts at block margins controlled later deformation during Phanerozoic extension. First, the formation of variably-oriented sedimentary basins in the Devonian to Triassic is consistent with reactivation of prior architecture and the distribution of major basin-dominated regions is indicative of differences in lithospheric rheology and composition - warmer and compositionally more fertile lithosphere is prone to subsidence. Second, the basement highs are aligned with key features of Gondwana breakup in the Jurassic to Eocene including the Africa-Madagascar-Sri Lanka triple junction, the Kerguelen Plateau, the George V fracture zone of Australian-Antarctic basin and the Macquarie Ridge. We suggest that the differential lithospheric structure of East Antarctica including mantle, crust and basins led to the localisation of these features and fundamentally controlled the geometry of Gondwana breakup.

In this investigation we model solid Earth deformation as constrained by vertical displacement of the Lower Mississippi River long profile over the past ~80 kyr. These observations are compared to output from a model that simulates glacial isostatic adjustment and sedimentary isostatic adjustment using a spherically-symmetric, viscoelastic Earth model. Observations of long-profile displacement based on optically-dated sediment cores, were revised to account for the effect of fault displacement in the southern end of the long profile inferred in some recent studies. Due to the relatively localized sediment loading associated with the Mississippi Delta System, the vertical displacement of the long profile over the past ~80 kyr is highly sensitive to lithospheric structure. For this reason, these observations offer a valuable opportunity to constrain mechanical properties of the lithosphere beneath the south-central United States. To pursue this opportunity, we consider multiple model scenarios in which the lithosphere is either entirely elastic (a common assumption in surface loading studies) or has internal viscosity structure. In the latter case, viscosity structures are determined using a range of plausible geothermal gradients and seismic constraints on Moho depth. In the elastic case, model lithosphere thicknesses are fixed at 46 km, 71 km, 96 km, or 120 km. For each modelling scenario (elastic vs viscous), constraints on lithosphere thickness and structure, and the ability of the model to match the observations will be presented.

The proliferation of Global Navigation Satellite System (GNSS) stations, and their derived 3D velocities, has offered both opportunities and challenges to image the surface deformation field. We merged and improved two existing robust imaging techniques: MELD (Kreemer et al. 2018, 2020) for horizontal strain rate and RNI (Kreemer et al., 2020) for vertical land motion. Both approaches aim at a robust high-resolution estimation with realistic uncertainties and without none to little a priori constraints. Our new algorithm (R3DI: Robust 3D Imaging) integrates both approaches and aligns the station selection.

MELD and R3DI rely on a multivariate median estimation of strain rate and plate rotation calculated from a set of stations and corresponding triangles. While MELD was developed specifically for imaging strain rates in low-straining areas, R3DI is designed more generally and based on an iteratively increasing number of stations until the results are significantly above a given SNR value. This approach allows a robust estimation, while the achieved spatial resolution depends solely on the station network's density and the local strain rate. The implemented concept was validated using synthetic data using a checkerboard test performed with real station locations in Europe and simulated 100x100km extension and compression cells.

After discussing the overall approach and the validation results, we will present horizontal and vertical deformation patterns derived from European and North American dense station networks. Finally, we will compare the results to the prior estimates for Europe from Kreemer et al. (2020) and North America from Kreemer et al. (2018).

The tectonic evolution of Eastern Arabia comprises three major events that must have modified the entire lithosphere below the present-day passive continental margins. Pan-African plate assembly during the Late Proterozoic established NNE-striking structural trends. Permo-Triassic Pangean breakup and rifting created two rift axes to form the present-day plate geometry. SW-directed obduction of the Semail Ophiolite during the Cretaceous shaped the present-day geology of northern Oman. Recent anisotropic ambient noise tomography, surface wave analysis of earthquake data and receiver function analysis reveal the present-day lithospheric thickness of ∼100 km and the highly variable internal structure of the East Arabian continental crust.

A NNE-striking contrast in the lower crust separates felsic from intermediate lithologies in northern Oman and is interpreted as being established during Pan-African orogeny. High V_S in the lower crust of northeastern Oman likely relate to Permian mafic intrusions emplaced during Pangean breakup. Mild crustal thickening below the topography is attributed to Late Cretaceous times, where continental subduction led to underthrusting and thickening of the crust and ultimately ophiolite obduction. Since present-day topography emerged only ~30 Ma after obduction ended, we argue that lithospheric thickness, margin perpendicular anisotropy and contemporaneous basanite intrusions are indicative of a relaxed state of stress at that time. Therefore, we propose that marginal erosion of the base lithosphere during Late Eocene facilitated margin-wide emergence of the Oman Mountains. Altogether, the lithospheric configuration in northeastern Arabia preserves imprints from Late Proterozoic Pan-African assemblage, Permian Pangean break-up, Late Cretaceous subduction and obduction, and Cenozoic post-obduction evolution.

The Xing'an-Mongolian Orogenic Belt (XMOB) is a key area to study the tectonic evolution of northeast Asia, as it has retained the records for the processes of both the closure of the Paleo-Asian Ocean and the Mongol-Okhotsk Ocean and the subduction of the (Paleo-)Pacific plate. We constrained the lithospheric structure across the XMOB by receiver function imaging and shear wave splitting analysis from a dense seismic array. The lithosphere–asthenosphere boundary (LAB) is coherently imaged in different tectonic blocks. The mid-lithospheric discontinuity is also identified at ~75-100 km depth over the deeper LAB (~110-130 km) beneath the western side of the North-South Gravity Lineament (NSGL), roughly at the same depth as the LAB beneath the eastern side of the NSGL. Distinct patterns in seismic anisotropy were identified which are roughly separated by the NSGL. The large variations in lithospheric thickness, seismic anisotropy and crustal structure between the two sides of the NSGL indicate that it might likely caused by different tectonic processes in the two sides, indicating that the NSGL might represent the western boundary influenced by the subduction of the (Paleo-)Pacific Plate. The eastern side of the NSGL is characterized by a thinned lithosphere of less than 100 km and dominant NW-SE fast shear wave polarization direction, which reflects considerable lithospheric deformation probably related to the Mesozoic-Cenozoic subduction of the (Paleo-)Pacific plate. An integration of our results and geological observations suggests that the area in the west of the NSGL may not have been affected by the (Paleo-)Pacific subduction.

Segmentation of the Indian lithosphere along the Himalayan arc: A multi-proxy approach

DOI: 10.57757/IUGG23-1048 - LINK

Ajai Manglik[1], Gayatri Pavankumar[1], Raj Sunil Kandregula[1]
[1]CSIR-National Geophysical Research Institute, Electromagnetic Geophysics, Hyderabad, India

Segmentation of the Indian lithosphere along the seismically active Himalayan collision belt, suggested by seismological and GPS studies, and analysis of topography and Bouguer gravity anomaly data, is one of the significant parameters to assess the maximum rupture area and hence the seismic energy release potential. These studies, confined to the Himalaya-Tibet region, linked major segmentation boundaries to pre-existing tectonic fabric of the Indian plate. We have studied this problem from the perspective of lithospheric flexural properties in the Himalaya-Ganga foreland basin system for possible segmentation. For this purpose, we have used the relationship between the foreland basin width (WFB) and the segment length between the Main Frontal Thrust and the Man Central Thrust (δFC) as a proxy to test possible correlation between these two parameters along the arc. The results suggest a major segmentation boundary along the Indo-Nepal border in addition to other previously discussed segmentations coinciding with major transverse ridges in the Ganga Basin. This segmentation boundary coincides with the Great Boundary Fault separating the Aravalli-Delhi mobile belt (ADMB) from the Vindhyan Basin further south. Further, we have analyzed a geomorphic index, normalized channel steepness (ksn), along the arc using the ALOS elevation dataset to test whether there is any relation between the ksn and the segmentation boundaries. Our results bring out spatial variability in the ksn along the arc and support the above segmentation. We infer a role of this segmentation boundary in limiting westward propagation of the rupture front of the 1505 paleo-seismic event.

The crust beneath a 250km long NW-SE trending profile across the Proterozoic Aravalli Delhi Fold Belt in northwestern India was imaged through P receiver functions(RF). We used teleseismic data recorded by 25 closely spaced(10-15km) broadband seismographs deployed on the profile passing through the Marwar craton(MC), Delhi fold belt(DFB), banded gneissic complex(BGC) and Vindhyan basin(VB). About 1600 RFs were generated using the iterative time domain deconvolution technique. The H-k grid search reveals the crustal thickness(H) and Vp/Vs(k) to be ranging from 35km to 53km and 1.70 to 1.90 respectively. Common conversion point image reveals lateral variations in the continuity of the Moho and the intra-crustal discontinuities. Crustal thickening upto 53km is observed beneath DFB while a flat Moho is imaged at ≈40km beneath the rest of the profile. A steep, SE dipping moho was imaged beneath DFB that may represent the subduction of the Marwar craton beneath the Aravalli craton in the east. A crustal scale feature dipping NW and extending from moho to the near surface beneath BGC was distinctively imaged that corresponds to the Jahazpur thrust. Low Vp/Vs(≈1.73) reveal a felsic crust beneath BGC while DFB and VB are characterized by high Vp/Vs(≈1.82) indicating an intermediate to mafic crustal composition. Neighbourhood algorithm inversion reveals ≈10km thick, high velocity layer(Vs≈4km/s) at the base of the crust suggesting significant magmatic underplating. Our results correlate very well with those of the deep seismic reflection studies along the same profile and provide additional information on the continuity of the crustal structure and composition.

[1]University of British Columbia, Earth- Ocean and Atmospheric Sciences, Vancovuer, Germany
[2]University of British Columbia, Earth- Ocean and Atmospheric Sciences, Vancouver, Canada
[3]University of Ottawa, Earth and Environmental Sciences, Ottawa, Canada

Detailed knowledge about the location and properties of the structures that host the megathrust is required to predict ground motions, model tsunami hazards and better understand subduction zone processes in Cascadia. Here we present our efforts to bring forward a new, detailed slab model based on azimuthally variable receiver functions from almost 300 on-shore 3-component broadband seismic stations.

We observe a characteristic succession of a negative top-, a positive central- and the positive oceanic Moho-conversion, where either the top or central conversion may be absent. We interpret it as the subducting oceanic crust that is at places overlain by, or contained within, a low-velocity zone. Inverse modeling of synthetic receiver functions allows us to resolve the strike and dip of this structure, the interface depths and seismic velocities of the intervening material along the fore-arc.

The top conversion exhibits a progressive landward evolution displaying (i) a weak contrast with overriding crust near the coast, (ii) full expression with the development of an upper low-velocity zone downdip, and (iii) disappearance in advance into the fore-arc, where the oceanic crust is inferred to turn to eclogite.

The thickness of the entire structure frequently exceeds the thickness of the oceanic crust offshore. At depth, the location of the central converter approximately correlates with the location of low-frequency earthquakes. These observations suggest that the subduction megathrust either continues downdip, a few kilometers below the top conversion, or widens into a distributed shear zone that includes upper plate material.

[2]Kangwon National University, Geophysics, Chuncheon, Korea Republic of

Estimating temperature in subduction zones is not easy because the tectonic structures in the area are complicated and it is not possible to reach and directly measure the temperature of subducting slab. In addition, existing water flows in the highly permeable sediment layer interfere with temperature measurements on the seafloor. The observed systematic decays of the seafloor spreading magnetic anomalies in subduction zone give insight into using it as a non-contact geothermometer. We interpret this first decay in the magnetic anomaly amplitude as reflecting the opening of normal faults and fissures from the outer flexural rise, and the renewed circulation of seawater into the oceanic crust, resulting in additional alteration of the magnetic mineral. And the systematic decays are happened in subducted oceanic crust following two steps: (1) the thermal demagnetization of the extrusive basalt layer where titanomagnetite and titanomaghemite reach their blocking temperature between 150-350°C; and (2) the magnetization of the deeper crustal layers slowly decreases, reflecting the progressive heating of the slab toward the Curie temperature of magnetite, 580 °C. These results indicate that the temperature of the subduction zone might be higher than the previous understandings. To identify it, we developed a numerical geodynamic model for subduction zones. Of course, the thermal structure in the subduction zone can be explained in large part by the heat conduction as in the existing geodynamic studies. However, our result support that hydrothermal circulations have a significant affect that changes in the physical properties and thermal structures of subduction zones.

Department of Geophysics Faculty of Physical and Mathematical Sciences, Santiago, Chile

In the southern Chile subduction zone, the Nazca plate is subducting beneath the South American plate. This region was recently struck by great megathrust earthquakes and is characterized by the existence of a volcanic chain. In this study, we calculated the three-dimensional thermal structure in the southern Chile subduction zone associated with the subduction of the Nazca plate by using numerical simulations. Based on the obtained temperature distribution, we determined the temperature ranges for the coseismic slips of the two megathrust earthquakes and temperatures at the hypocentres of the interplate earthquakes. In addition, the distributions of the water content and dehydration gradient were calculated by using the phase diagrams and were compared with the location of the volcanic chain. As a result, we found that coseismic slips occurred only at temperatures lower than the 350 °C isotherm. This finding occurs because the effective friction coefficient increases as the slip velocity increases at the plate boundary where the temperature is higher than 350 °C. In addition, the hydrous minerals in and above the slab release fluids through dehydration reactions, which decrease the melting point of the mantle wedge, contributing to the formation of the volcanic chain.

In the southern Chile subduction zone, the Nazca plate is subducting beneath the South American plate. This region was recently struck by great megathrust earthquakes and is characterized by the existence of a volcanic chain. In this study, we calculated the three-dimensional thermal structure in the southern Chile subduction zone associated with the subduction of the Nazca plate by using numerical simulations. Based on the obtained temperature distribution, we determined the temperature ranges for the coseismic slips of the two megathrust earthquakes and temperatures at the hypocentres of the interplate earthquakes. In addition, the distributions of the water content and dehydration gradient were calculated by using the phase diagrams and were compared with the location of the volcanic chain. As a result, we found that coseismic slips occurred only at temperatures lower than the 350 °C isotherm. This finding occurs because the effective friction coefficient increases as the slip velocity increases at the plate boundary where the temperature is higher than 350 °C. In addition, the hydrous minerals in and above the slab release fluids through dehydration reactions, which decrease the melting point of the mantle wedge, contributing to the formation of the volcanic chain.

Using aeromagnetic, geologic and tectonic data to establishing relationship between hydrothermalism and fracturation: Case of Ain Ouarka western Algeria

DOI: 10.57757/IUGG23-3909 - LINK

Zaagane Mansour[1], *Refas Soraya*[2], *Hadjou Fatiha*[3], *Bendella Mohamed*[3]
[1]*geology, agrnomic sciences, Mascara, Algeria*

The present work is based on a correlation with surface geothermal manifestations, aeomagnetism, and tectonic fracturing of Ain Ouarka zone, which is located in the Western Saharan Atlas of Algeria.

Using multi-source data, 114 fracture faults are identified and analyzed especially in the Mesozoic formations.

Our results show that fractures are distributed along three main directions NNW/SSE and WNW/ESE and an atlasic direction oriented N70°. For the faults depth, we relied on the processing of aeromagnetic data. Our results show that the depths of the tectonic structures argue in favor of a collapsed zone along the W-E fault of Ain Ouarka where the depths increase from 0.5 km to more than 2 km approaching the central zone. It is in this zone of cataclysm that the emergence of sources of hot water are noted. The results obtained after the processing of the magnetic data show that the distribution of the depths of the basement on the two banks of the W-E fault reaches almost 100 m thus showing the vertical throw of the W-E fault. The hydrodynamic model elaborate, show that under a regional tectonic regime probably recent, a collapsed zone has been highlighted. This cataclysm engendered uplift of plutonic reservoir at shallow depth. Rainwater infiltrates through permeable Mesozoic formations, flows towards the cataclysm zone. Subjected to high temperatures of plutonism, these waters warm up and rise under the effect of the low density to reach the surface in the form of hydrothermal springs.

Deduction of Heat flow from aeromagnetic anomalies of Gongola sub-basin, northern Benue trough, Nigeria

DOI: 10.57757/IUGG23-2133 - LINK

Levi Nwankwo[1], Michael Ohakwere-Eze[1], Musa Hayatudeen[1]
[1]Federal University Kashere, Physics, Gombe, Nigeria

Heat flow investigation of the Gongola sub-basin in northeastern Nigeria has been done from a 2D spectral analysis of recently acquired high-resolution aeromagnetic data as a means to elucidate likely concealed geothermal reservoirs in the basin. The aeromagnetic data, bounded by latitudes 9.0^{o}N and 12.0^{o}N and longitudes 10.0^{o}E and 12.5^{o}E, were divided into 20 overlapping blocks of 180 x 180 km and each block analyzed to estimate the Curie-point depths and ensuing geothermal gradients and heat flow isotherms. The results revealed Curie-point depths ranging from 20.03 to 29.83 km, geothermal gradients ranging from 19.44 to 28.69 ^{o}C/Km, and the ensuing heat flow varying between 48.61 and 72.39 mW/m^2. The results demonstrate that the study area is dominated by a thick crustal layer (above 15 km) and heat flow that is less than both the global average of 87 mW/m^2 and the accepted value of 80 - 100 mW/m^2 for anomalous geothermal conditions. Therefore, this study deduces that the area may not have traces of anomalous geothermal settings, having shown no zone of considerable crustal attenuation and elevated heat flow. Even so, the study contributes to the understanding of the thermal state of the lithosphere and regional heat flow variations of the geological formation of the Gongola sub-basin.

[4]AIST, Geological Survey of Japan, Tsukuba, Japan
[5]VSEGEI, Geophysics, St. Petersburg, Russian Federation
[6]Université des Sciences et Technologies Houari Boumediene, Geophysics, Algiers, Algeria

The last version of the World Digital Magnetic Anomaly Map (WDMAM v. 2.0) was released in 2015 (Dyment et al., EPSL, 2015; Lesur et al., EPS, 2016) with the mandate to update it using the same methodology when new data become available. The new version 2.1, compiled at 5 km interval, at 5 km altitude above the continents and at sea-level over the oceans, includes new datasets: (1) the complete digital aeromagnetic map of Brasil made available by ANP; (2) an improved version of the aeromagnetic map of Russia prepared by V-SEGEI; (3) the second version of the Antarctic Digital Magnetic Anomaly maP (ADMAP; Golynsky et al., GRL, 2018) which results from a remarkable international effort during and after the Second International Polar Year; (4) a new map of the Caribbean Plate and Gulf of Mexico (Garcia and Dyment, EPSL, 2021, 2022); (5) the updated Magnetic Anomaly Map of Eastern Asia prepared by the CCOP (MAMEA; Ishihara and Uchida, 2021); and (6) a new marine magnetic anomaly data compilation prepared by T. Ishihara and coworkers. The remaining data gaps are filled with a satellite anomaly model (Thebault et al., GRL, 2021). Long wavelengths of degree and order lower than 120 are filtered and replaced by those computed between order and degree 16 and 120 using the same satellite magnetic anomaly model from CHAMP and Swarm data. The new map will be presented and its significant improvements over the previous version discussed.

The mineral system concept considers the processes and large-scale controlling structures involved in the generation, emplacement and preservation of mineral deposits, not just the characterisation of individual near surface regions of economic potential. Archean cratonic environments such as the Canadian shield, Gawler Craton - Australia, and the Fennoscandian shield are home to some the world’s largest known mineral reserves typically along their margins. Despite a long history of study, the processes responsible for generation and emplacement of these large mineral rsources remain equivocal, however, what has become clear is that much larger regional scale geophysical imaging of Archean cratons is required to understanding these systems. Sub-continental lithospheric mantle (SCLM) and crustal architecture which have traditionally been viewed as secondary considerations in understanding the distribution of major mineral deposits have recently been shown through the large scale approach employed in D-REx as fundamental in understanding the larger scale mineral system. Surface geologies and upper crustal structure are often broadly similar in endowed and lesser endowed terranes suggesting the difference in endowment level may result either from: a deeper burial depth of endowment beyond the depth resolution and/or depth of interest of more traditional exploration approaches; or differences in the deeper SCLM and mid-lower crustal evolution of these regions. The D-REx approach has allowed identification of the early earth history and processes responsible for the concentration of metals in the current uppermost crust of the Fennoscandian shield and identified key structural controls at SCLM depths indicative of near surface metal endowment.

Whole of lithosphere and mineral systems connection - insights from new magnetotelluric arrays across the Gawler craton, South Australia

DOI: 10.57757/IUGG23-4806 - LINK

Stephan Thiel[1]
[1]*Geological Survey of South Australia, Department for Energy and Mining, Adelaide, Australia*

Lithospheric cratons withstand significant tectonic events over time due to their strong rheology and buoyancy. The Archean-Proterozoic Gawler Craton, South Australia, experienced heightened tectonic activity between 2.0 and 1.4 billion years ago, leading to a metasomatised mantle signature and world-class mineral systems including iron-oxide copper gold (IOCG) deposits and gold deposits. While the various deposit styles are often hundreds kilometers apart, vast arrays of magnetotelluric (MT) data point to a common primary architecture, in which the deposits are ultimately linked to a common metasomatised mantle source. Along the eastern margin of the Gawler Craton, the IOCG deposits have been extensively imaged with MT, including the super-giant Olympic Dam deposit. Here, we present new magnetotelluric data across a 12.5 km array and two closely spaced profiles totalling ~ 400 new broadband MT stations, across the western margin of the Gawler craton. The new data reduces the 50 km site spacing from the existing AusLAMP (Australian Lithospheric Architecture Magnetotelluric Project) by a factor of four to increase the resolution of the resistivity structure from the lower to upper crust. The scale reduction will constrain the magma and fluid pathways in between Archean lithologies present in the crust beneath the survey area and inform the genesis of the prevailing gold and nickel-copper deposits throughout the western Gawler craton. The 3D models show unprecedented insight into fossilised pathways of Proterozoic fluid flux along the craton margin.

Mapping of the Moho geometry could serve as an effective tool for visualization of the tectonic features/processes and their interactions beneath a region of interest. In this study, we employed a high-resolution (25″×25″ grid) tailored Bouguer gravity data to explore the mechanisms of tectonism beneath a highly rifted continental plate of the Southeastern Nigeria. Hence, we separated the Bouguer gravity data into shallow (high-pass) and deep (low-pass) gravity signals before carrying out gravimetric inversion. To obtain suitable estimates of gravimetric inversion parameters (reference depth and density contrast), we numerically computed and stochastically evaluated a seismically and our gravimetrically determined crustal thickness until a minimum RMS of their differences was achieved. Our obtained crustal thickness data range from 22 to 36 km with a stochastically determined optimal reference depth of 26 km and density contrast of 0.45gcm^{-3}. The crustal thickness map reveals a dense magmatic feature traversing the central portion of the study area in northeastern, southeastern, and southwestern directions leading to the thinning of the crust in those regions. We have been also able to refine and depict the lateral extent of the different sub-basins, ridges, crustal architecture, and the geophysical processes (magmatism, faulting/fracturing, mantle uplift, crustal thinning/thickening) of continental separation within the study area from our crustal thickness map. Considering the fine-scale discontinuity and continuity of tectonism revealed in our crustal thickness map, we conclude that a narrowing of two or more conjugate plates might have mainly occasioned those visible and complex geophysical phenomena.

Crustal Architecture of sub-basalt structures of Deccan Volcanic Province, India

DOI: 10.57757/IUGG23-2566 - LINK

Tabish Khan[1], *Anand S.p*[1]
[1]*Indian Institute of Geomagnetism, Solid Earth Geophysics, Navi Mumbai, India*

The Deccan Volcanic Provinces (DVP) is one of the Largest Igneous Province (LIP) of the world covering an area of half a million sq. km in central and western India. Due to the blanketing by the lava flows the geology and tectonics of sub-basalt remain speculative both in terms of resources as well as hazards assessment. However, recent advances in instrumentation & processing methodology leading to refined interpretation techniques have contributed to a quantum jump in the application of geophysical techniques to sub-basalt exploration as well as understanding the crustal configuration. In this study, we have utilized ground geopotential data (gravity and magnetic) with constraints from other studies to look at the structures below the basaltic terrain. From the combined analysis of the geopotential data, we could delineate the extension of several lineaments/faults, schist belts, etc below the trap cover. For the first time, we have identified several NE-SW trending lineaments within the DVP cutting across the NW-SE lineaments and giving rise to block structural architecture within the DVP. To have a better insight into the rheological, thermal, and petrological details of the study area we have computed the moho depth using inversion of gravity data while the depth to the bottom of the magnetic sources was computed using the power spectral methods. Combined two-dimensional modeling along two profiles provided better insights into the structures below the traps. The results of these analyses will be presented.

Geochemical signatures of the Volcano-sedimentary rocks of mauranipur-babina greenstone belt, bundelkhand craton, India: Implications for tectonic setting and depositional environment

DOI: 10.57757/IUGG23-0862 - LINK

Konduri S V Subramanyam[1], Surya Pratap Singh[2], Manikyamba Chakravadhanula[1], Mutum Rajanikanta Singh[3]
[1]CSIR-National Geophysical Research Institute, Geochemistry, Hyderabad, India
[2]Institute of Earth Science- Bundelkhand University-, Department of Geology, Jhansi- Uttar Pradesh, India
[3]Wadia Institute of Himalayan Geology-, Petrology & Geochemistry, Dehradun- Uttarakhand, India

The Bundelkhand Craton has a well-developed E-W trending Mouranipur-Babina Greenstone Belt (MBGB), which has excellent preservation of BIFs, cherts, sandstones, greywackes, quartzites, and associated komatiite-basalt-andesites. The pillow, massive basalts, komatiite basalts, andesites of Baragaon, BIFs of Saprar and Babina, chocolate-colored cherts from Babina, sandstones of Bhauti, fuchsite quartzites and metagreywackes from Swargeswarashram are studied for petrology and geochemistry to decipher the tectonic evolution of the Bundelkhand Craton. The CaO/Al_2O_3, $(Gd/Yb)_N>1$, positive Nb anomalies, La/Sm, La/Ta, Nb/Th, and high MgO contents (>20 wt.%) of the komatiite basalts reflect a mantle plume source for the early stage greenstone growth. Bimodal metavolcanics with tholeiitic to calc-alkaline affinity shows basalt-andesite-dacite-rhyolite differentiation trend in a convergent setting (arc-back arc), where partial melts are generated from thick metamorphosed basaltic crust after mantle plume. The metagreywackes, sandstones, and cherts are derived from felsic to mafic sources as indicated by their Cr_2O_3, TiO_2-Al_2O_3, and Zr, Th/Yb-Ta/Yb relationship. The BIFs of Saprar are characterized by low silica and high iron, whereas for Babina, the opposite is true. The Cu, Zn, Pb, V, Sr, and Ba contents of Babina BIF are very high compared to BIFs of Saprar, which in turn record high Sc, Cr, and Zr contents. ∑REE-Cu+Co+Ni, SiO_2-K_2O/Na_2O, and Cr-Ni discriminations infer that BIFs of MBGB are of Algoma type. Thus, the geochemical signatures of the volcano-sedimentary sequences strongly endorse Neoarchean plume-arc accretion tectonics in this greenstone belt, like other north-south trending greenstone belts of India.

Hunga Tonga islands evolution from remote sensing and future detectability with Next Generation Gravity Satellites

DOI: 10.57757/IUGG23-4697 - LINK

Carla Braitenberg[1], *Alberto Pastorutti[1]*
[1]University of Trieste, Department of Mathematics and Geosciences, Trieste, Italy

The Hunga Tonga Hunga Ha'apai (HTHH) islands have evolved since 2014, as we trace back through the SAR and multispectral satellite imaging of the Sentinels 1 and 2. The modulations of the outline of the islands are accompanied by mass changes, possibly detectable through a variation of the gravity field. These mass changes are the sum of the height changes of the emerging parts of the volcano, and the volume changes concealed below the ocean surface. The goal of the study is to define realistic mass changes that are associated to the evolution of HTHH, then to estimate the gravity changes in space and time, and finally estimate the sensitivity of observational methods to the gravity changes. Present ongoing efforts define the noise level in acquisitions of multi-satellite constellations carrying innovative instrumentation as quantum technology gravimeters or gradiometers [1,2]. The MAGIC mission planned for end of the 2020ties shall combine an inclined and polar pair of a GRACE-like mission to achieve a significant improvement in the recovery of the time variable gravity field. We find that the improvements of the future satellite missions should allow us to detect the subsurface mass changes generated by submarine volcanic activity, although the estimated mass changes for HTHH pose a challenge for the detectability. Next to HTHH we make a review of other known submarine eruptions and find that bigger volcanic mass changes are documented, which could be effectively observed.

The MAGIC mission planned for end of the 2020ties shall combine an inclined and polar pair of a GRACE-like mission to achieve a significant improvement in the recovery of the time variable gravity field. We find

that the improvements of the future satellite missions should allow us to detect the subsurface mass changes generated by submarine volcanic activity, although the estimated mass changes for HTHH pose a challenge for the detectability. Next to HTHH we make a review of other known submarine eruptions and find that bigger volcanic mass changes are documented, which could be effectively observed.

A major seismovolcanic crisis has afflicted the islands of Mayotte, Comoros Archipelago, since May 2018, although the origin is debated. The region of Mayotte is composed predominantly of two main islands, namely, Grande Terre (363 km2) to the west and Petite Terre (11 km2) to the east. In May 2018, an offshore seismovolcanic crisis initiated approximately 50 km to the east of Mayotte; the crisis included the largest seismic event ever recorded in the Comoros with a Mw=5.9 and an estimated 5 km3 of lava was released from an eruptive site. Magnetotellurics (MT), which is sensitive to hydrothermal and/or magmatic fluids and can map the subsurface electrical resistivity structure, can provide insight by revealing the internal structure of the volcanic system. We report the results of a preliminary land and shallow marine MT survey performed on and offshore the island nearest the crisis. The 3D inversion-derived electrical resistivity model suggests that the island is underlain by a shallow ~500-m-thick conductive layer atop a deeper, more resistive layer, possibly associated with a high-temperature geothermal system. At depths of ~15 km, the resistivity drops by almost two orders of magnitude, possibly due to partial melting. Further petrophysical and geophysical studies are underway for confirmation and to map the geometry and evolution of the volcanic system.

Identifying the observables that warn of volcanic unrest and eruptions is one of the greatest challenges in natural hazard management. Recently, Girona et al., 2021 (https://www.nature.com/articles/s41561-021-00705-4), discovered that volcanic edifices may slightly warm in the years leading up to both phreatic and magmatic eruptions. This warming, or low-temperature (low-T) geothermal anomaly, was found by analyzing ~16 years of long-wavelength (~11 μm) thermal infrared radiance data recorded by the moderate-resolution imaging spectroradiometers (MODIS) aboard NASA's Terra and Aqua satellites. However, many questions remain open. For example: What is the link between the spatiotemporal distribution of low-T geothermal anomalies and subsurface gas transport? We address this question by updating the remote sensing-based methodology proposed by Girona et al. (2021), by testing different physics-based, finite element (COMSOL) simulations to model gas and heat transport through volcanic edifices, and by using the 2021 Cumbre Vieja (La Palma, Spain) eruption as a case study. Our remote sensing-based analysis reveals that the 2021 Cumbre Vieja eruption was preceded by ~10 years of low-T geothermal anomalies in the crater of Taburiente caldera, located 10-to-12 km to the north of the 2021 eruptive center. Moreover, our models suggest that the pre-eruptive, low-T geothermal anomalies were possibly controlled by the latent heat released during the subsurface condensation of magmatic and/or hydrothermal H_2O. The possibility of tracking the spatiotemporal distribution of low-T geothermal anomalies using satellite data opens new horizons to indirectly detect the pre-eruptive transport of hot gas towards the surface and potentially better forecast eruptions from space.

The receiver function analysis (RF) is a well-established method to investigate the crustal and upper mantle structure in different geodynamic settings. It is highly sensitive to seismic discontinuities and provides information about P- and S-wave velocities beneath a seismic station.

This work aims to study the crust and the upper mantle of La Palma Island up to 50 km of depth by using RF analysis. La Palma is one of the youngest oceanic volcanic islands of the Canary archipelago, with a complex internal structure that makes applying conventional RF challenging. The island was affected in 2021 by the devastating Tajogaite eruption which occurred on the Cumbre Vieja volcano.

For this study, we obtained RFs of five stations using multi-taper deconvolution. After that, we applied the transdimensional approach of Bodin et al. (2012) to determine 1D profiles of P- and S-wave velocities and the probability of a discontinuity beneath each station.

Each 1D model was interpolated to build a N-S trending seismic section that allowed us to correlate the different discontinuities. We observe a Low-Velocity Zone in the upper mantle beneath the Cumbre Vieja volcano and four different layers with a significant change in their Vp/Vs ratios. These results are compared with the seismicity recorded beneath the island from 2017 until the pre-eruptive phase of the Tajogaite eruption. Hypocenters are mainly located at the base of the crust (10-15 km deep) and in the upper mantle (20-30 km deep), possibly related to the presence of two subcrustal magmatic reservoirs.

Volcanic eruptions are often preceded by episodes of inflation and emplacement of magma along tensile fractures, forming dikes or sills. Here, we present evidence for crater alignments and for a complex tensile fracture dissecting part of the eruption cone, during the very late stages of the Cumbre Vieja eruption. We use satellite radar amplitude image observations, together with photogrammetrically processed drone and time-lapse camera data, to determine scale and complexities associated with the late fracturing event. In a rapid response task force we acquired in-situ data, which we complement by the use of analog models to show that formation of the tensile fractures are strongly influenced by topography, diverging at topographic highs and converging at topographic lows. The observations at the late eruption phase and from our models are of importance for understanding tensile fracture sets at the already pronounced volcano topography of La Palma, and allow speculation of a shallow topographic driver responsible for a localized dike propagation.

Volcanic eruptions pose a major threat to many communities around the world. Yet openly accessible, real-time, multi-parameter data are available only for a few volcanic systems. While efforts are made to tackle the significant logistical and financial challenges involved with improving instrumentation at remote systems, it is important to also ensure a robust and easy-to-implement pathway from the point of acquisition to public repositories. An effective stream of multi-parameter observations from active volcanoes will drive the development of the next generation of physics- and data-based eruption forecast models. Here we report the development and field testing of a multi-parameter, real-time, open-data volcano monitoring system through our collaborative project AVERT: Anticipating Volcanic Eruptions in Real-Time.

The AVERT system has been deployed on Cleveland (open-vent) and Okmok (closed system) volcanoes—situated in the remote Aleutian arc—in partnership with the Alaska Volcano Observatory. Novel instruments, e.g. continuous fluxgate magnetometers, synchronised visible and infrared cameras, and soil probes for temperature and CO_2 flux, were installed in addition to seismic, GNSS, and gas sensors. A low-power single-board computer coordinates data archiving and telemetry—via radio and various satellite pathways—at each node in the network. In-situ analysis of data facilitates optimised data telemetry and lower latency detections of changes in the state of volcanic unrest. The small form factor, modular design of the system enables rapid deployment and straightforward incorporation of a wide variety of instruments into the data telemetry system. Design plans and software will be available to the community following successful proof-of-concept testing.

During eruptions, volcanoes produce air-pressure waves inaudible for the human ear called infrasound, which are very helpful for detecting early signs of magma at the surface. Compared to violent ash-rich explosions, recording more discreet atmospheric disturbances from effusive eruptions remains a practical challenge. Wind and human activity are other powerful sources of unwanted infrasound noise masking volcanic ones. At Nyiragongo volcano (D.R. Congo), close to a one-million urban area, the drainage of the world's largest lava lake concomitant with short-duration lava flows on its flank and the renewal of an effusive eruption within its crater a few months later were a series of major volcanic events in 2021, all monitored with infrasound sensors. First, we explore these records for characterizing the temporal and spatial evolution of the flank eruption on May 22, 2021. In a second step, we show evidence of the infrasonic rumbling of a nascent lava lake starting a few months later detected up to the volcano observatory facilities in Goma city center about 17 km from Nyiragongo's crater. These results show remarkable local recordings of eruptive infrasound from rural and city-based stations and have significant implication for optimizing future monitoring efforts in a harsh field environment.

Villarrica volcano, in the Southern Andes of Chile, is at the top of the Specific Threat Ranking for Active Volcanoes, published by the National Geology and Mining Service of Chile during 2019.
In recent years, broadband magnetotelluric measurements have been carried out around this volcano, to study its internal structure. Combining these data with information obtained from long-period magnetotelluric stations, an electrical resistivity model for this volcano and its surroundings is presented, identifying highly conductive anomalies down to depths of 15 km below sea level.The model obtained and presented in this work is complementary to the project of monitoring geophysical variables such as electrical resistivity in volcanoes, through the installation of permanent magnetotelluric stations.
Villarrica volcano is now the first volcano with magnetotelluric monitoring in Chile, in a collaborative project between the University of Chile and the National Geology and Mining Service (SERNAGEOMIN), through the Southern Andes Volcano Observatory (OVDAS). Details about the installation, measurements and first results of this experiment will be part of this presentation.

Detection of geophysical signatures associated with a geologic event, such as a volcanic eruption, is key to understanding the underlying physical processes and making an accurate hazard assessment. Magma reservoirs are the main repositories for eruptible magma, and understanding them requires the ability to detect and interpret changes in the magmatic system from surface measurements. Traditionally, monitoring for these changes has been done with seismic and geodetic approaches, both of which require dynamic 'active' changes within the magmatic system. Neither of these techniques is sensitive to the petrology or temperature of the magma though. Thus, additional monitoring techniques able to detect 'static' phase changes in the evolving magma and the thermal structure of the magma reservoir are needed. The magnetotelluric method, measures subsurface electrical properties and is sensitive to both 'magma on the move' and petrological changes that occur within the magma reservoir. Using Mount St Helens where a detailed magnetotelluric survey was completed during the most recent dome building eruptive phase 2005-06, and is now in a period of quiescence, we compare the original measurements to repeated measurements in the same locations in 2022 to develop temporal analysis approaches required for monitoring. In addition to the repeat campaign we have deployed 4 long-term continuous monitoring stations with telemetry to local servers. First, qualitative, comparisons of the data from different time periods indicate some significant changes in subsurface conductivity. We present an overview of the newly acquired data and the monitoring setup and discuss where the most significant changes occur.

The Cascade arc runs from Southern British Columbia through Northern California and developed by the subduction of the Juan de Fuca plate beneath North America. Among the volcanoes of the Northern Cascades, Mount St Helens (MSH) is the most active. Inter-connected melt within the underlying magmatic systems of volcanic regions allow identification of the system via Magnetotelluric (MT) imaging due to the sensitivity of the method to electrical conductivity. Time variance of the properties of the melt due to changes in eruptive activity may result in significant conductivity changes that can be identified with continuous MT monitoring. Galvanic distortions resulting from the small near-surface conductivity variations may can be difficult to separate from the expected subtle observational differences. However, impedance phase relations in MT are free of these galvanic distortions. Thus, by exploiting changes in the phase response (the MT Phase tensor), it is possible to identify the temporal conductivity changes associated with changes occurring within the magmatic system.
Prior MT results in the Washington cascades show a significant conductive anomaly underneath the MSH attributed to be partial melt supplying the volcano. With the aim of revealing conductivity changes beneath MSH, both a campaign style reoccupation of measurements completed during the 2004-2008 dome building eruption, and installation of four ‘continuous’ monitoring MT stations has been completed. Among the new MT dataset, a preliminary comparative phase tensor analysis of 56 repeated measurements identifies conductivity changes at frequencies that correlate the depth of the partial melt within the magmatic system.

Improved Estimates of Crustal Magmatic Storage at Arc Volcanoes Through Seismic Receiver Functions

DOI: 10.57757/IUGG23-4789 - LINK

Helen Janiszewski[1], Ian Wynn[1], Casey Wandasan[1], Lara Wagner[2], Diana Roman[2], Daniel Portner[3], Madeleine Tan[4]
[1]University of Hawai'i at Mānoa, Earth Sciences, Honolulu, USA
[2]Carnegie Science, Earth and Planets Laboratory, Washington- D.C., USA

[4]University of Michigan, Earth Sciences, Ann Arbor, USA

Recent research points to complex, multi-layered, transcrustal magmatic systems beneath volcanoes. But constraints on depths of magma storage in the mid-to-deep crust beneath volcanoes remain an enigmatic target. At volcanic arcs, magmatic processes at these depths are a critical link between the input from the slab and mantle wedge, the emplacement processes that build and alter arc crust, and the shallow crustal reservoirs that drive eruptions. Magmatic storage depths and pathways may be governed by a variety of properties, including volatile content, crustal stress regime, prexisting structures, and more. To better understand how these variables may impact arc volcano processes, we must employ techniques that allow us to characterize magma storage depths at volcanoes globally. Here, we investigate receiver functions as a technique to provide systematic, first-order constraints on magma storage depths in the mid-to-deep crust using data from the Alaska-Aleutian island arc as a case study. Receiver functions are sensitive to abrupt seismic velocity boundaries, and have detected low velocity zones in the crust interpreted as magmatic-mush systems at Akutan and Cleveland, two Alaska-Aleutian arc volcanoes. They do not rely on the presence of local seismicity, do not require a wide-aperature array to image the whole crust, and can be analyzed at volcanoes with relatively few (< 4) local instruments. We present results of the application of this technique across the Alaska-Aleutian arc, and examine along-arc trends in receiver function properties.

Recent research points to complex, multi-layered, transcrustal magmatic systems beneath volcanoes. But constraints on depths of magma storage in the mid-to-deep crust beneath volcanoes remain an enigmatic target. At volcanic arcs, magmatic processes at these depths are a critical link between the input from the slab and mantle wedge, the emplacement processes that build and alter arc crust, and the shallow crustal reservoirs that drive eruptions. Magmatic storage depths and pathways may be governed by a variety of properties, including volatile content, crustal stress regime, prexisting structures, and more. To better understand how these variables may impact arc volcano processes, we must employ techniques that allow us to characterize magma storage depths at volcanoes globally. Here, we investigate receiver functions as a technique to provide systematic, first-order constraints on magma storage depths in the mid-to-deep crust using data from the Alaska-Aleutian island arc as a case study. A review of the contribution of real-time GNSS to disaster prevention and mitigation in Japan

DOI: 10.57757/IUGG23-1032 - LINK

Yusaku Ohta[1]
[1]*Tohoku University, Graduate School of Science, Sendai, Japan*

Rapid monitoring of large earthquakes, associated tsunamis, volcanic eruptions, and other phenomena is extremely important for understanding the underlying phenomena, as well as for disaster prevention and mitigation. In Japan, the Geospatial Information Authority of Japan (GSI) operates a continuous nationwide GNSS network (GEONET) across Japan. Based on the lessons learned from the 2011 Tohoku-Oki earthquake, the GSI and Graduate School of Science, Tohoku University, have jointly developed a new crustal deformation analysis system using GEONET data for quasi real-time earthquake size estimation, known as the GEONET analysis system for rapid deformation monitoring (REGARD) (Kawamoto et al. 2016, 2017). The results of REGARD is used by the JMA as supporting information when issuing tsunami warnings/advisories. The fault models of REGARD were also adopted as sources to estimate tsunami inundation, and resulting damage. The system has been adopted as part of the Disaster Information Systems (DIS) operated by Japan’s Cabinet Office (Musa et al. 2018; Ohta et al. 2018) and will use the generated information for the initial governmental response after tsunamigenic earthquakes. In the presentation, the roles of real-time GNSS in disaster prevention and mitigation will be discussed, focusing on these developments of REGARD and others.

High-precision real-time GNSS have recently expanded to monitoring and early detection of natural hazards. German research project EWRICA (Early-Warning and Rapid ImpaCt Assessment with real-time GNSS in the Mediterranean) funded by the national Ministry for Education and Research aims for the prototype implementation of the GNSS-augmented seismic source inversion and rapid impact assessment in the seismically active regions of Mediterranean. The project runs in close cooperation with partners operating high-rate GNSS networks RING (Italy) and NOANET (Greece). An overarching goal is to compute robust local ground motion models shortly after an earthquake to assess areas of strong shaking as well as secondary effects such as tsunamis and landslides. The four work packages - (1) real-time processing of coseismic displacements (RT-multi GNSS with regional augmentation, streamed in miniSEED format via SeedLink server, optionally joint processing with collocated accelerometers); (2) fast source inversion (Bayesian moment-tensor solution with Pyrocko tools); (3) rapid impact assessment (neural network predictions of ground motion maps with uncertainties, also coupled to probabilistic tsunami forecasting PTF at INGV); and (4) system prototype -- end up with an operational system prototype to demonstrate the full operational processing chain by hindcasting selected historical (e.g., 2016 M6.2 Norcia; 2020 M7 Samos) and synthetic event scenarios. EWRICA may serve as a blueprint for other regions of the world: currently EWRICA's tools are being tested for application in Indonesia, together with the colleagues from the Geospatial Agency (BIG) and from the national tsunami warning center InaTEWS.

Integrated processing of high-rate GNSS and accelerometer data can overcome the disadvantage of each individual sensors and to increase the quality of derived co-seismic displacement. However, the contribution of accelerometer is usually underestimated by estimating baseline shifts epoch-wise which in fact happened very rarely. To take full advantage of both sensors, we propose a sliding window based Kalman filter to detect baseline shifts according to the disagreement of GNSS and accelerometer data and to estimate only the detected baseline shifts. The relationship of the window width, minimal detectable baseline shift and the displacement accuracy is investigated. The performance of the proposed approach is demonstrated by datasets collected during Samos Island earthquake (Mw 7.0, 30th October 2020). The results show that the baseline shifts in accelerometers can be precisely detected and estimated according to the very good agreement of the displacement integrated from accelerometer data after applying baseline shift corrections and that estimated from high-rate GNSS. Furthermore, the baseline corrected accelerometer data provides tight and reliable constraints on position and velocity to facilitate correct PPP ambiguity resolution. Thanks to the proposed approach, the complementary of GNSS and accelerometers is fully employed, consequently the co-seismic displacements of the tightly integrated processing are significantly improved.

Interoperability of data and products among disciplines is becoming a key aspect within the scientific community to allow the optimal integrated exploitation of data, taking advantage of modern real-time work-flows using also AI techniques. Within the EWRICA project, aiming at creating robust local ground motion models shortly after an earthquake to assess secondary effects such as tsunamis and landslides, one of the tasks focussed on integration of near-field seismo-geodetic data into real-time source inversion. To enable this task, Real-Time Precise Point Positioning (RT-PPP) data have been converted to miniSEED records on the fly by using a tailored plugin for SeisComP developed within the project. The real-time data in GFZ Displacement Real-Time (GDRT) format have been mapped to miniSEED channels as described in the SeisComP documentation [1]. The initial mapping has been defined considering also one additional use case implemented in the TURNkey project where RT-PPP data were generated from a newly developed standalone instrument. RT-PPP has been integrated in the data flow and sent out to clients via seedlink for processing in the known data and metadata format enabling faster and improved assessment of seismic moment, hypocentre and rupture kinematics.
In this presentation we introduce the gdrt_plugin released for the first time in June 2022 with the SeisComP v5.0.0 [2], we outline the initial process of mapping the GNSS products to existing data and metadata formats and would welcome discussions about further integration in seismology through the FDSN.

The HF Doppler ionospheric measurements can along with identification of medium scale wave activity provide also estimation of the level of the related GNSS positioning errors.
The paper demonstrates the rise of GNSS positioning error with increasing wave activity at ionospheric heights and with changing parameters representing ionospheric waves as measured by Czech Continuous Doppler Sounding Systems (CDSS) deployed around Europe, Argentina, South Africa and Taiwan.
Results using state-of-the-art Septentrio GNSS receivers applying various combinations of GNSS frequencies (L1&L2&L5+SBAS as its accuracy depends on the allocated signal bandwidth and modulation schemes) confirmed in all those scenarios correlation of positioning precision with the Medium-scale Traveling Ionospheric Disturbance (MSTID) activity-related ionospheric disturbances as monitored by the CDSS.
The most significant relation was found between the CDSS Doppler frequency-shift measurements (dF), even stronger than one naturally occurring during indications of ionospheric SpreadF.

GSeisRT: regional GNSS point positioning for wide-area seismic monitoring in real time

DOI: 10.57757/IUGG23-5024 - LINK

Jianghui Geng[1], *Shaoming Xin*[1], *Kunlun Zhang*[1]
[1]*Wuhan University, GNSS Research center, Wuhan, China*

GSeisRT software developed by Wuhan University is dedicated to real-time GNSS data processing, and it is free and open for the science community under mutual agreement. GSeisRT consists of a server end and a client end. GSeisRT server can use a regional GNSS network to estimate satellite clocks and phase biases independently or access IGS (International GNSS Service) real-time clock and orbit products to estimate satellite phase biases, which is more flexible and compatible with different data scenarios. Then GSeisRT client can realize multi-GNSS (GPS/GLONASS/GALILEO/QZSS/BeiDou) precise point positioning with ambiguity resolution (PPP-AR) and achieve centimeter-level to sub-centimeter-level precision in real time based on the products of GSeisRT server or IGS real-time service. The acquisition of real-time position can be applied to scenarios such as earthquake displacement monitoring, which is necessary and socially significant. In addition, GSeisRT will provide a lite version of the client with a user interface that can estimate and display the ionospheric delay of multi-GNSS satellites in real time. Considering user privacy and data security, GSeisRT could not only support the processing of public data streams but also be deployed in a private operating environment to process proprietary data streams, then users' data security and autonomy can be guaranteed.

Recent advances in high-precision real-time applications of the Global Navigation Satellite System (GNSS) have expanded to monitoring and early detection of natural hazards. The real-time Precise Point Positioning with Regional Augmentation (PPP+RA) technique has become increasingly popular for providing rapid and precise ground displacement information due to the availability of real-time precise GNSS satellite orbit and clock products, as well as high-rate observations. In this contribution, we implemented the PPP+RA technique to the Early-Warning and Rapid Impact Assessment with real-time GNSS in the Mediterranean (EWRICA) project for earth surface displacement monitoring. A real-time GNSS precise positioning system is developed for the project. About 80 stations from the RING network in Italy are used to evaluate the performance the system. It's worth noting that more than half of the receivers in the RING network are LEICA receivers that support GPS only. We use GFZ's real-time precise satellite orbit and clock products for the data processing. The results show that the daily averaged accuracy of PPP+RA is 1.08 cm, 1.15 cm, and 3.20 cm in the east, north, and up directions, respectively, with a Time To First Fix (TTFF) of 1.1 minutes. Additionally, the system provides short-term relative positioning accuracy within 10 minutes, with a precision of a few millimetres, demonstrating its capability to detect even slight ground movements in real-time.

The INGV RING research infrastructure is based on a permanent GNSS network developed to measure deformation at different spatial and temporal scales in the Mediterranean region. The network (http://ring.gm.ingv.it/) consists of ~250 real-time transmitting remote sites, using standard RTCM format, towards the Irpinia acquisition centres (Southern Italy). Data streaming is managed by a Ntrip Caster (https://igs.bkg.bund.de/ntrip/bkgcaster), whose sourcetable is synchronized with the RING database, thus guaranteeing reliable metadata for the analysis. Within the EWRICA project, the real-time data analysis is performed by using the RTPPP software (Ge et al.,2012) that provides different Precise Point Positioning products with increasing accuracies (standard PPP, PPP-AR and PPP-RA). On 24-h data, the ambiguity resolution (PPP-AR) and the regional augmentation (PPP-RA) allows accuracies of ~1 cm and ~3 cm for the horizontal and vertical components, respectively, at the best sites. Using shorter sliding windows (i.e. 60 s or 120 s, thus simulating a real-time situation), the accuracies are ~0,5 cm and ~1 cm for horizontal and vertical components, respectively. We also tested a homemade algorithm able to detect co-seismic static offsets in real-time in a simulated real-time strategy. The first results make the RING real-time solutions a potential contribution to be tested in earthquake and tsunami warning systems in Italy and surrounding regions. We will show the RING architecture, from the data to the PPP results, an evaluation of the uncertainties, and some examples of offset detection for recent earthquakes.

Real-time monitoring of earthquake-triggered surface deformation is becoming required to characterize the effect of an earthquake, either transient or permanent deformation. Indonesia as a country located in the active deformation region, through Geospatial Information Agency (BIG) has built 397 Real-Time Global Navigation Satellite Systems (RT-GNSS) stations that can be used to observe this phenomenon. The availability of RT-GNSS stations motivates us to provide real-time surface deformation information using the appropriate RT-GNSS processing method. We implement Precise Point Positioning with Regional Augmentation correction (PPP-RA) for stations if there are sufficient regional corrections, and Precise Point Positioning with Ambiguity Resolution (PPP-AR) otherwise. The result shows from Kota Fajar station in Sumatera Island (CKTF), the accuracy can be achieved at ± 1.4 cm, ± 1.8 cm, and ± 6.5 cm for the North, East, and Up components, respectively. we use the earthquake location information produced by Indonesia Tsunami Early Warning System (InaTEWS) operated by the Meteorological, Climatological, and Geophysical Agency (BMKG) to automatically collect the nearby stations from the epicenter. Then, we compute the displacement from each of its stations every second when the earthquake occurred. As a result, we can detect the transient deformation of the Banda Sea earthquake 7.6 Mw at depth of 108 km on January 9, 2023, with a maximum dynamic displacement at the nearest station to the source is 6.6 cm in the North-South direction and 8.7 cm in the East-West direction. This result suggests that this system is effective in displacement detection due to earthquakes.

Real-time monitoring of earthquake-triggered surface deformation is becoming required to characterize the effect of an earthquake, either transient or permanent deformation. Indonesia as a country located in the active deformation region, through Geospatial Information Agency (BIG) has built 397 Real-Time Global Navigation Satellite Systems (RT-GNSS) stations that can be used to observe this phenomenon. The result shows from Kota Fajar station in Sumatera Island (CKTF), the accuracy can be achieved at ± 1.4 cm, ± 1.8 cm, and ± 6.5 cm for the North, East, and Up components, respectively. we use the earthquake location information produced by Indonesia Tsunami Early Warning System (InaTEWS) operated by the Meteorological, Climatological, and Geophysical Agency (BMKG) to automatically collect the nearby stations from the epicenter. Then, we compute the displacement from each of its stations every second when the earthquake occurred. As a result, we can detect the transient deformation

of the Banda Sea earthquake 7.6 Mw at depth of 108 km on January 9, 2023, with a maximum dynamic displacement at the nearest station to the source is 6.6 cm in the North-South direction and 8.7 cm in the East-West direction. This result suggests that this system is effective in displacement detection due to earthquakes.

GNSS tsunami early warning for the South Pacific

DOI: 10.57757/IUGG23-1252 - LINK

John L. LaBrecque[1]
[1]*University of Texas, Center for Space Research, West Palm Beach, USA*

The IUGG Commission on Geophysical Risk and Sustainability will join other national and international organizations to support a Coordinating Group for the development of a GNSS based Early Warning System (GTEWS) for the Oceania Region of the South Pacific. I will examine the state of GTEWS technology, its motivation, and the planning underway to explore the development of GTEWS for the South Pacific Region.

The IUGG 2015 General Assembly Resolution #4 called upon IUGG membership to work toward the implementation of a Pacific GTEWS as an augment to existing tsunami warning systems. The Group on Earth Observation (GEO), the UN International Committee on GNSS (ICG) and 17 agencies from 12 countries have joined the IUGG in calling for the implementation of GTEWS. Currently GTEWS are prototype national systems. A Pacific Basin system remains elusive largely due to the reluctance to share mesoscale real time GNSS data and the need for station upgrades.

The IUGG, GEO and the ICG will address these challenges through a cooperative effort amongst the nations of the South Pacific, international and national organizations, and the private sector. Australia and New Zealand are operating high quality real time GNSS networks and analysis centers. However, there is little intra-regional networking amongst the nations of Oceania. We seek a regional GTEWS network that will serve as a prototype for the development of a Pacific-wide GTEWS capability. (Ref: GTEWS 2017)

Using GNSS receiver as a tsunami monitoring supplement: A case study of the 2023 M7.8 Turkiye earthquake

DOI: 10.57757/IUGG23-1721 - LINK

Haishan Chai[1], *Kejie Chen*[1]
[1]*Southern University of Science and Technology, Department of Earth and Space Sciences, Shenzhen, China*

Over the past years, with the rapid progress of Global Navigation Satellite System Interferometric Reflectometry (GNSS-IR) technique, near-shore geodetic GNSS receivers have been attempted to retrieve dynamic sea-level variation induced by storm surges and tsunamis. As the largest event since 1939, the 2023 M7.8 Turkiye earthquake not only caused terrifying building collapses on land but also generated observable tsunamis in the sea as recorded by coastal tide gauges. In this study, we thus try to verify the performance of GNSS-IR sea-level retrieval for tsunami monitoring based on GNSS data from IGS and TPGN(Turkish Permanent GNSS Network). Our preliminary findings show that, in spite of a continental strike-slip rupture, a tsunami with 30 cm wave height, following days of ocean resonance, is clearly seen by GNSS-IR, consistent with nearby tide gauge records. Furthermore, we also perform a finite source inversion to explore whether a submarine landslide contributes to the tsunami.

Our work demonstrates the capability of GNSS-IR for detecting medium and small tsunamis accurately. In fact, such geodetic GNSS receivers have been now well-deployed for co-seismic displacement monitoring and fast earthquake source characterizing for tsunami early warning in many places in the world. If more receivers can be installed near-shore, without extra operational costs, such a network will extend our tsunami observation power and improve the robustness of the tsunami early warning system.

Full integration of new data types into Indonesian Tsunami Early Warning System (InaTEWS) is among the enhancements being pursued at BMKG. Leveraging on external projects and partnership Real-Time Precise Point Positioning (RT-PPP) data from BIG have been integrated in the processing chain at BMKG. This GNSS data product has the potential contribute to faster and more accurate scenario selection and validation in case of large tsunamigenic events. Real-time waveforms displacement obtained with the method of Precise Point Positioning with Regional Augmentation correction (PPP-RA) and Precise Point Positioning with Ambiguity Resolution of the RT-PPP-Client, is thus acquired in SeisComP via a dedicated seedlink plugin developed within the project of Early Warning and Rapid ImpaCt Assessment (EWRICA) in the Mediterranean. Once integrated into SeisComP precise point positioning time series are integrated into the processing pipeline of the BMKG. We have successfully integrated RT-PPP processed by Geospatial Information Agency (BIG) into InaTEWS which is managed by the Meteorological, Climatological, and Geophysical Agency (BMKG). Next, waveforms will be used to improve and speed-up the earthquake parameter determination for large tsunamigenic events.

JS06a - Joint Inversion of Different Geophysical Data Sets (IASPEI, IAGA, IAG, IAVCEI)

Building probabilistic quasi-geology models and mapping mineral resources using joint inversion and geology differentiation

DOI: 10.57757/IUGG23-4333 - LINK

Jiajia Sun[1], *Xiaolong Wei*[1]
[1] *University of Houston, Department of Earth and Atmospheric Sciences, Houston, USA*

Multiple data sets are typically collected in an airborne survey. The standard way of interpreting multiple airborne data sets is to invert them separately to obtain a set of physical property models, e.g., a density contrast and a susceptibility model. There are two issues with this approach. First, it does not make use of the complementary information contained in different data sets. Secondly, it is not straightforward to interpret multiple physical property models in terms of geological structures and compositions. We propose a new workflow to integrate the information from multiple geophysical data sets and prior geology information, if available, into a 3D quasi-geology model. This new workflow has two components: mixed Lp norm joint inversion and geology differentiation. Joint inversion allows for the reconstruction of structurally consistent physical property models. Geology differentiation is a process of classifying the recovered physical property values into distinct classes, each of which is characterized by a unique range of physical property values and can be interpreted as an individual geological unit. We have applied this workflow to a set of airborne geophysical data over the Decorah area in northeast Iowa, USA, and successfully created a probabilistic quasi-geology model that informs the geological structures and compositions in this area. The workflow has also been applied to the multiple airborne data sets collected over the QUEST project area in British Columbia, Canada, to help map prospective areas of mineral resources.

Geothermal energy is an attractive renewable energy; however, its exploitation requires a sound knowledge of the nature, quality and boundaries of the reservoir to evaluate the resource potential and reduce the risk of induced seismicity. The purpose of this project is to use broad-band magnetotelluric (MT) data to investigate a medium-enthalpy geothermal zone in the region of Annecy, France. In this pre-alpine area, karstic limestones constitute a deep aquifer (up to ~2 km) intersected by the Vuache fault, an active strike-slipe fault where a M5.3 earthquake occurred in 1996.

A data set of 27 MT sites was acquired, with generally all 5 components measured. Data quality was mostly satisfactory up to 3 Hz and sometimes up to 1 s. Major problems were related to the presence of electromagnetic noise in this urbanized region, mitigated by the careful use of advanced processing methods (FFMT). For the 3-D inversion required by the data (phase tensors, WAL, topography), we have chosen a joint inversion of induction vectors, phase tensors and off-diagonal impedances (previously corrected for static shift with help of phase tensor inversion and few TDEM measurements). This allowed us to obtain a suitable 3D model using the ModEM inversion code, explaining all three data types reasonably well.

We aim at the integration of the obtained resistivity models with already existing results (seismic reflection, borehole information) into a geological model, which will be used within re-inversion of the MT data by turning off the smoothing across interfaces detected by seismic reflection.

In recent years, joint inversion of magnetotelluric (MT) and seismological receiver function (RF) methods has provided valuable information about crustal structures and demonstrated a complementary tool. Joint inversion of such datasets that are not well correlated physically has been generally applied as structurally coupled in the literature. These are based on constraining the directions of parameter changes by a spatial regularization operator and placing their spatial changes at similar positions. However, the electrical conductivity and seismic velocity, which are the model parameters for MT and RF, may have different characteristics for the changes in the crustal zone, such as porosity, permeability, and temperature, and the unpredictable relationship between these parameters prevents full correlation. In this study, we jointly inverted the MT and RF data utilizing Pareto-based multiobjective particle swarm optimization (MOPSO) based on a structurally constrained approach without restricting the direction of the model parameters and compared the results with structurally coupled approach. MOPSO, which overcomes the difficulties of traditional inversion such as the dependence on the initial model and the trapping of local minima, achieves a global solution without requiring a regularization operator for either the model parameters or misfit functions. The presented approach was verified on synthetic models and an application from field data obtained from measurements at a single station on the Biga Peninsula in Turkey. The results of these analyses confirm the usefulness of the method as a new approach for joint inversion of geophysical data sensitive to different physical phenomena.

Landslides represent one of the greatest challenges of modern earth sciences. Vulnerable to external as well as anthropogenic factors, these phenomena require extensive research and monitoring of zones at risk of their occurrence. In this work we present an integrated approach to such phenomena, using the example of a landslide in the Outer Carpathians. In the case described, active seismic methods such as reflection imaging, refraction tomography and surface wave analysis were combined with electrical resistivity and magnetic methods. The entire data set is complemented by a detailed terrain model made using the TLS technique and passive seismological monitoring from 5 temporary broadband stations located around the landslide. The result of 4 years of observations is an accurate image of changes in the landslide zone at very high resolution, with analysis of uncertainty. As a result of the study, it was possible to separate the natural triggers of the landslide, from the anthropogenic ones, as well as to determine the influence of each type on the evolution of the slip zone. The presented research is an important example for problems of much greater strategic importance, where similar effects are to be expected in the results of observed climate changes.

This research was funded by the National Science Centre, Poland (NCN), grant number 2020/37/N/ST10/01486.

Determining high-resolution lithospheric structure by joint inversion of body wave arrival times, surface wave dispersion data and receiver functions

DOI: 10.57757/IUGG23-1162 - LINK

Haijiang Zhang[1], *Shoucheng Han*[1], *Aowei Hao*[1], *Ying Liu*[1]
[1]*University of Science and Technology of China, School of Earth and Space Sciences, Hefei, China*

Different types of seismic data, including body wave arrival times, surface wave dispersion data and receiver functions, have been widely used to determine the lithosphere structure through seismic traveltime tomography, surface wave tomography and receiver function imaging, respectively. However, different data types have different strengths on resolving the lithospheric structure. For example, seismic traveltime tomography using body wave arrivals only better resolves the structure where ray paths are dense and generally the shallow structure is poorly resolved. Surface wave tomography can determine the shallow structure well if shorter periods of dispersion data are available but generally has poorer model resolution in depth. In comparison, receiver function imaging can resolve the interfaces in depth but is not very sensitive to the absolve velocity changes. Therefore, it is necessary to develop a joint inversion algorithm to combine these different seismic data to better determine the lithospheric structure.

We have developed a new joint inversion method that incorporates body wave arrival times, surface wave dispersion and receiver functions to simultaneously update earthquake locations and constrain three-dimensional P-wave (Vp) and S-wave velocity (Vs) models. Synthetic tests demonstrate the advantages of this new joint inversion algorithm in resolving velocity structures, especially in constraining velocity gradients across the Moho interface. We have applied the new algorithm to different tectonic regions including south China, north China, and southwest China. Combined with geochemical data, we have gained new insights on the lithospheric structure of these regions.

[3]*ISTerre, Volcano geophysics and geothermics, Le Bourget du Lac, France*

Magma is a viscous fluid that can propagate through the crust by fracturing rocks and flowing through them. These magma-filled fractures are called dykes. Magma pressure is the force ensuring the opening of the fracture and maintaining the magma flow. We combine numerical modeling with geophysical data to explore the dynamics of dyke propagation. Although physics-based models provide simplified but reliable representations of dykes, few account for the full interaction between rock fracturing and magma viscous flow. They are limited to planar fracture propagation, and cannot address any change in the direction of propagation of an intrusion. To overcome this challenge, we developed a modeling scheme for the propagation of magmatic dykes by implementing viscous flow equations in an existing 2D boundary element model. Given the crustal stress state, the physical parameters of the crust and magma, and the initial geometry of the fracture, our model allows to jointly estimate the shape, trajectory and velocity of a dyke. Once the results of the model have been validated with analytical solutions, we applied it to the vertical propagation of the 1998 intrusion at Piton de la Fournaise (La Réunion Island). We constrained part of the model parameters with observations and varied the dyke length and the fracture toughness of the rocks, obtaining different propagation velocities, which we compared with the spatio-temporal evolution of volcano-tectonic events recorded before the eruption. Finally, the best-fit solution of this forward method is put into perspective with previous deformation sources resulting from geodetic data inversion.

The joint analysis of multiparametric datasets in geophysics and, in general, in geosciences is often challenging due to the highly different measurement types. During the last decades, data mining techniques have been subject to intense development, which allows the detection and characterizing of "hidden patterns" within complex datasets.
One of the most successful and widely used techniques is the Independent Component Analysis (ICA) which allows for identifying spatio-temporal patterns related to independent sources from dense geospatial datasets. In this work, we apply an extension of the ICA named Independent Vector Analysis (IVA) to analyze a multiparametric dataset of spontaneous potential, CO_2 and H_2S flux and thermal gradient measurement realized in the crater of Mt. Teide (Tenerife, Canary Islands), from 2020 to 2023. While ICA allows studying spatio-temporal patterns of a single quantity, IVA allows dealing with means multiparametric measurements realized on a single point, which means using vector data instead of a simple scalar.

The relationship between spontaneous potential and gas emission is well known and testified by numerous case studies. In this work, however, we exploit for the first time this quantitative approach to separate and characterize endogenous and external factors in this dataset. The approach we propose in this work has a broader application to repeated multiparametric geophysical surveys and in combining geophysical datasets with other kinds of data.

Dealing with sparse geophysical data interpretation, limits of gravity inversion

DOI: 10.57757/IUGG23-0094 - LINK

<u>Lucian Besutiu</u>[1], Luminita Zlagnean[2]
[1]Institute of Geodynamics of the Romanian Academy, Solid Earth Dynamics, Bucharest, Romania
[2]Institute of Geodynamics of the Romanian Axcademny, Solid Earth Dynamics, Bucharest, Romania

The paper addresses consequences of an inappropriate geophysical observations' coverage on the quality of data interpretation. For instance, investigation of volcanic areas often faces the problem of data scarcity due to access difficulties. The case study of Ciomadul, the youngest volcano in the Carpathian-Pannonian region has been considered. Previous research, based on sparse MTS data inversion had suggested the presence of a large magma chamber beneath it, at a relatively shallow depth, raising the issue of the volcanic hazard. A subsequent joint gravity and magnetic survey outlined a mass deficit beneath the volcano, overlapping the electrical resistivity anomaly outlined by previous electromagnetic survey and interpreted as an active magma chamber.

Anyway, geological interpretation of the gravity inversion proved to be misleading as long as the suggested model was not supported by results of the geomagnetic inversion and geological constraints. Consequently, limitations of the gravity inversion were subject to basic research. It demonstrated that (quasi) one-dimensional sources such as low-density narrow volcanic conduits (having cross-section size inappropriate to the survey's Nyquist frequency) may be reflected by gravity inversion as three-dimensional mass deficits due to an inappropriate spacing between observations.

Given the shortcomings revealed, gravity data were re-interpreted by jointly employing the inversion results and forward modelling approach, and a new model of the volcano structure has been proposed. It substitutes the formerly assumed magma chamber by a well-developed plumbing system with volcanic conduits of high fluid content, including electrolytes that may also fully justify the geoelectric anomaly previously outlined.

The paper addresses consequences of an inappropriate geophysical observations' coverage on the quality of data interpretation. For instance, investigation of volcanic areas often faces the problem of data scarcity due to access difficulties. The case study of Ciomadul, the youngest volcano in the Carpathian-Pannonian region has been considered. Previous research, based on sparse MTS data inversion had suggested the presence of a large magma chamber beneath it, at a relatively shallow depth, raising the issue of the volcanic hazard. A subsequent joint gravity and magnetic survey outlined a mass deficit beneath the volcano, overlapping the electrical resistivity anomaly outlined by previous electromagnetic survey and interpreted as an active magma chamber.

Anyway, geological interpretation of the gravity inversion proved to be misleading as long as the suggested model was not supported by results of the geomagnetic inversion and geological

constraints. Consequently, limitations of the gravity inversion were subject to basic research. It demonstrated that (quasi) one-dimensional sources such as low-density narrow volcanic conduits (having cross-section size inappropriate to the survey's Nyquist frequency) may be reflected by gravity inversion as three-dimensional mass deficits due to an inappropriate spacing between observations.

Given the shortcomings revealed, gravity data were re-interpreted by jointly employing the inversion results and forward modelling approach, and a new model of the volcano structure has been proposed. It substitutes the formerly assumed magma chamber by a well-developed plumbing system with volcanic conduits of high fluid content, including electrolytes that may also fully justify the geoelectric anomaly previously outlined.

In March 2021 an earthquake sequence, including three Mw ~6 normal fault earthquakes on the 3rd, the 4th and the 12th of March, shook Thessaly in central Greece. The epicentres of the three mainshocks propagated northwestward to rupture the northern tip of a large-scale (>100 km) fault relay structure that traverses central Greece. InSAR analysis coupled with field investigations show that only the first and largest earthquake is characterized by a clear rupture that reached the surface along a mapped fault with sharp geomorphic signature. In contrast, the following two large earthquakes were blind, despite the presence of clear pre-existing fault traces near the respective epicentres. Here, we present a kinematic source optimization for which we combine teleseismic waveforms, InSAR and GNSS displacements together with geological constraints to estimate the first-order rupture parameters for location, geometry, slip mechanism and rupture dynamics. This multidisciplinary approach provides a robust source solution, particularly for the first two earthquakes that occurred less than 24 hours apart. The short interval between these events means that with InSAR data the two ruptures were only separately imaged from ascending satellite look direction. In our optimization we consider the individual data errors in data weighting and we perform a fully Bayesian source model uncertainty analysis. Our results reveal the sequential activation of at least 8 individual faults along the relay fault zone, including numerous syn-seismically activated secondary faults. These, together with remapping and analysis of regional faults, reveal the presence of a mature large-scale relay zone.

Crustal rheology and seismicity in the eastern Central Asian Orogenic Belt and its tectonic implications

DOI: 10.57757/IUGG23-0336 - LINK

Peng Yang[1], Shaowen Liu[1,2]
[1]*Nanjing University, School of Geography and Ocean Science, Nanjing, China*
[2]*University of Tokyo, Earthquake Research Institute, Tokyo, Japan*

The Central Asian Orogenic Belt (CAOB), located between the Siberia and Baltica cratons to the north, and the Tarim and North China cratons to the south, is a large and long-lived accretionary orogen that extends from the Urals in the west through Kazakhstan, Magnolia, China to the Okhotsk Sea in Russia, with the ocean closing during Neoproterozoic to the Late Phanerozoic. Quaternary volcanoes and earthquakes are widespread in the northeastern China of eastern CAOB, along with high heat flow background, obviously affected by the subduction of the Pacific slab; however, the range and manner of this subduction effects still remain elusive. Seismogenic depths in northeastern China show that, bounded by the Great Xing'an Range, the seismicity in the west is diffusely distributed in the crust, with a bimodal pattern as the upper and middle/lower crust (15-25 km); while for the east area, the seismicity only occurs in the upper crust (~15 km). Rheological modeling demonstrates, only the rheologically weak crust in the east with wet condition and strong crust in the west with dry condition, can reconcile the observed seismicity, suggesting the control of differential crustal rheology. Combing with other geological and geophysical observations, we propose that the stagnation and associated dehydration of the subducted Pacific slab underneath the northeastern China could account for this rheological contrast. Our findings further confirm that the North-South Gravity Lineament in East China, geographically representative of the Great Xing'an Range-Taihang Mountain, as a large-scale tectonic boundary, marks the westward limit of the subduction.

Stable stratified layer near CMB plays a significant role both on the flow pattern in the outer core, as well as the morphology of the geomagnetic field. Using a radially varying heat source various temperature profiles have been generated. These profiles are characterised based on the presence of a stable stratified layer, of varying thickness, near the outer boundary. The dynamics of the Earth's outer core convection is the central focus of this study. Heat flux variation at the outer boundary, with three different amplitudes of spherical harmonic pattern, is imposed to mimic core-mantle thermal interactions. The flow structures are analysed based on the vorticity dynamics and the role of helical flow structures, responsible for dynamo action and generating magnetic fields. It is observed that although the anticyclonic helicity is dominant over the cyclonic helicity, positive heat flux promotes the cyclonic helicity whereas the negative heat flux promotes the anticyclonic helicity in strongly driven convection. In rapidly rotating regime, thicker stratified layer tries to damp the magnetic field across the layer resulting in a large scale field at the CMB. Finally, it is also seen that high heat flux boundary forcing causes the dynamo action to fail.

The core-mantle boundary (CMB) is one of the most stable interfaces inside the Earth due to the large density and viscosity contrasts. Despite significant differences in physical, chemical, and transport properties, the possible mechanisms where the core and mantle can interact has become an active area of research. Detection of chemical signatures from the CMB can provide an unprecedented glimpse into the Earth's deep interior and ancient past, with some studies suggesting certain isotopic and elemental anomalies in ocean island basalts to be core tracers. However, there is still uncertainty regarding processes that can convey chemical signatures from the core to the mantle. A recent study proposed a new hybrid mechanism that results from collaborative feedback between dynamic topography, percolation of liquid metal into submerged rock, the gravitational collapse of a metal-silicate mush, and induced small-scale mantle circulation above this mushy layer. The grain-scale intrusion of liquid iron into mantle rocks offers an opportunity for chemical and isotopic exchange to take place, while the gravitational collapse of the mushy layer can "soften" the CMB and enhance downwellings, thereby encouraging further chemical exchange. Using a mantle convection model coupled to the gravitational spreading of a thin layer at the CMB, we will show how the enhancement of downwellings change with the rheology of the mantle, and if the reacted mantle materials emerge from the mushy layer with a certain buoyancy ratio, how much of it will be entrained in upwelling plumes.

It has been proposed that magnetic flux expulsion due to outer core fluid upwellings may affect the geomagnetic secular variation on the core-mantle boundary (Bloxham, 1986). In this process intense horizontal field lines are concentrated below the outer boundary, introducing small radial length scales and consequently strong radial diffusion. We explore such magnetic boundary layers in numerical dynamo simulations with heterogeneous outer boundary heat flux inferred from a tomographic model of lower mantle seismic shear waves velocity anomalies. Our scheme associates magnetic boundary layers to peak horizontal magnetic fields at the top of the shell. In our models mean magnetic boundary layer thickness ranges ≈200-400 km and decreases with increasing magnetic Reynolds number. Extrapolation or interpolation to Earth's core conditions based on total core flow amplitude or its poloidal part gives mean magnetic boundary layer thickness of ≈220 and ≈260-330 km, respectively. We find magnetic boundary layers associated with the azimuthal field at the equatorial region, whereas magnetic boundary layers associated with the meridional field are found at mid latitudes. Negative outer boundary heat flux anomalies yield preferred locations of expulsion of azimuthal field below Africa and the Pacific (at low latitudes of the Northern Hemisphere.), while positive outer boundary heat flux anomalies yield preferred locations of expulsion of meridional field below the Americas and East Asia. Our results suggest that the local diffusion time is on the order of several kyr and the local magnetic Reynolds number is on the order of ≈10, both much smaller than classical estimates.

Precession-driven flows and turbulence in planetary liquid cores

DOI: 10.57757/IUGG23-0849 - [LINK]

Jeremie Vidal[1], *David Cébron*[1]
[1]*CNRS - Université Grenoble Alpes, ISTerre, Grenoble, France*

The deep interior of planets can be indirectly investigated using rotational motions such as precession or nutations. Turbulent flows driven by precession have also been proposed for generating dynamo in planetary cores (e.g. to explain the early Earth or Moon's paleofield). In the frame of the ERC THEIA, we focus on bulk turbulent flows that are promising for planetary applications (since they are driven by topographic effects instead of viscosity). To probe the low-viscosity regime of planetary interiors, we investigate precession-driven flows in stress-free ellipsoids using asymptotic analysis and simulations. Contrary to previous expectations, we show that this model could unlock numerical difficulties of no-slip simulations. In a regime relevant to planets, we obtain the flow forced in triaxial cores, exhibiting a second mode resonance. Then, we investigate the transition towards turbulence through the bulk instabilities driven by precession in ellipsoids (the conical-shear instability and the inertial instabilities). We also provide scaling laws for the saturation amplitude of these instabilities, which are relevant for planetary applications but often hampered in experiments or no-slip simulations. Then, we study the dynamo capability of these flows for the Earth and Moon over geological times. Finally, we outline that precession could interact nonlinearly with the nutations, which might be key to interpret the dissipation at the core-mantle boundary observed in the nutation data.

Topographic coupling in the outermost stratified layer of the Earth's core

DOI: 10.57757/IUGG23-0848 - LINK

Rémy Monville[1]*, David Cébron*[1]*, Dominique Jault*[1]
[1]*CNRS- Université Grenoble Alpes, ISTerre, Gieres, France*

The accurate tracking of the Earth's rotation allows us to constrain the coupling between the liquid core and the mantle. However, despite well-constrained values, the coupling mechanisms are still disputed. These couplings are not straightforward to calculate and can originate from pressure, gravity, viscous, or electromagnetic forces. Studies have therefore studied whether these observations can be due to the laminar dynamics of a stratified fluid layer, below a bumpy Core-Mantle boundary (CMB). Investigating the stress generated by the flows in this thin layer, they concluded that they could explain the observed Earth length-of-day variations (Jault, 2020; Glane, 2018) or the dissipation of the annual nutation (Buffett, 2010). However, these conclusions rely on leading order perturbative calculations, sometimes applied beyond their range of validity e.g. by using too high topographies, in addition to having been performed under multiple assumptions. Our code, based on plane-wave perturbations in a local reference frame, allows us to estimate the torque at the CMB using mixed high-precision symbolic calculations. We calculate "higher-order" solutions that go beyond the forced-wave linear regime. This new method explores a wide range of parameters and boundary conditions for arbitrary topography shapes. We also consider the spherical geometry via spatial integration, which includes the lateral variations of the magnetic field and the rotation vector's orientation.
Funded by ERC THEIA (grant agreement no.847433)

The instabilities that arise in a rotating plane layer due to imposed vertical temperature form the basis of fluid flow structures in outer Earth's core. The temperature profile in the Earth's outer core, being affected by various conditions such as secular cooling, bottom heating at the inner core surface, is believed to be modulated by thermal conditions near the core-mantle boundary. The present study investigated the role of such modulations by imposing a layer of stably stratified fluid near the top boundary and imposing a sinusoidal temperature variations over and above the reference case of isothermal condition used in the classical Rayleigh–Benard convection. Such conditions result in the top–bottom flow asymmetry that cause flow localization and changed temporal dynamics compared to the classical Rayleigh–Benard cells. The minimum buoyancy forcing required for convection is also lowered with flows in surplus heat flux regions. The flow suppression in the stable layer is overcome by the effects of rapid rotation enhancing the penetration of convection columns with smaller length scales. The heterogeneous temperature conditions imposed at the top boundary also cause axially penetrative convection instabilities unlike the reference case. The onset of oscillatory convection modes is dominant in low Prandtl number cases, which is relevant to the Earth's core conditions. The dominance of Coriolis force for rapid rotation cases causes a traveling wave instability, the propagation direction of which is determined by the heat flux occurring at the top boundary.

The Earth's interior, particularly the Earth's fluid outer core, possesses a broad dynamics of processes involving mass variations. Theoretical models predict variations of the gravity field at low degrees and at inter-annual / decadal time scales. These include dynamic pressure changes at the Core Mantle Boundary (CMB) associated with core flows reconstructed from geomagnetic observations and reorientation of the inner core controlled by gravitational coupling with the mantle. The hypothetical effects due to some dissolution/crystallization at the CMB introduce a time-varying roughness of the interface. Taking into account these considerations, for the first time, we investigate the density and pressure changes obtained from magneto-hydro-dynamics (MHD) simulations that reproduce geomagnetic jerks.

Besides the geomagnetic information, we also are interested in exploiting long series of gravity measurements. The time-variable Earth's gravity field is measured by satellite missions such as GRACE and GRACE Follow-On and by Satellite Laser Ranging (SLR). These products enable to study continental hydrology, oceanic and atmospheric loading, post-glacial rebound, glaciers, earthquakes and other phenomena that involve mass variations. The comparison of GRACE and SLR gravity field variations with Earth's core predicted signals gives new inputs on parameters of the Earth's core processes. This study provides new upper-bound values for pressure anomalies at the CMB and angle of reorientation for the inner core.

Separation of core and lithospheric signals in satellite magnetic data

DOI: 10.57757/IUGG23-2850 - LINK

Mikkel Otzen[1], Christopher Finlay[1], Clemens Kloss[1]
[1]Technical University of Denmark, DTU Space, Lyngby, Denmark

Satellite observations of the geomagnetic field contain signals that originate both from electrical currents in the core and from magnetized material in the lithosphere. At short wavelengths the lithospheric signal dominates, obscuring the signal from the core. The standard procedure is to simply take the internal field up to spherical harmonic degree 13 to be the core field. Here we demonstrate that separate models of the core and lithospheric fields, overlapping in spherical harmonic degree, can be co-estimated provided one makes use of relevant prior information on the sources. Using a maximum entropy modelling approach, we find models for the time-dependent core field and static lithospheric field that satisfy the constraints provided by satellite observations, as well as statistical prior information on the sources (the expected variance and correlation functions for the radial field), but are otherwise maximally non-committal with regard to the distribution of radial magnetic field at the source surfaces. Tests using synthetic data are encouraging, indicating that using our approach it is possible to retrieve parts of the core field beyond degree 13 and the lithospheric field below degree 13. Results for the time-dependent field at the core surface up to spherical harmonic degree 30 will be presented and implications for our understanding of the core dynamo, in particular its high latitude flux patches, the field structure inside the tangent cylinder, and the nature of westward drifting field concentrations at low latitudes, will be discussed.

Here we demonstrate that separate models of the core and lithospheric fields, overlapping in spherical harmonic degree, can be co-estimated provided one makes use of relevant prior information on the sources. Using a maximum entropy modelling approach, we find models for the time-dependent core field and static lithospheric field that satisfy the constraints provided by satellite observations, as well as statistical prior information on the sources (the expected variance and correlation functions for the radial field), but are otherwise maximally non-committal with regard to the distribution of radial magnetic field at the source surfaces. Tests using synthetic data are encouraging, indicating that using our approach it is possible to retrieve parts of the core field beyond degree 13 and the lithospheric field below degree 13. Results for the time-dependent field at the core surface up to spherical harmonic degree 30 will be presented and implications for our understanding of the core dynamo, in particular its high latitude flux patches, the field structure inside the tangent cylinder, and the nature of westward drifting field concentrations at low latitudes, will be discussed.

Intradecadal variations in the length-of-day (ΔLOD), once corrected for atmospheric effects, can reveal changes in angular velocity interpreted as due to Earth's core. Previous studies have identified periodic oscillations of around 6 and 8 years (6YO and 8YO, respectively). To complement widely used Fourier methods, we investigate the ΔLOD record from 1962—2023 in the time domain, seeking smooth variations using cubic splines.

We analyse in several ways. A smooth (but not band limited) curve fit with least-squares splines allows removal of the long-term behaviour of ΔLOD. We then fit the residual with a pure cosine-wave of varying period but examine the data fits carefully in case the signal is non-stationary (for example from impulsive forcing). Alternatively, a penalised least-squares spline fit allows isolation of coherent variations from analysing the first and second derivatives.

All approaches show clear evidence of signals with periods around 6 and 8 years. Earlier work (Holme and de Viron 2013) focussed on a 5.88 year variation for the period in 1962—2010, although, this appeared to break down, with the next extremum following in only 4 years. However, the next maximum has appeared in 2021, consistent overall with an approximate 6 year variation. We explain this from periodic discontinuities in the 6YO with an ~8 year period, providing a new explanation for the nature of the 8YO as an episodic rather than harmonic signal. Given that frequency-domain based methods do not treat discontinuous signals, this feature will be lost using Fourier theory.

Investigating the dynamics of liquid iron at the top of the core requires an inversion process from magnetic field measurements. Due to possible leakage, traditional spectral techniques are not optimal for regional investigations or studies of Secular Variation (first time derivative of magnetic field, SV) on short-time periods. Improved data coverage and quality from satellite missions have provided insight into short-period dynamics (such as jerks and waves), and improved understanding of localised features. However, there continues to be a need for new techniques for better spatio-temporal models of flow motions at the top of the core, especially for regional investigations.

The aim of this work is to investigate regional dynamics at the Core-Mantle Boundary (CMB) using the SOLA (Subtractive Optimally Localised Averages) methodology. This method allows us to create point estimates of radial field SV at the CMB by considering global satellite measurements. The SOLA methodology allows for a local estimate of radial field SV at any desired location directly at the CMB, which opens the way to investigations of regional dynamics. Producing localised-average estimates at the CMB bypasses many problems encountered when using only a subset of magnetic satellite data, downward continuing data, and models based on spherical harmonics.

Finally, we discuss how the SOLA methodology can be incorporated into the PyGeodyn code to produce core flow models. This approach can provide additional information on wave-like flow motions at the top of the Earth's core where these are most prominent, and permits new investigations of shorter period phenomenon.

Our knowledge of the Earth's liquid core dynamics is based on indirect information sources. One of the crucial information comes from the geomagnetic field observations, which can be used to infer variations of the fluid motion at the top of the core. The dynamic of the fluid core is associated with redistributions of the internal mass, which feature density heterogeneities, and the exchange of angular momentum with the solid Earth. Consequently, these processes occurring in the core can produce signatures in the gravitational field. Previous studies indicate that the leading mode of the global temporal gravity variations can be correlated with the leading mode of secular acceleration of the radial geomagnetic field. In this study, by applying several statistical Blind Source Separation (BSS) methods, we investigate the common space-time variabilities that emerge in the geomagnetic and gravity fields. Oscillations around 6-7 years are present in most of the analyses of both fields. The common areas where both magnetic and gravity field exhibit such variations include the South-Pacific Ocean, the northern part of Africa, and India. We note that 6-7 year oscillation in the geomagnetic field has also been reported in some previous studies as a mode attributed to the Quasi-Geostrophic (QG), Magneto-Coriolis (MC) and Alfvén waves in the liquid core. The possible causes for such oscillations in the gravity field are still under investigation.

Numerical simulations of the geodynamo are used to investigate the transfer of angular momentum between the core and the mantle, in the presence of both an electro-magnetic torque and a gravitational torque between the inner core and the mantle. Over a broad range of periods, angular momentum changes are accurately explained when deriving geostrophic motions (organized as cylinders co-axial with the Earth's rotation vector) from core surface motions. Inverted core surface flows can thus be used to infer the core angular momentum budget. In the dynamo, the largest part of the EM torque variations is associated with the evolution of the solid body rotation, with little contribution from electrical currents originating deep inside the core (the "leakage torque", formerly associated with the westward drift of the geomagnetic field). A 1D model of geostrophic motions is furthermore used to estimate the efficiency of torsional eigenmodes to couple with the solid Earth. From this we revisit the estimate of the mantle conductance from 1D simulations of geostrophic motions stochastically forced in the volume. We then discuss the ability of torsional waves to trigger the interannual oscillations observed in the length-of-day series, and the relative importance of forcing versus resonances in angular momentum changes at various time-scales.

The large-scale electrical conductivity structures in the deep Earth's mantle can be in principle determined from Swarm-observed induction response to time-variable magnetospheric currents. Here we present a new sensitivity study based on the 3-D time-domain modelling of the electromagnetic induction in the Earth's mantle, aimed at the lowermost mantle. So far, these efforts have been encumbered by limited spatio-temporal description of the magnetospheric field from moving satellite platforms. In particular, the polar electrojets (PEJs) and field-aligned currents (FACs) are sources of a strong bias in the spherical-harmonic analysis of Swarm magnetic data. Our approach exploits the recently introduced improvements to the processing of Swarm magnetic data. An electric circuit model of PEJs and FACs provides a novel data processing tool to suppress the bias and provide a reliable model of the large-scale magnetospheric field during magnetically disturbed times. In this contribution we determine the sensitivity and resolution of the inverse problem, and proceed with regularized 1-D and 3-D inversions to update the electrical conductivity model of the lower mantle.

The variations of the Earth's length of day (LOD) exhibit several interannual oscillations. The first detected one, with a period of 5.9-year, is better seen after removing the atmospheric contribution. More recently was isolated an oscillation of period ~8.5-year, distinct from the previous one. Torsional waves could explain both signals, although recently discovered non-axisymmetric magneto-Coriolis waves may also be involved. With a much smaller amplitude, a 7.3-year fluctuation was also detected in LOD data but no physical mechanism has been proposed. We show using a continuous wavelet transform analysis of synthetic oscillators embedded into a random noise, the limits of isolating damped signals with nearby periods in time series of limited duration. In particular, we emphasize the possibility that the 7.3-year oscillation could originate from an artifact due to the restricted length of the LOD series. Finally, we perform a wavelet coherence analysis between geodetically observed LOD variations and predicted LOD changes from geomagnetically inferred core flow models. Observed coherence at 5.9-year and ~8.5-year periods most probably confirms the fluid outer core origin for these two oscillations. Two coherent oscillations around 3.5 and 5-year periods are also conspicuous. Torsional Alfvén waves and/or Quasi-geostrophic magneto-Coriolis waves are natural explanations to the presence of various quasi-periodic signals in the LOD at interannual time-scales.

Core surface flow inversion using physics-informed neural networks and dynamic mode decomposition of the core flow

DOI: 10.57757/IUGG23-1274 - [LINK]

Yufeng Lin[1], *Jinfeng Li*[1]
[1]*Southern University of Science and Technology, Department of Earth and Space Sciences, Shenzhen, China*

In this study, we use physics-informed neural networks to inverse the core surface flow from the geomagnetic observations. We start from the radial component of the induction equation under the frozen-flux approximation and tangentially geostrophic flows assumption. We retrieve the core surface flow field between 2000 and 2020 using the core magnetic field model CHAOS-7. We then perform the dynamic mode decomposition for the retrieved core flow. This method decomposes the flow field and SV into several eigenmodes with time evolution. The consistency time evolution between the flow and the SV modes indicates the inversion algorithm is stable. Moreover, we calculate the secular acceleration (SA) of the magnetic field for each dynamic modes and find the mode with a period of about 8 years can match the jerk events occurred in the equatorial region.

Hydromagnetic Waves in the Equatorial Region: Analysis Using Dynamic Mode Decomposition and Complex Empirical Orthogonal Functions

DOI: 10.57757/IUGG23-2128 - LINK

Rodrigo Chi-Durán[1], *Bruce Buffett*[1]
[1]*University of California- Berkeley, Department of Earth and Planetary Science, Berkeley, USA*

Short-period fluctuations in the Earth's geomagnetic field have been observed through satellite observations over the past 20 years. Our previous study (Chi-Durán et al., 2020) found evidence of eastward and westward traveling waves with periods of 7.08 ± 0.58 and 15.73 ± 4.44 years, respectively, in the Atlantic and South Asia regions. These estimates were obtained by applying complex empirical orthogonal functions (CEOFs) to the geomagnetic secular acceleration from localized regions of the CHAOS6 model (Finlay et al., 2016). More recently, we have applied dynamic mode decomposition (DMD) to investigate the temporal evolution of the radial magnetic field (Br) and secular variation (SV) at high latitudes using CHAOS7 (Finlay et al., 2020). In this study, we extend the DMD analysis to the entire equatorial region using Br and SV. We discover traveling waves with propagation directions and periods close to those detected using COEFs. The consistency of the two results points to a common underlying dynamics in the CHAOS models. An unexpected advantage of the DMD method is that it can recover localized dynamics, even when applied to a much broader region (i.e. the entire equatorial region). These findings emphasize the potential of DMD as a tool for identifying traveling magnetic waves in the core and provide an additional understanding of CEOFs. These results are significant for comprehending the dynamics of the geomagnetic field and its impact on the Earth's outer core structure.

New heat flow measurements in the Alboran Sea, westernmost Mediterranean Sea

DOI: 10.57757/IUGG23-0737 - LINK

Frederique Rolandone[1], Sylvie Leroy[1], Jeffrey Poort[1], Léa Vidil[1], Alana Oliveira de Sa[1], Elia d'Acremont[1], Sara Lafuerza[1]
[1]Sorbonne Université, ISTeP, Paris, France

15 new heat flow measurements were obtained during the ALBACORE cruise (R/V Pourquoi Pas ?) in 2021 in the Alboran Sea, the westernmost part of the Mediterranean Sea. Temperature gradients were measured using autonomous thermal probes attached to sediment corers with a length of 6 meters. Thermal conductivity was measured onboard using a needle probe instrument on recovered sediment cores. In previous studies, a large difference in heat flow has been observed between the western and eastern parts of the Alboran Basin, 69 ± 6 mWm^{-2} versus 124 ± 8 mWm^{-2}. Here we focus on the mainly North-South Bokkoya and Al Idrissi active strike-slip fault zones between these two domains. Three heat flow profiles were performed perpendicular to the fault zones that show a marked difference in heat flow values along and between these profiles. The northern profile, 2.5 km long, indicates a homogeneous heat flow with a mean value of 65 mWm^{-2}. The middle profile shows a heterogeneous heat flow with a mean of 81 mWm^{-2} and variations of ± 30 mWm^{-2} over a 400 m distance. The southern profile indicates high and heterogeneous heat flow values varying between 155 and 204 mWm^{-2} over the 550 m long profile. These local thermal anomalies could be associated with hydrothermal activity along the fault segments. Transport of heat by hydrothermal circulation has been observed in different geological settings. In the Alboran sea basin, some segments of the active fault zones may thus display suitable pathway for hydrothermal circulation.

Heat flow density measurements in offshore continental crust

DOI: 10.57757/IUGG23-3382 - LINK

Maria Rosa Duque[1]
[1]*Universidade de Évora, Physics, Evora, Portugal*

The heat flow in offshore sedimentary basins may be measured using techniques developed for marine domain or using data acquired in wells drilled in oil/gas prospecting works. Sometimes the depth reached in these wells may be very different in relatively close wells. In the deepest wells heat flow variations with depth can be studied and the differences in heat flow values at the surface may be explained.

The problem is ilustrated using a real exemple with heat flow density values obtained in a region located in the Southern border of the Eurasion plate in three wells, located at similar latitudes, drilled for oil/gas prospecting works. The region has been studied by several teams trying to obtain a tectonic model, without sucess until now.

The heat flow density values obtained in two of the wells are similar but in the third well, the deepest one, the heat flow value is the highest. Gamma-ray,density and porosity logs were used to obtain information about heat sources and thermal conductivity values in depth. The results obtained in the third well show an increase of heat flow with depth, possibly related with turbidity currents in the region and horizontal movement of matter (water and sediments) and heat release by advection.

Heat flow and thermal structure of the South China Sea

DOI: 10.57757/IUGG23-0334 - LINK

Wenjing Zhu[1], *Shaowen Liu*[1,2]
[1]*Nanjing University, School of Geography and Ocean Science, Nanjing, China*
[2]*The University of Tokyo, Earthquake Research Institute, Tokyo, Japan*

As the biggest marginal sea in western Pacific region, the South China Sea (SCS) has attracted increasing attention owing to its resource potential and environmental capacity. However, the origin and opening process of the SCS remains elusive. Thermal imprints could provide clues for regional tectonics. This paper aims to decipher the thermal state of the SCS integrating the IHFC heat flow dataset with new measurements (a total of 902 measurements). Results show the SCS has an average heat flow of 75 mW/m^2, and nearly 80% of the heat flow values range between 50-100 mW/m^2, indicative of a hot basin in geothermal characterization. Heat flow pattern of the SCS shows remarkable lateral variations in different tectonic units. Among which, the Central Oceanic Basin exhibits the highest heat flow, and the average values of the northwest sub-basin, the southwest sub-basin and the eastern sub-basin are 98 mW/m^2, 99 mW/m^2 and 91 mW/m^2, respectively. Both the western margin and southwestern continental margins are characterized by generally high heat flow accompanied with large faults. The heat flow in the northern margin increases from the continental shelf to the slope, as a result of differential crustal extension. In contrast, the eastern margin is quite cold, owing to the subduction induced cooling effect. The thermal structure shows that heat flow from mantle is dominative in observed seafloor heat flow. Besides, local heat flow anomalies within the SCS can be attributed to hydrothermal circulation, magmatic activities and sediment thermal effects.

Results show the SCS has an average heat flow of 75 mW/m^2, and nearly 80% of the heat flow values range between 50-100 mW/m^2, indicative of a hot basin in geothermal characterization. Heat flow pattern of the SCS shows remarkable lateral variations in different tectonic units. Among which, the Central Oceanic Basin exhibits the highest heat flow, and the average values of the northwest sub-basin, the southwest sub-basin and the eastern sub-basin are 98 mW/m^2, 99 mW/m^2 and 91 mW/m^2, respectively. Both the western margin and southwestern continental margins are characterized by generally high heat flow accompanied with large faults. The heat flow in the northern margin increases from the continental shelf to the slope, as a result of differential crustal extension. In contrast, the eastern margin is quite cold, owing to the subduction induced cooling effect. The thermal structure shows that heat flow from mantle is dominative in observed seafloor heat flow. Besides, local heat flow anomalies within the SCS can be attributed to hydrothermal circulation, magmatic activities and sediment thermal effects.

Heat flow is reported at eight sites drilled into the Guaymas Basin, Gulf of California, during the International Ocean Discovery Program Expedition 385. This expedition seeks to understand the thermal regime of the basin and heat transfer between off-axis sills intruding the organic-rich sediments of the Guaymas Basin, and the basin floor. The relatively high sedimentation rates combined with active tectonism and voluminous shallow off-axis magmatism characterizes this basin. Our results bridge a data deficiency allowing basin-wide interpretations shading light on this young rift basin. Results show sedimentation corrected heat flow values range between 119 and 221 mW/m^2 in the basin and between 257 and 1003 mW/m^2 at the site of a young sill intrusion, termed Ringvent. Thermal analysis shows that heat in the Guaymas Basin is being dissipated by conduction for plate ages >0.2 Ma, whereas younger plate ages are also dissipating heat by advection. Drilling data show that an active ring of hydrothermal vent root to a shallow sill fueling low-temperature hydrothermal fluids with discharge velocities of 10–200 mm/yr. Possible recharge sites are located ~1 km away from the sill's border. Modeling of the heat output and assuming supplied by a cooling sill, we estimate a sill thickness at Ringvent of ~240 m. A simple order-of-magnitude model predicts that relatively small amounts of magma are needed to account for the elevated heat flow in non-volcanic, sediment-filled rifts like the central and northern Gulf of California where heating of the upper crust is achieved via advection by sill emplacement and hydrothermal circulation. Multiple timescales of cooling control the crustal, chemical and biological evolution of the Guaymas Basin. Here we recognize at least four timescales: the time interval between intrusions (~10^3 yr), the thermal relaxation time of sills (~10^4 yr), the characteristic warming time of the sediments (~10^5 yr), and the cooling of the entire crust at geologic timescales.

Heat flow measurements collected throughout the Auka and JaichMaa ja' ag' hydrothermal vent fields in the central graben of the Southern Pescadero Basin, southern Gulf of California, indicate upflow of hydrothermal fluids associated with rifting dissipate heat in excess of 10 W/m^2 around faults that have a few kilometers in length. Paradoxically, longer faults do not show signs of venting. Heat flow anomalies slowly decay to background values of ~2 W/m^2 at distances of ~1 km from these faults following an inverse square-root distance law. We develop a near-fault model of heat transport in steady state for the Auka vent field based on the fundamental Green's function solution of the heat equation. The model includes the effects of circulation in fracture networks, and the lateral seepage of geothermal brines to surrounding hemipelagic sediments. We use an optimal fitting method to estimate the reservoir depth, permeability, and circulation rate. Independently derived constraints for the model, indicate the heat source is at a depth of ~5.7 km; from the model, permeability and flow rates in the fracture system are ~10^{-14} m^2 and 10^{-6} m/s, respectively, and ~10^{-16} m^2 and 10^{-8} m/s in the basin aquitards, respectively. Model results point to the importance of fault scaling laws in controlling sediment-hosted vent fields and slow circulation throughout low permeability sediments in controlling the brine's chemistry. Although the fault model seems appropriate and straightforward for the Pescadero vents, it does seem to be the exception to the other known sediment-hosted vent fields in the Pacific.

A large part of the recent oil discoveries in the world is linked to the Brazilian Pre-Salt, and part of the mapped giant/supergiant reservoirs are found in the Campos basin at the Brazilian eastern continental margin. The onshore part of this basin is bordered by the Ribeira Orogenic Belt (ROB), which represents a NE–SW trending system controlled by sliding shear belts, reactivated during its evolution since the Paleoproterozoic. Crustal thermal models have been developed to examine the implications of the observed intracratonic variations on heat flow and thus build an understanding of the geodynamic parameters of basin formation. The geothermal database used in this modeling includes direct and indirect measurements, and was expanded with over 56 locations, providing a spatial extent of 0.5 x 0.5 degrees in the continental part of the basin. The thermal model took into account the variation of thermal conductivity with temperature, as well as the variation of radiogenic heat generation with depth. Results show high values for the heat flow (>70mW/m^2) in the region of the Quadrilátero Ferrífero in the southern part of São Francisco Craton, surrounded by moderate heat flow pattern but increasing significantly in offshore regions where the crustal thickness is much smaller (aprox. 25km). Results of the crustal thermal model integrated with multiphysics (gravity, magnetic and seismic) datasets generate tools for imaging deep structures, especially in the distal portion of the Campos Basin, and map potential basement paleo highs and intrusive magmatic/volcanic features possibly associated to hydrocarbon and geothermal prospects.

The Wilson Cycle describes how plates break apart to form new lithosphere and collide to form orogens. The different stages of this cycle from continetal rifting to passive margin formation and oceanic spreading followed by subduction of oceanic lithosphere until continents collide again creates specific lithospheric configurations characterized by a distinct geophysical fingerprint. Using data-integrated models of orogens and their foreland basins, of rifts and passive margins as well as transform faults we assessed the first-order controlling factors of the related 3D thermal fields. We find that the superposed effects of different thermal conductivities, variable contributions of radiogenic heat in response to crustal thickness and composition, and variations in the average geothermal gradient in response to the thermal thickness of the lithosphere together create setting-specific 3D thermal fields controlling the local rheological configuration and thus deformation. In all settings this basic thermal fingerprint is additionally influenced by moving fluids in the shallow, permeable part of the crust. We show how understanding deformation and finding the geothermal “sweet spots” can profit if the specific local pattern can quantitatively be described.

Heat flow data collected along the San Andreas plate boundary and in the subduction to translation transition at the Mendocino Triple Junction (MTJ) have played a defining role for the geodynamic processes associated with this fundamental change in plate boundary tectonics. In the 1980s, heat flow data led to the recognition that the frictional strength of the San Andreas fault is low (Lachenbruch and Sass, 1980), and there is a slab window in the wake of MTJ migration (Zandt and Furlong, 1982). More recently, heat flow data constrain crustal deformation along the San Andreas corridor (Mendocino Crustal Conveyor; Furlong and Govers, 1999; Guzofski and Furlong, 2002; and Furlong and Schwartz , 2004). These results explain the magnitude and spatial wavelength of the transition from low heat flow within the Cascadia subduction zone to elevated heat flow along the San Andreas plate boundary. Within this broad low-to-high heat flow pattern, there are locations of anomalous heat flow that remain enigmatic. In the region straddling the MTJ, observed heat flow values (75 mW/m2) are substantially higher than are seen both north and south of that region (~ 35 - 50 mW/m2). Combining these heat flow data with new crustal and upper-mantle seismic tomography and tectono-thermal modeling, we constrain the processes of MTJ-related crustal deformation and place the elevated seismicity in the vicinity of the MTJ into its seismo-tectonic context. The elevated heat flow is most likely a consequence of rapid exhumation following the passage of the southern edge of the subducting slab.

Lithospheric thermal constraints from thermal data and indirect proxies

DOI: 10.57757/IUGG23-2865 - LINK

Akiko Tanaka[1]
[1]*Geological Survey of Japan- AIST, institute of earthquake and volcano geology, Tsukuba, Japan*

Heat flow data is the fundamental parameter in thermal lithospheric studies, which greatly influences tectonic and geological processes. The International Heat Flow Commission (IHFC) has been supporting the compilation of global heat flow data since 1963, and renewed data structure and database is released in 2021 (Fuchs et al., 2021a, b). Besides heat flow data, geothermal gradient and thermal conductivity data may also be useful. However, these data distributions have remained highly uneven, and the data are sometimes uncertain and are likely spatially variable. Therefore, to provide more reliable lithospheric thermal constraints, other proxies based on the complementary interpretation of different geophysical data sets are used. One of the promising proxies is the cut-off depth of crustal seismicity since it has been attributed primarily to the temperature. Another derivative method for constraining lithospheric thermal structure is the depth of magnetic sources based on spectrum analysis of magnetic anomaly data, although this analysis is still controversial. Good inverse correlation between the cut-off depth and heat flow and good correlation between estimated depths of crustal magnetic sources and heat flow suggest that these proxies may reflect the broad average temperature. We discuss the advantages and limitations of each data and method.

Renewable energy sources are crucial for achieving a transition to a cleaner energy system. Geothermal energy, in particular, is a promising source of energy production. However, its effectiveness depends on a thorough understanding of temperature distribution, fluid circulation, and lithological and petrophysical properties of the crust. Over the past two decades, several methodologies and numerical codes have been developed to better understand the properties of the thermal lithosphere, including its temperature, density, and composition. In this presentation, we summarize the major advances in these developments and discuss their geodynamic implications in the Iberian Peninsula and surrounding regions. Based on available thermal modelling results, we present a compilation of the temperature distribution at different depths in the Iberian Peninsula and the thermal Lithosphere-Asthenosphere Boundary. At a depth of 5 km, temperatures exceed 110°C, with higher local anomalies in the Iberian Massif and Cenozoic volcanic provinces. Similar patterns are observed at depths of 10 and 20 km, with temperatures exceeding 190°C and 350°C, respectively. Although no lithospheric anomalies are observed that could produce high temperatures at shallow depths, there is significant potential for exploitation at intermediate depths. Overall, the potential for direct use of geothermal energy for district and greenhouse heating, as well as for industrial processes, is significant throughout the Peninsula. The main challenges in exploiting this potential are the availability of groundwater and the cost of drilling.

Whether active fractures are thermal anomalies is a cutting-edge scientific issue in geothermics. Geothermal measurements of the San Andreas Fault reveal no heat flow anomaly, and then the "heat flow paradox" was proposed. The Tan Lu Fault Zone (TLFZ) is the most important fault in eastern Asia and is still active currently. We have carried out extensive geothermal measurements in the south-central TLFZ: the heat flow in the southern TLFZ is concentrated in the range 55-65 mW/m^2; the highest heat flow site LZSD (93 mW/m^2) is determined by the high heat production rocks, so the southern TLFZ is not a thermal anomaly. In contrast, the heat flow value in the middle section of the TLFZ is over 80 mW/m^2, which is likely to be a thermal anomaly zone. Simulations and calculations show that the heat generated by the fault activity is not significant (1-6 mW/m^2). Detailed two-dimensional temperature field simulation work also confirms these conclusions. The differences in the present-day thermal state of the TLFZ are the result of differences in the influence of tectono-thermal events in different regions, with the "Craton destruction event" at the late Early Cretaceous having altered the property of lithosphere in East China (Lower Yangtze Craton and the north part of the eastern North China Craton), while the south part of the eastern has only undergone the lithospheric thinning process. The difference in paleo-lithosphere thickness is likely the main reason for the different thermal state of the TLFZ.

Geothermal heat flux (GHF) is a critical boundary condition that influences subglacial hydrology and the fast flow of the Antarctic ice sheet and is related to crustal and lithospheric architecture and composition. Despite its importance, Antarctic GHF heterogeneity remains poorly constrained and this hinders broader efforts to study solid earth influences on subice hydrology and ice sheet behaviour.

Within the 4D Antarctica ESA project we produced a new continent-wide aeromagnetic anomaly compilation, conformed at longer wavelengths with SWARM satellite magnetic data and then applied Curie Depth Point (CDP) estimation approaches to provide new estimates of regional-scale GHF heterogenity beneath the West and East Antarctic ice sheets.

Enhanced GHF is revealed beneath the most rapidly changing part of the West Antarctic Ice Sheet along the coast of the Amundsen Sea Embayment. It is inferred to arise from dynamic interactions between the West Antarctic Rift System and anomalously warm Pacific upper mantle underlying the thinned rifted lithosphere. Potential thermal anomalies are also detected beneath the Byrd Subglacial Basin between Thwaites and Pine Island glaciers, and several linear belts of enhanced GHF underlie the Siple Coast ice streams and associated active subglacial lake districts. In East Antarctica, intriguing regions of enhanced GHF are unveiled beneath the Dome C and Dome F lake districts. These may reflect either cryptic intraplate Mesozoic to Cenozoic fault reactivation and/or elevated intracrustal heat production in the inferred Proterozoic crust. Our CDP estimates provide further boundary conditions for the development of next-generation thermal models required to constrain regional GHF heterogeneity.

Geothermal heat flux (GHF) is a critical boundary condition that influences subglacial hydrology and the fast flow of the Antarctic ice sheet and is related to crustal and lithospheric architecture and composition. Despite its importance, Antarctic GHF heterogeneity remains poorly constrained and this hinders broader efforts to study solid earth influences on subice hydrology and ice sheet behaviour.

Within the 4D Antarctica ESA project we produced a new continent-wide aeromagnetic anomaly compilation, conformed at longer wavelengths with SWARM satellite magnetic data and then applied Curie Depth Point (CDP) estimation approaches to provide new estimates of regional-scale GHF heterogenity beneath the West and East Antarctic ice sheets.

Enhanced GHF is revealed beneath the most rapidly changing part of the West Antarctic Ice Sheet along the coast of the Amundsen Sea Embayment. It is inferred to arise from dynamic interactions between the West Antarctic Rift System and anomalously warm Pacific upper mantle underlying the thinned rifted lithosphere. Potential thermal anomalies are also detected beneath the Byrd Subglacial Basin between Thwaites and Pine Island glaciers, and several linear belts of enhanced GHF underlie the Siple Coast ice streams and associated active subglacial lake districts. In East Antarctica, intriguing regions of enhanced GHF are unveiled beneath the Dome C and Dome F lake districts. These may reflect either cryptic intraplate Mesozoic to Cenozoic fault reactivation and/or elevated intracrustal heat production in the inferred Proterozoic crust. Our CDP estimates provide further boundary conditions for the development of next-generation thermal models required to constrain regional GHF heterogeneity.

The scientific drilling project "Collisional Orogeny in the Scandinavian Caledonides" (COSC) involved the drilling of two vertical boreholes through the Paleozoic Caledonian orogen in Central Sweden. The present contribution focuses on heat flow determination and evaluates the likely paleothermal state of the lithosphere of Baltica at the onset of the Caledonian orogeny. We concentrated on the results obtained from COSC-1, which was drilled, fully cored and repeatedly logged for temperature down to ~2.5 km depth. Average heat generation of the penetrated Caledonian metamorphic rocks was derived from the spectral gamma ray logs. The analysis yields a low average value of 0.8 μW/m^3. Thermal conductivities were determined from 105 core samples. On average, thermal conductivity equals 2.8±0.4 W/(m K), down to ~2 km depth, and increases to 4.1±1 W/(m K) in the lowermost section of the borehole. The thermal gradient shows obvious paleoclimatic disturbances but seems largely unaffected below ~2 km depth and no advective signal is detected. The calculated heat flow for the deepest section of the well amounts to ~82 mW/m^2. This unusually high heat flow value for cratonic lithosphere reflects, most likely, dominant input from the underlying highly radioactive Transscandinavian Igneous Belt (TIB), which is Late Proterozoic in age. We therefore propose that the lithosphere of Baltica involving the TIB was relatively warm at the time of the Caledonian orogeny. We anticipate that the relatively high temperatures of the margin of Baltica strongly influenced deformation style.

Heat flow plays a vital role in estimating the lithospheric temperature distribution, which is an essential parameter in understanding the evolution and stabilization of the cratons. Heat flow is determined in the Mesoarchean Singhbhum Craton, one of the oldest cratons in the Indian shield, for the first time from seven locations. This enabled us to construct plausible 1-D crustal thermal models and to estimate mantle heat flow by considering a few crustal heat production/thermal conductivity models based on crustal structures from the geological/geophysical studies of the study region.

In the present study, detailed radioelemental abundances (Th, U, K) and heat production are measured for the Paleoarchaean gneiss (OMTG) and Singhbhum Granites (SBG) of the craton. The result shows that both OMTG and SBG, which cover most of the craton, have, in general, low radioelemental abundances and heat production with an average of 1.3 ± 0.2 mWm^{-3}. Heat flow ranges from 27-34 mWm^{-2}, with an average of 30 ± 3 mWm^{-2}, which is lowest than most of the cratons. Interestingly, the value is also half that observed in the Singhbhum Shear Zone (61 ± 2 mWm^{-2}), situated in its north. The 1-D thermal models indicate that mantle heat flow and Moho temperature range from 14-16 mWm^{-2} and 330-370 °C, respectively. These fall within the range observed for the Archaean cratons despite their lowest surface heat flow. It is mainly due to the distinct crustal heat production scenarios and upper crustal thermal conductivity profiles, which provide clues to understanding the craton formation.

This laboratory study presents thermophysical rock measurements of 31 carbonates outcrop samples from the main geological formations of western Umbria (central Italy). Mineralogical analysis indicates that the formations under examination are mainly composed of calcite, with an abundance of quartz for some samples.

The conductivity and thermal diffusivity were determined with varying temperatures and both under dry and saturated conditions. Dry thermal conductivity measured with three different transient technique (optical scanning, transient plane source, transient hot wire method), differ by less than 10%.

At ambient temperature of 20 – 25°C, conductivity varies from 1.8 to 3.0 W/(mK) for samples with predominant calcite and show values greater than 3.6 W/(mK) for samples with larger quantities of quartz. For temperatures up to 200°C, conductivity for most of the samples decreases by about 30%.

Porosities reveal values of less than 5%. Theoretical mixing models based on the mineralogical composition and porosity were analysed to find the right fit with the measured values, with the possibility of extending the results to other parts of the world.

The results obtained from the study represent the basis for a more complete evaluation of the temperature trend with depth, useful for the evaluation of geothermal systems and for defining the rheological behaviour of the crust.

Multi-well Horner Correction to Bottom Hole Temperatures in depleted oil and gas fields

DOI: 10.57757/IUGG23-2064 - LINK

Jeffrey Nunn[1], Sandra Saldana[2], Chadwick Holmes[2]

[2]Chevron Technical Center, Subsurface Innovation Lab, Houston, USA

Depleted oil and gas fields contain a wealth of subsurface information that can be repurposed for geothermal, hydrogen, or carbon sequestration applications. The most common temperature measurement in oil and gas fields is the Bottom Hole Temperature (BHT). BHTs need to be corrected for disturbances to the thermal field by circulation of cool mud during drilling. The Horner correction is commonly used to correct temperatures back to in-situ conditions. It uses two and preferably three or more temperatures at the same depth measured at different times after mud circulation stops. This information is used to estimate an equilibrium temperature. Unfortunately, very few oil and gas wells have three or more BHT measurements that can be used in the Horner correction. For example, in southwest Weld County of Colorado which is part of the Denver-Julesburg (DJ) basin, there are only 12 wells out of more than 6,000 wells that have been Horner corrected because of the lack of same-depth measurements. In this study, we test whether BHT from nearby wells measured within a few tens of meters of each other in terms of depth can be used to make a Horner correction. We tested horizontal search radii of 400 m and 800 m and vertical search radii of 15 and 50 m. While results need to be screened for obvious errors such as positive Horner slope or unrealistically large correction, this method added hundreds of additional Horner corrected values.

[1]Polish Geological Institute - National Research Institute, Lower Silesian Branch - Computational Geology Laboratory, Wrocław, Poland

Polish Geological Institute is carrying out a project entitled "Geothermal atlas of the Sudetes and their foreland", which will fill the gap in knowledge about the geothermal potential of SW Poland. The project assumes the utilization of a large set of petrophysical measurements, together with logs from boreholes and surface geophysical data. More than 1000 samples were collected from outcrops and cores. This material was examined for K, U, and Th concentrations by gamma spectrometry. These results, together with density measurements, allowed for radiogenic heat map preparation. The values of radiogenic heat vary from nearly 0 to over 15 µW/m3, for Ślęża ophiolite massif and Karkonosze batholith, respectively. Thermal conductivity was measured by steady-state technique (FOX-50 apparatus) for over 100 samples. The homogenous rocks like granites show conductivity between ca. 2.8 and 3 W/mK, while other lithologies, i.e. gneisses, indicate values from ca. 1 to 4 W/mK. The thermal conductivities were also calculated based on the quantitative XRD analyses for 100 samples. The temperature logs from boreholes from the study area were digitised and analysed. A database containing 99 logs was prepared. The depth of these wells ranges from 201 to 2500 m, while the bottom temperature falls between 20 and 50 °C for the majority (71) of wells. The project is focused on continuing analyses for obtaining most complete view of the geothermal potential of SW Poland. At this stage, the Karknosze Granite Massif and part of the Intra-Sudetic Basin can be pointed as the most promising regions.

Signature of climate changes in subsurface temperatures. A case study from Northern Bohemia, Czechia

DOI: 10.57757/IUGG23-1561 - [LINK]

Jan Safanda[1], Petr Dědeček[1], Vladimír Čermák[1], Tomáš Uxa[1]
[1]Institute of Geophysics, Surface processes and paleclimate, Prague, Czech Republic

A 1.7 km long equilibrium temperature log from borehole Litoměřice, Czechia, measured 13 years after drilling provided a detailed knowledge of temperature gradient. Its most conspicuous feature is a gradual increase with depth from 22.0 K/km to 25.6 K/km within a lithologically homogeneous depth section 900–1700 m occupied by mica-schist. Conductivity and diffusivity was measured on drill-core samples from the upper part of this borehole section. Due to (i) the homogeneous lithology of mica-schist, (ii) a small scatter of the measured conductivity values and (iii) no trend in the dip angle of foliation, we assumed no depth trend of conductivity in the section 900–1700 m other than that resulting from pressure-temperature corrections. However, they introduce only a slight trend with values decreasing from 3.34 W/(m.K) at 900 m to 3.29 W/(m.K) at 1700 m, i.e. about 1.5 %, that cannot explain the observed 16% increase of the temperature gradient. We interpreted the increase as a transient feature generated by long-term ground surface temperature changes during the last glacial cycle. The inversion technique applied to the temperature log section 900–1700 m indicated the magnitude of the last glacial–Holocene warming of 13–15 K and the occurrence of a temperature minimum 15–20 ka. The long-term mean ground surface temperature of 1–2 °C suggests that the borehole site was permafrost-free for most of the last glacial cycle. The existence of about 100 m deep permafrost is possible in the coldest part of the last glacial.

The Surface Heat Flow of Mars – and an attempt to measure it in-situ

DOI: 10.57757/IUGG23-0713 - LINK

Tilman Spohn[1]
[1]*DLR, Institute of Planetary Research, Berlin, Germany*

NASA's InSight mission [1] has installed the first geophysical observatory on Mars, including a seismometer, a magnetometer, sensors to track the rotation of the planet, an atmosphere science package and a heat flow probe HP^3 [2]. Cosmochemical and geophysical models [e.g., 3,4] suggest that the average Martian surface heat flow is around 25mW/m^{2}and may vary across the surface between 17 and 50mW/m^2. HP^3 was planned to use a small penetrator - nicknamed the "mole" – to install a string of temperature sensors up to a depth between 3m and 5m. A radiometer to measure the surface radiation temperature complemented the package. Sensors on the mole would measure the thermal conductivity as a function of depth. Depending on the final depth reached, temperature was to be measured daily for a period of months up to one Martian year. Unfortunately, the mole failed to penetrate to the required depth because of unexpected soil properties. Instead, it was used as a penetrometer and thermal probe to measure the thermal and mechanical properties of the top 40cm of the Martian soil. Inversion of the seismic recordings of Marsquakes allowed an estimate of the variation of the near surface temperature with depth and of the heat flow [5,6]. These estimates are consistent with the estimates from the earlier models [3,4].

Investigations of potentially promising areas for the development of Renewable Geothermal Energy in Uzbekistan

DOI: 10.57757/IUGG23-0118 - LINK

Rasul Saxobidinov[1], Irina Sidorova[1]
[1]*Institute of Geology and Geophysics of Uzbekistan, Lab. Structure of Lithosphere, Tashkent, Uzbekistan*

Anomalous areas of Heat Flow Density in Uzbekistan were identified at the stage of preliminary studies on the territory of the Republic. A Multidisciplinary Geophysical surveys (Seismic, Magneto telluric and Gravity exploration) now being implemented on the studied areas in Central Kyzylkum, Gissar and Aral regions. The goal of the development of geothermal resources are as follows: (1) develop a conceptual model to characterize the geology, geophysics and thermodynamics of resources; (2) develop, using this model, a cost-effective strategy for continuing exploration, delineating and evaluating a resource that provide depth and quality data necessary for making decisions regarding plans for the further development of promising geothermal areas in Uzbekistan. The results of geophysical studies, used in combination with geological data, allowed the construction of three-dimensional depth models of the structure of the studied areas with the location of the heat source and provide targets for test (exploration) drilling.

Deep geothermal potential of Norway based on borehole data

DOI: 10.57757/IUGG23-3807 - LINK

Yuriy Maystrenko[1], Marco Broenner[1], Harald Elvebakk[1], Odleiv Olesen[1], Trond Slagstad[1]
[1]Geological Survey of Norway NGU, Geophysics, Trondheim, Norway

During the last decades, more than 30 relatively deep boreholes were drilled onshore in Norway. According to thermal logging, the highest temperatures (up to 28.2 °C at 800 m depth) were observed in the boreholes, located on the Svalbard archipelago which has signs of Quaternary magmatic activity. In contrast, the tectonically quiescent northernmost Norway is characterized by the lowest measured temperatures (slightly more than 9 °C at 650 m depth). The highest temperature in Central Norway (22.2 °C at 800 m depth) was measured on the small island close to the deep sedimentary basins in the Norwegian Sea. The southwestern part of Norway shows relatively low temperatures (e.g., 17.6 °C at a depth of 800 m near Stavanger). These low temperatures can be a result of groundwater flow that cools down the uppermost crust in this region. The area around the Oslo Fjord shows a complicated thermal pattern in the subsurface. There, at 800 m depth, the measured temperature ranges from 16 to 24 °C.

The described differences in the measured temperatures reflect the tectonic differentiation of the areas. A variation in the content of radioactive elements is also reflected by the measured temperatures. Consequently, the superposition of tectonic structure/evolution and compositional features controls the subsurface thermal pattern of Norway which is locally disturbed by the groundwater flow. Moreover, the paleoclimatic thermal effect is still present in these 300 to 1500-m-deep boreholes. Therefore, the above-mentioned factors must be evaluated in detail before planning the first deep geothermal site in Norway.

The De-risking Ireland's Geothermal energy potential (DIG) project aims to de-risk borehole drilling costs to promote geothermal energy in Ireland. High-quality maps of the geothermal gradient and temperature are essential when assessing the geothermal potential of a region. However, determining geothermal potential is a challenge as direct measurements of in situ temperature are sparse and individual geophysical methods are sensitive to a range of parameters, not solely temperature. We develop a novel approach to determine the geothermal gradient using a joint geophysical-petrological thermochemical inversion (Fullea et al., GJI 2021), which requires thermal property data, seismic and additional geophysical datasets. The multi-parameter models produced by the integrated inversions fit the surface-wave, heat flow and additional data, revealing the temperature, lithospheric structure and geothermal gradient within the crust and mantle.

Here we present a new map of Ireland's subsurface temperature. Our new methodology produces results comparable to past temperature and geophysical measures, and enhances resolution. Critically the maps are consistent with borehole temperature measurements providing confidence in the results. Lithospheric and crustal thickness play a key control on the temperature gradient with areas of thinner lithosphere resulting in elevated geotherms. In some locations we observe geotherms elevated beyond expectations which result from high radiogenic heat production from granitic and muddy limestone rocks. This new methodology provides a robust workflow for determining the geothermal potential in areas with limited direct measurements. The final temperature model updates previous maps of Ireland and will be used for future geothermal exploration and utilisation.

Since 1963, the International Heat Flow Commission (IHFC) has been fostering and maintaining the compilation of the Global Heat Flow Database (GHDB). Over time, techniques and methodologies in heat-flow density determination evolved and called for frequent updates of the database. The increasing number of data and their diverse underlying methods also require an adequate and consistent evaluation scheme to assess the quality of the respective heat-flow density determination. Here, we provide the intermediate results of a collaborative, community-driven approach started in 2021 to set-up a new, authenticated GHDB. We document the new basic structure to report heat-flow data to the IHFC and present a newly developed consistent evaluation scheme. The quality scheme, for the first time, combines three independent quality criteria in one combined score, comprising the quantified uncertainty, the methodological quality, and the status of overruling effects. It allows a quick comparison of heat-flow data and reveals missing data or insufficient documentation at one glance. With the new quality scheme, users are enabled to select appropriate reliable heat-flow values for their specific purpose. The process to screen and update incomplete, wrong or empty database entries is ongoing and will last for a couple of years. The most recent intermediate update – the data release 2023 – contains data generated between 1939 and 2022. The data release contains 73,033 heat-flow data from 1,414 publications. 55% of the reported heat-flow values are from the continental domain (n ~40,082), while the remaining 45% are located in the oceanic domain (n ~32,951).

In the context of Earthquake Early Warning (EEW) applications, the high-speed rail networks are of particular interest due to their strategic role for private/public transportation. In Italy, in the frame of an industrial partnership, the University of Naples Federico II was recently commissioned by Rete Ferroviaria Italiana (RFI) S.p.A. to design, develop, and implement a prototype EEW system on the High-Speed Railway line between Rome and Naples. In case of a relevant earthquake, the system has the main goal of issuing an automatic alert that makes it possible to slow down high-speed trains, by resorting to a specific interface with existing signalling systems. The EEW methodology implements an evolutionary, P-wave based approach combining the single station and the network-based approaches. A probabilistic decision scheme for the alert declaration is implemented, accounting for the exceedance probability of a given PGA threshold value and for the uncertainty associated to the empirical scaling relationships. A final decision module evaluates whether and where the predicted PGA exceeds the established threshold and declares the alert at the nodes of the line where the most relevant shaking is expected. Here we will overview the basic principles and methodologies of the EEW platform and introduce a quantitative performance assessment, based on a retrospective off-line analysis of the system outputs. The performance analysis allows evaluating both the system rapidity in providing alerts and the quality/reliability of these predictions and represents the key element for stakeholders and end-users, to properly configure and setup the operational system.

The ShakeAlert Earthquake Early Warning (EEW) System issues public alerts in the states of California, Oregon, and Washington with a mission of reducing injuries and property loss from damaging earthquakes. Shortly after ShakeAlert went live in 2019, the Ridgecrest earthquake sequence provided a major test of the system's capabilities. For several reasons ranging from the inherent limitations of EEW, to data telemetry and algorithm deficiencies, ShakeAlert failed to provide useable warnings for most locations where people were in danger for both the M6.4 and M7.1 mainshocks [Chung et al. 2020]. Since Ridgecrest, the ShakeAlert algorithm development and testing team has improved all components of the software and evaluation mechanisms, resulting in dozens of updates to the operational system. We expect version 3.0 of the ShakeAlert software to go live in the summer of 2023. This version is the first to include a geodetic algorithm aimed at large subduction ruptures in Cascadia. We will present various evaluations of expected performance of ShakeAlert in large earthquakes from offline testing. For instance, over 70% of instrumented sites that experienced strong or greater shaking in the 2016 M7.1 Kumamoto earthquake could have received at least 10 s of warning before strong shaking began using the ShakeAlert MMI 4 contour product depending on delivery latencies. Similarly, during the 2022 M6.4 Ferndale earthquake in Northern California, the real-time system published the MMI 4 contour product more than 10 s before strong shaking at about 50% of instrumented sites.

The ATTAC project, or Alerta Temprana de Terremotos en América Central, aims to establish public earthquake early warning (EEW) systems in Central America. The region experiences frequent subduction and shallow crustal earthquakes and has a vulnerable building stock, along with a rapidly growing population density. EEW can reduce the fatalities and injuries that occur during strong earthquakes. The ATTAC project is building national EEW systems at seismic agencies in each of Guatemala (INSIVUMEH), El Salvador (MARN), Nicaragua (INETER), and Costa Rica (OVSICORI-UNA), with the collaboration of SED at ETH Zurich.

The EEW systems are based on the ETHZ SeisComP EEW (ESE) add-on modules and include the Virtual Seismologist and FinDer algorithms. The project has deployed 70 low-latency accelerographs across the region and has implemented performance-tracking tools to monitor the network and EEW results in terms of accuracy and speed. The ESE dissemination module allows to select the best of the EEW solutions and to deliver targeted alerts via a mobile application and digital TV.

Data analysis of the mobile application has shown promise (74% of users notified in 5 seconds). Although the number of active recipients is in the low thousands, it is scaling up. We demonstrate successful EEW for recent earthquakes with delay from event initiation to alert dissemination ranging from 10 to 15 seconds for shallow onshore seismicity and from 20 to 25 seconds for offshore or deep events. We focus on false alerts with software and configuration optimizations and establishing best practice in network management.

A regional hazard-based approach for seismic network design for earthquake early warning

DOI: 10.57757/IUGG23-2978 - LINK

Glenn Biasi[1], *Igor Stubailo*[2], *Mark G. Alvarez*[1]

Seismic network optimization for Earthquake Early Warning (EEW) differs from the more general mission of regional monitoring. A network designed for EEW must prioritize speed of detection, the magnitude and rate of occurrence of likely earthquakes, and the location of seismic sources relative to population centers. A recent analysis by Böse et al. combines these elements in an end-to-end analysis for EEW monitoring in Switzerland. They sample from the combined instrumental and historical catalog for the region to evaluate hazard and losses. We have developed a similar approach based on gridded USGS National Seismic Hazard Map (NSHM) inputs. Hazard maps include catalog and historical seismicity, but also synthesize geologic and geodetic slip rates, geophysical inputs and paleoseismic event information. They are also extensively reviewed. The US NSHM maps are extrapolated from hazard curves calculated on a grid. We extract from the hazard curves the return time at a given shaking intensity, e.g. PGA=0.1 g, as a proxy for how often a station at that location will contribute to EEW detection from nearby earthquakes. The ground motion intensity corresponds to an approximate magnitude and location distribution that can be used in a forward calculation with attenuation to find impact on population centers. Stations near active faults generally minimize detection time and maximize warning time. Stations with shorter return times contribute more often and are generally near larger earthquakes. The best station distribution will give the greatest number of people the most useful warning.

[2]*Goethe University, Department of Geosciences, Frankfurt am Main, Germany*

The identification and rapid estimation of earthquake parameters such as Peak Ground Acceleration are crucial for Earthquake Monitoring and Earthquake Early Warning especially for strong earthquakes. The conjugation of seismic waves with the layers of geological media of varying elastic properties results in a varying PGA from site to site. The local site effects heavily influence the PGA values , for instance if the site is composed of soft-sediments the amplification within the ground motion is more prominent than that of a rocky terrain or very firm sediments. We use deep learning to model these nonlinearities to identify the PGA value of the incoming earthquake signal. We use the global data STanford EArthquake Dataset, STEAD benchmarked for Machine Learning applications. The proposed model architecture may be considered as a priliminary prototype that could be adapted into EEW systems for effective emergency response.

Nowadays, Tsunami Early Warning Systems (TEWS) issue the first alert between three and five minutes after the occurrence of a potentially tsunamigenic earthquake. For offshore earthquakes, for which a significant network azimuthal gap limits the accuracy of standard techniques for source location, this time is spent to obtain stable estimations of the event magnitude and depth. This large warning time affects the efficiency of TEWS for near-coastal large earthquakes. Recent developments in Earthquake Early Warning Systems (EEWS) mitigates this issue. Here, we consider a P-wave, shaking-forecast based EEW method (Zollo et al., 2023) to provide fast and accurate estimations of event location and magnitude along with the Potential Damage Zone (PDZ). As a first test of a combined E- and T- EWS, we applied the method by playing-back the simulated records of two events of Mw 6 and 7 in the Messina strait, with source characteristics that mimic the 1908 Messina earthquake. The events are simulated at the INGV and RAN seismic stations along the Sicily and Calabria coasts. We estimated stable and accurate hypocenter locations and magnitude determinations in 20-25 seconds for both events. The shape of the PDZ obtained after 30 s from the earthquake origin well reproduces the geometry of the rupture surface. These first results show that combining EEWS and TEWS can speed up the tsunami forecasting, thus increasing the lead-time available for actions to protect the exposed population.

Reducing false tsunami early warnings by combing high-rate GNSS-detected ground movement and ionospheric disturbance

DOI: 10.57757/IUGG23-3789 - LINK

Kejie Chen[1], Jiafeng Li[1]
[1]Southern University of Science and Technology, Department of Earth and Space Sciences, Shenzhen, China

The current tsunami early warning systems usually issue alarms once large undersea earthquakes are detected, inevitably resulting in false warnings since there are no deterministic scaling relations between earthquake size and tsunami potential. In this study, we attemp to characterize tsunami potential more precisely to avoid uncessary alarms by analyzing both the co-seismic displacement waveforms (CDWs) and ionospheric disturbances (CIDs) as detected by high-rate Global Navigation Satellite System (GNSS) observations. We examined CDWs and CIDs of three megathrusts including the 2014 Mw 8.2 Iquique, the 2015 Mw 8.3 Illapel, and the recent 2021 Mw 8.2 Alaska events. We found that CDWs generated by the 2021 Mw 8.2 Alaska event indicating ruptures far away from the trench and CIDs near the epicenter event were significantly weaker than those of the two Chilean events, despite having similar earthquake magnitudes. Furthermore, the propagation direction of CIDs from the Mw 8.2 Alaska earthquake also confirmed slips toward the deeper seismogenic zone, consistent with CDWs infer and both implied less seafloor uplift and hazardous flooding. Our work sheds light on incorporating both GNSS-based CDWs and CIDs for more trustworthy tsunami warning systems.

Natural hazards (earthquakes, tsunamis, volcanic eruptions, *etc.*) have devastating human and economic consequences. Their early detection and characterization lead to timely evacuations, which are critical for significantly reducing casualties and economic cost. However, traditional early warning systems (EWS) are limited by inherent challenges. We present two novel GNSS-based methods that are viable augmentations to EWSs.

The first, developed at Central Washington University, monitors earthquakes and tsunamis globally, based on low-latency in-situ measurements from ~1800 globally-distributed receivers. The system can rapidly characterize moment release, as ruptures unfold. Position time series are continuously streamed as local 3D coordinates into monitoring algorithms, and also broadcast for third-party use. The system's average latency is ~0.5 seconds, and its average position variance remains below 8 cm. This system captured the 2019 M7.1 Ridgecrest earthquake on 12 nearby stations within 22 seconds after onset; the system's estimates of co-seismic deformation were within 10% of the post-processed "true" values.

In addition, another remote sensing technique leverages ionospheric total electron content (TEC) measurements. Indeed, through mechanical coupling, large air and ground perturbations at the Earth's surface propagate up as low-frequency atmospheric waves. Eventually disrupting the ionosphere, those waves can be observed through ground-based GNSS measurements. In particular, we present the GUARDIAN system, developed at JPL (https://doi.org/10.1007/s10291-022-01365-6), which runs in near-real-time (latency < 5 minutes) using multi-GNSS data from 80 stations from JPL's GDGPS network around the Pacific Ocean. GUARDIAN outputs TEC time series to a user-friendly public website, and are routinely validated against traditional ionospheric post-processing techniques.

The system's average latency is ~0.5 seconds, and its average position variance remains below 8 cm. This system captured the 2019 M7.1 Ridgecrest earthquake on 12 nearby stations within 22 seconds after onset; the system's estimates of co-seismic deformation were within 10% of the post-processed "true" values.

In addition, another remote sensing technique leverages ionospheric total electron content (TEC) measurements. Indeed, through mechanical coupling, large air and ground perturbations at the Earth's surface propagate up as low-frequency atmospheric waves. Eventually disrupting the ionosphere, those waves can be observed through ground-based GNSS measurements. In particular, we present the GUARDIAN system, developed at JPL (https://doi.org/10.1007/s10291-022-01365-6), which runs in near-real-time (latency < 5 minutes) using multi-GNSS data from 80 stations from JPL's GDGPS network around the Pacific Ocean. GUARDIAN outputs TEC time series to a user-friendly public website, and are routinely validated against traditional ionospheric post-processing techniques.

Rapid estimation of the coseismic fault model for medium-to-large-sized earthquakes is key for disaster response. To estimate the coseismic fault model for large earthquakes, the Geospatial Information Authority of Japan and Tohoku University have jointly developed a real-time GEONET analysis system for rapid deformation monitoring (REGARD). REGARD can estimate the single rectangular fault model and slip distribution along the assumed plate interface. The single rectangular fault model is useful as a first-order approximation of a medium-to-large earthquake. To obtain a more robust fault model with its estimation uncertainties, we developed a new method to estimate the coseismic fault model and model uncertainties in real-time based on the Bayesian inversion approach using the Markov Chain Monte Carlo (MCMC) method. In general, MCMC requires a long mixing time to obtain posterior probabilities, but the developed method can obtain a solution within about 20 seconds after the permanent displacement is acquired, thanks to parallel tempering and other computational efficiency improvements. The developed method has already been implemented in REGARD and has been successfully demonstrated to obtain real-time solutions for several moderate-size earthquakes. Tohoku University and the GSI are also developing a fast estimation method of slip distribution at plate boundaries using MCMC. The presentation will include a more detailed discussion of the advantages of using MCMC to estimate the slip distribution at the plate boundary.

The rise of early warning systems is enabling proactive responses to natural hazards such as floods. However, such systems could have restricted user access, limited geographical coverage, and either minimal or absent predictions in areas with few observations. In the case of flooding, the costliest natural hazard, this may translate into issues such as a lack of insight into the hydrological situation in poorly gauged areas, and downstream regions having limited information on upstream river conditions. The Global Flood Awareness System (GloFAS) addresses these issues by providing a global hydrological forecast and monitoring system that produces forecasts even in poorly gauged areas, and is open access and transboundary. Fully operational as part of the European Union's Copernicus Emergency Management Service since 2018, the system provides flood forecasts up to 30 days lead time and monthly seasonal streamflow outlooks via the GloFAS online map viewer. Complementary information on forecast skill and hydrological model performance is also made available to aid users' interpretation and understanding of forecast quality, alongside regional flood impact assessment estimates. Here, we give an overview of the GloFAS forecasting system and the available products, including an introduction to the GloFAS map viewer products. Lastly, we also present the GloFAS data made available on the Copernicus Climate Data Store, which alongside the forecasts includes sub-seasonal and seasonal reforecasts and a reanalysis dataset covering over 40 years. We also present our recently created training material to help users access and explore the GloFAS data from the Climate Data Store.

Early warning systems can help mitigate the damage caused by floods by increasing preparedness. However, to be useful in the event of a flood the products from these early warning systems must be actionable. The European Flood Awareness System (EFAS), part of the European Commission's Copernicus Emergency Management Service, provides complementary flood forecasts to EFAS partners across the whole of Europe. The EFAS 'post-processed forecast product' is generated for the location of approximately 1600 river gauge stations where sufficient historic and near-real time river discharge observations are available. The aim of this product is to provide an error-adjusted forecast up to a maximum lead-time of 15 days. Recently, the temporal resolution of this product has increased from daily to 6-hourly timesteps providing an ideal opportunity to identify future developmental priorities. Following a workshop with the EFAS partners a roadmap for future developments of the EFAS post-processed forecast product was designed to ensure the user's changing requirements are satisfied. Here, we present this roadmap, and the results of the first stages, which include improvements to the post-processing methodology to better account for the different hydroclimatic regimes across Europe, and changes to the post-processed forecast product to make it more locally relevant and useful to the EFAS Partners.

In recent decades, meteorology has made great progress in producing reliable probabilistic forecasts. However, forecasts and especially weather warnings continue to be communicated almost exclusively in deterministic terms. The failure to communicate probabilistic information not only hinders shared decision-making between meteorologists, organisations and the public. This practice also does not take into account that probabilistic information may well be preferred by laypersons, may increase confidence in forecasts and may lead to better decisions. For the practical use of uncertainty information, it must be clarified, for example, under which conditions it is helpful, how it should be processed verbally and graphically, and which institutional and operational questions must be clarified.

In this presentation, we present exemplary results of our own social science studies within the framework of the WEXICOM project of the Hans Ertel Centre for Weather Research (HErZ) on the following questions: What do users know about the uncertainty of forecasts? What attitudes do users have towards providing uncertainty information, e.g. do they want to receive this information? How is uncertainty communicated verbally? Which graphical representations do users prefer? At what probability would users react? What influence do space and time references of uncertainty information have on the understanding of the information and how do they influence the use for decisions? Finally, we present the challenges and new approaches for the communication and use of uncertainty information in weather forecasting.

Near Real-time Flash Flood - Landslide Early Warning System Using Combined Low-cost Sensors and Rain Radar Composites In Northeastern Thailand

DOI: 10.57757/IUGG23-3516 - LINK

Flash floods and landslides are severe natural hazards caused by heavy rainfall. When aiming for a robust real-time early warning system, rain radar products are key for tracking heavy storms and quantifying hydrological behavior in mountainous catchments. The precision of radar rainfall estimates remains an essential concerns in the application of radar-based observation. Finally, composite radar products of 2 or more rain radar observation are required to improve the quality of the radar product to visualize the distribution and movement of precipitation over a large area.

In our research, we aim to build a near-real time flash flood and landslide EWS for a hazard-prone Khao Yai NP in northeastern Thailand. Specifically, we evaluate low-cost sensors, linked to high resolution radar rainfall observations. These sensors measure a.o. soil moisture, precipitation, water and air pressure, and transmit real-time data via NB-IoT mobile signals. The rain gauge rainfall data will be merged with weather radar data to compute radar rainfall bias adjustment for preparing high-quality gridded rainfall over the study area. Moreover, we investigate the controlling factors influencing the quality of radar composites over and quantify the rain radar composites. The results indicated that specific quality indexes could be used to identify areas with inaccurate or unreliable raw data. The low-cost sensors and radar composites are subsequently used in spatially distributed models that are the basis of an early warning systems that is under development in this hazard-prone mountainous region.

Submarine landslides represent a significant marine geohazard that can be triggered by multiple factors, but most commonly by earthquakes. Seismically-induced submarine landslides (SISLs) could further trigger tsunamis or be converted into high-speed moving turbidity currents, generating the chain disasters and resulting in the destruction of coastal and submarine infrastructures. Unfortunately, most earthquakes, including many of the devastating earthquakes, occurred in subduction zones or other plate boundary fault systems which are near enough to the coast. Therefore, SISLs often provide a short tsunami warning time. However, the SISLs and their chain disasters still remain poorly understood, and are seldom considered in tsunami warnings. This study reviews various aspects of SISLs, from their occurrence mechanisms and dynamics, to submarine slope stability assessment under seismic shaking. We summarize the chain disasters caused by SISLs globally since 1900 including the chain of earthquake - submarine landslides - tsunami and the chain of earthquake - submarine landslides - turbidity currents - cables break. For the first time, primary characteristics of these SISLs, such as volume, initial water depth and slope, and distance from the coast and seismogenic fault, are collected and summarized in detail. We investigate the quantitative relationships between earthquake magnitudes and distances between the SISLs and the seismogenic faults and calculate the ground acceleration (PGA) generated at the SISLs position during the corresponding earthquake. The results of this study are useful for increasing the understanding of SISLs and their chain of cascading events, which is essential for local tsunami warnings and hazard prevention.

Institute of Risk Analysis- Prediction and Management Risks-X, Shenzhen, China

The China Earthquake Administration (CEA) has launched an ambitious nationwide earthquake early warning (EEW) system project, which will consist of approximately 15,000 seismic stations and be the largest EEW system in the world. In 52%, 30% and 17% of Chinese mainland, the inter-station distance will soon be smaller than 50 km, 25 km and 15 km, respectively. The effectiveness of the EEW system expected inside Chinese mainland can be quantified via the metric given by the radius of the blind zone (no-warning zone). Using theoretical network-based method, we generate the spatial distribution of the blind zone radii predicted for the new seismic network based on its configuration. The densified new seismic network is expected to have excellent EEW performance from the perspective of blind zone. The area covered by blind zones that are smaller than 30 km will soon rise from 1.6% to 24.3% inside Chinese mainland, which means that the area will increase by 2.6 million km^2. We claim that every 1,000,000 RMB (158,000 USD) invested to densifying the planned network will increase the area where the blind zone radius is smaller than 30 km by 3,000 km^2. Continuing to increase the density of stations in some key regions with the blind zone radii ranging from 20 to 40 km is still necessary to control the unexpected expansion of blind zones due to the possible (and common) stations failure. Our investigation provides a useful reference for the real functioning and further optimization of the EEW system in Chinese mainland.

Low-cost methods for early warning to geohazards

DOI: 10.57757/IUGG23-4317 - LINK

Tahmeed Malik Al-Hussaini[1], *Saleh Hamza*[1], *Mustafa A. Nakib*[1], *Shoriful Islam*[1], *Mostafa Kamal*[1]
[1]*Bangladesh University of Engineering & Technology, Civil Engineering Department, Dhaka, Bangladesh*

The northern boundary region of Bangladesh and neighbouring North-East Indian states of Meghalaya and Assam are capable of producing large (M≥7) to great (M≥8) earthquakes as historical evidence shows. Such earthquakes can cause havoc and wide spread damage in densely populated cities of Bangladesh including the capital city of Dhaka. If an earthquake monitoring system can be installed in towns near Bangladesh-India border, a warning time of several seconds will be available before the earthquake waves reach Dhaka city. This time may be used for quick safety measures such as taking appropriate shelter, building evacuation, shutting off gas etc. A low-cost seismic accelerometer with alert system and backup battery has been manufactured using available low-cost accelerometer sensor and data acquisitions system. It sends warning message using mobile network whenever the acceleration exceeds selected threshold value. Because of its low cost it can be easily deployed in large numbers and can provide early warning for distant large magnitude earthquakes. In recent years, landslides have emerged as recurring natural hazards in hilly urban areas of Chittagong and Rangamati causing human casualties. A low-cost computational method based on rainfall data and hill-slope data is briefly discussed. To monitor vulnerable hill slope, low-cost inclinometer can also be assembled which will send a warning message when there is significant soil movement resulting in tilting of the inclinometer. Early warnings made possible by installing such low-cost devices can play a major role in reducing casualties and property losses during a major earthquake or landslide event.

Because of their social, economic and political contexts, and their intrinsic multi-hazard nature, volcanic islands are one of the most vulnerable environments, where natural hazards (volcanic and non-volcanic) tend to occur in a simultaneous way causing cascading effects. To date, most of the scientific knowledge, as well as hazard assessment and risk management protocols focus on individual hazards and risks, while it remains a challenge to correctly predict the outcomes and impacts of a multi-hazard scenario where several hazardous phenomena may interact in simultaneous or consecutive ways. The multi-hazard concept originated in the 1990s in the international political context precisely to respond to this need. After its first appearance, different–and often, contradictory–usage perspectives of the multi-hazard concept have been increasingly put forward, thus making it difficult for this new approach to be fully implemented into disaster reduction policies. The present study assesses the current status of the application of the multi-hazard approach in existing risk management systems, and proposes future improvements to disaster risk reduction. It also presents the multi-hazards to which volcanic islands are exposed and analyses their potential impacts, taking the Canary Islands as a case study. In doing so, it emphasizes the need to establish a cross-sectoral, climate change-oriented, socially-inclusive, multi-risk management system, based on scientific knowledge and linked to critical societal demands and solutions.

La Soufriere Volcano eruption 2020-21 - testing the integration of Community Volcanic Emergency Plans and national EWS in St. Vincent

DOI: 10.57757/IUGG23-5034 - LINK

Richard Robertson[1]
[1]*The University of the West Indies, Seismic Research Centre, St. Augustine, Trinidad and Tobago*

Caribbean Small Island Developing States are exposed to a multiplicity of natural hazards and St. Vincent and the Grenadines, home of La Soufriere Volcano, is one of the most disaster-prone. Overcoming the challenges associated with operating a geophysical monitoring network aimed at providing early warning of an impending eruption has required the use of several strategies. A key component of these have been building partnership with local disaster management officials and community members in high-risk zones on the volcano.

We have worked with disaster management officials and community members to help them develop Community Volcano Emergency Plans (CVEPs) that incorporated multi-hazard mapping, vulnerability and capacity assessments, training and equipping of Community Emergency Response teams and testing of plans through simulation exercises. Activities such as evacuation routing, identification of shelters and muster points and stocking of emergency supplies were all integral elements in these plans.

CVEPs aim to effectively illustrate the role of and actively engage with monitoring scientists, disaster management agencies and citizens in dealing with volcanic emergencies. The 2020–2021 eruption of La Soufrière volcano served as an important test to the entire system. The eruption involved a series of explosions from 9–22 April 2021 that were preceded by three months of effusive activity, which commenced with a very low level of detected unrest. It occurred against the backdrop of the Covid pandemic which presented multiple challenges to effective response.

In this presentation we share our experience of integrating community response with EWS and review its performance during the 2020-21 eruption.

The 2020–2021 eruption of La Soufrière volcano served as an important test to the entire system. The eruption involved a series of explosions from 9–22 April 2021 that were preceded by three months of effusive activity, which commenced with a very low level of detected unrest. It occurred against the backdrop of the Covid pandemic which presented multiple challenges to effective response.

In this presentation we share our experience of integrating community response with EWS and review its performance during the 2020-21 eruption.

The Santiaguito Volcanic Complex is located in Guatemala's Western Volcanic Highlands, along the westernmost section of the Central American Volcanic Arc. Santiaguito presents multiple hazards (including pyroclastic density flows, lava flows, lahars, explosions and debris avalanches) to the local population, which numbers 1.6 million people within the 30 km2 around the volcano. Lahars are mixtures of water and pyroclastic debris that includes gases which can rapidly initiate and flow at speeds of tens of meters per second down wide barrancas (canyons) making them highly destructive. Lahar occurrence strongly correlates with rainfall at the volcano and they are commonplace in the long rainy season. They pose a great hazard to local inhabitants who regularly cross the channels as they live and work on farms on or near the flanks of the barrancas. INSIVUMEH, the national seismic and volcano monitoring agency, has recently built a network of 10 seismic stations that can monitor these flows, in collaboration with external agencies. Using the seismic data from the 2022 rainy season we have built a Lahar catalogue. We supplement the dataset by adding synthetic Lahar waveforms to it, informed by the existing recorded events. We then use the hybrid catalogue to develop a Convolutional Neural Network Lahar detector, always testing on real events. We test using different input lengths to find an ideal timeliness/accuracy ratio for Lahar early warning. We plan to extend the method for Lahar location tracking. We expect the method to be portable to other volcanic areas.

Anatomy of the tsunami and Lamb waves-induced ionospheric signatures generated by the 2022 Hunga Tonga volcanic eruption

DOI: 10.57757/IUGG23-3407 - LINK

Edhah Munaibari[1], Lucie Rolland[1], Anthony Sladen[1], Bertrand Delouis[1]
[1]Université Côte d'Azur- Observatoire de la Côte d'Azur- CNRS- IRD- Géoazur, Alpes-Maritimes, Valbonne, France

As tsunamis propagate across open oceans, they remain largely unseen due to the lack of adequate sensors. To address this fundamental limitation of existing tsunami warnings, we investigate Global Navigation Satellites Systems (GNSS) data to monitor the ionosphere Total Electron Content (TEC) for Traveling Ionospheric Disturbances (TIDs) created by tsunami-induced internal gravity waves (IGWs). The approach has been applied to regular tsunamis generated by earthquakes, while the case of undersea volcanic eruptions injecting energy into both the ocean and the atmosphere remains mostly unexplored. With both a regular tsunami and air-sea waves, the large 2022 Hunga Tonga-Hunga Ha'apai volcanic eruption is a challenge. Here, we show that even in near-field regions (1000-1500km), despite the complex wavefield, we can isolate the regular tsunami signature. We also highlight that the eruption-generated Lamb wave induces an ionospheric disturbance with a similar waveform and an amplitude spatial pattern consistent with IGW origin but with a quasi-constant propagation speed (~ 315m/s). These results imply that when GNSS-TEC measurements are registered near an ocean bottom pressure sensor, they can help discriminating the regular tsunami from the initial air-sea waves appearing in the sensor observations.

Instantaneous and Adjusted Radiative Forcing and Volcanic Cloud Evolution of the January 2022 Hunga Tonga-Hunga Ha'apai (HTTH) Eruption

DOI: 10.57757/IUGG23-4066 - LINK

Georgiy L Stenchikov[1], *Alex Ukhov*[1], *Sergey Osipov*[1]
[1]*King Abdullah University of Science and Technology, Physical Sciences and Engineering, Thuwal, Saudi Arabia*

We modified the regional WRF-Chem model to study the evolution and radiative forcing of the January 2022 HTHH eruption. We use the Single Moment 5-class cloud microphysics scheme to handle the water in the troposphere and stratosphere. The Rapid Radiative Transfer Model (RRTMG) for shortwave (SW) and longwave (LW) radiation is used for radiative transfer calculations. We simultaneously inject SO_2 and water vapor at 35 km and conduct simulations in the (50S-10N) latitude belt for three months with 25 km spatial resolution. Initially, the volcanic cloud cools by thermal radiation and descends. The instantaneous radiative forcing was calculated by double call at the same meteorological fields. We found that in a month, the water vapor radiative forcing averaged over the latitude belt at the top of the atmosphere (TOA) reaches -0.016 W/m^2. The water vapor solar forcing is positive but two orders of magnitude smaller than LW forcing. Sulfate aerosol develops almost immediately after the injection. In two months, the sulfate SW forcing at TOA reaches -0.3 W/m^2. The sulfate LW forcing at TOA is positive but does not exceed 0.07 W/m^2 averaged over the domain. The volcanic cloud is cooling from the top at 0.1 K/day and warms from the bottom at 0.06 K/day. Thus, in our calculations, water vapor, nonuniformly distributed in the upper and middle stratosphere, cools the planet, although it is a greenhouse gas. However, the radiative effect of water vapor is 20 times smaller than sulfate aerosols.

The eruption of the Hunga submarine volcano on 15 January 2022 was likely the most explosive event of the modern observational era. Its plume reached altitudes over 50km over ground and carried large amounts of water vapor into the typically dry stratosphere. Simulations with the Chemical Lagrangian Model of the Stratospheric (CLaMS) could demonstrate that the behaviour of the injected water vapour could reproduce observations by the Microwave Limb Sounder (MLS) among others for about a month (Khaykin et al., 2022). After one year water vapour in the upper stratosphere is still significantly enhanced compared with the longtime record according to satellite observations by MLS. Here we investigate also the water vapour distribution over this period using a continuation of this CLaMS simulation based on ERA-5 reanalysis data.

The Comprehensive Nuclear-Test-Ban Treaty (CTBT) prohibits all nuclear explosions. For detection of potential non-compliance, the International Monitoring System (IMS) with 321 stations is being installed. The International Data Centre in Vienna provides standard data products. The discrimination of the event character is the responsibility of the State Signatories who are encouraged to make use of additional data, so called national technical means.

The explosive eruption of the Hunga Volcano on 15 January 2022 provides an ideal test case for reviewing established methods to analyse source processes. This is due to its enormous force and its explosive source mechanism close to an expected one but still featuring significant differences. Discriminating different kinds of explosive sources such as a nuclear test and a volcano eruption is a key task in the CTBT context.

We apply standard techniques to all four data types, i. e. three waveform technologies (seismology, infrasound, and hydroacoustic) and atmospheric transport modelling of radionuclides. Assessing the potential of these methods to discriminate a source, we can show that they work very well to identify, investigate, and discriminate an event of interest. During discrimination we could not only exclude a shear-source (i.e. an earthquake) but also distinguish the volcanic explosion in contrast to a man-made explosion. However, some tasks remain difficult (e.g. strength and therefore yield estimation). In addition to evaluating the methods, we could relate our results with specific phases of the volcanic processes providing a more detailed insight of what happened during the eruption.

More than two dozen MERMAIDs floating in the South Pacific recorded the hydro- and seismo-acoustic signals excited by the 15 January 2022 Hunga Tonga Hunga Ha'apai eruption. MERMAID, short for Mobile Earthquake Recording in Marine Areas by Independent Divers, is an oceanic mid-column float designed to autonomously record and report high-frequency (~1 Hz) teleseismic P waves useful for global tomography. MERMAID is a diver: it records acoustic data streams via its hydrophone at depth and surfaces roughly once a week to transmit those data via satellite. Its algorithms prioritize the isolation of short (minutes-long) data segments containing P waves. However, MERMAID's data buffer remains retrievable via two-way Iridium communication for one year. We made first-of-their kind multi-hour requests to capture the eruptive process recorded across the South Pacific Plume Imaging and Modeling array. We primarily focus on the high-frequency (5+ Hz) T-wave signals, broadly described as a double-peaked onset followed by a sustained high-SNR ``rumble'' lasting roughly 30 minutes. Many MERMAIDs across the array — at varied distances and backazimuths — exhibit high correlations of this main wave packet, however some do not. We investigate the reasons for intra-array variability in the shape and amplitude of the main wave packet, with particular emphasis given to understanding the role of bathymetry. Finally we discuss the public MERMAID data set currently available through EarthScope, and their accompanying new metadata standard called GeoCSV, which was recently approved for implementation by the FDSN Working Group 5 to track our, and other, moving seismometers.

Worldwide seismic observations of low frequency signals generated by the 15 January 2022 Hunga-Tonga eruption

DOI: 10.57757/IUGG23-1979 - LINK

Jordi Diaz[1]
[1]*Geo3Bcn-CSIC, -, Barcelona, Spain*

The eruption of the Hunga-Tonga volcano produced a high-energy explosion that was recorded globally by different scientific instruments, including broad-band seismometers. Seismic data recorded on global seismic networks are used to explore three main topics; the time evolution of the eruption, the atmospheric waves revolving around the Earth and the low-frequency, long-lasting signals recorded worldwide in the hours after the main event. From the inspection of the data we can assess that the eruption started on January 15 around 04:05 UTC, several minutes before the origin time reported in the seismic catalogs and included two large explosions at 05:30 and 08:35. As for the atmospheric waves, their energy was enough to be detected seismically during more than two complete circumambulations of the Earth, during a time span of three and a half days. The most notable seismic feature has been the low-frequency signals detected over several hours and interpreted as resulting from the excitation of Earth normal modes. To our knowledge, there are no previous examples of atmospheric-solid Earth coupling over such a long time interval and only two examples of normal mode excitation following volcanic eruptions, identified for the 1982 El Chinchón and the 1991 Mount Pinatubo eruptions.

Typical volcano-seismic signals on volcanoes include LP events, VT events and tremor. These events are detected and listed in catalogs as well as located and interpreted in the context of the volcano. Normally seismometers are used for these tasks. However, besides the translational ground motion, these events also generate rotational ground motion. Within this presentation we will highlight how rotational sensors can be used in this context. Following a few huddle tests in the field, we have installed the sensors in volcanically active regions such as Mount Etna and several interesting sites in Iceland. As a community effort we also started the python package TwistPy, to which more codes will be added in the future.

Analyzing and interpreting continuous seismic data in a timely manner, which could provide the potential for an operational forecast is an important goal in volcano seismology. Among these, detecting and understanding the precursors of volcanic eruptions have a key role in volcanic risk mitigation efforts. However, the complexity of processes prior to an eruption makes the study of the eruption preparatory phase challenging. More specifically, detecting volcanic tremor signals, which could serve as a sign of magma reaching the surface, can be difficult due to the high rate of seismic activities before eruptions. Although the seismicity rate usually increases before eruptions, elevated seismicity could occur without ensuing an eruption as well. In this study, we demonstrate that the clustering of volcanic tremors using deep neural networks trained on single-component spectrograms can reveal the precursory volcanic tremor signals three days before the 2021 Geldingadalir eruption albeit the signal was not directly visible in the seismic waveform. In general, we observe that the clustering results are consistent with the major phases of the eruptive activity ranging from unrest activities, continuous lava extrusion, and different levels of lava fountaining as have been described in previous studies. In particular, the temporal evolution of cluster memberships as a result of the deep embedded clustering supports the interpretation that an increase in discharge rate in late April 2021 led to the shifting of eruption style from vigorous outflow to lava fountaining in early May.

3-D seismic modeling of "calabash-resonances": Conduit-guided-wave excitation by magma-chamber wavefield capturing

DOI: 10.57757/IUGG23-1971 - LINK

Numerical simulations of seismic wave propagation in magma-filled conduits, located within the volcanic edifice, have been described in several previous publications. The calculations are usually limited to 2-dimensional vertical cross-sections through the edifice and consider the excitation of seismic waves by events located within the conduit. Under such configurations, the conduit, due to its lower seismic velocities, can act as an efficient wave guide. The effects on the seismic wavefield have been used to explain observations of relatively long-period seismicity observed at several volcanoes. In our numerical study (based on the "Salvus" software package), we perform wavefield calculations for 3-dimensional models of the volcanic edifice and include a magma chamber at the base of the conduit. Furthermore, in contrast to previous studies, we consider wavefield effects due to earthquakes located within and below the edifice, but outside of the conduit. The results show that the magma chamber acts as a trap for the incident wavefield and further redirects it into the conduit. The capturing of the wavefield is more efficient if the magma chamber is relatively large. The multiple reflections of the wavefield from the boundaries of the magma chamber cause long-lasting reverberations which are effectively channeled along the conduit. These "calabash resonances" may be responsible for some of the low-frequency seismic signals observed at volcanoes and can potentially be used to better constrain the geometry of the magmatic plumbing system.

Estimating the seismic moment-based magnitude for earthquakes occurring in Mt. Etna volcano area

DOI: 10.57757/IUGG23-1528 - LINK

Angela Saraò[1], *Luca Moratto*[1], *Elisabetta Giampiccolo*[2], *Ornella Cocina*[2]
[1]*Istituto Nazionale di Oceanografia e di Geofisica Sperimentale - OGS, Centro di Ricerche Sismologiche, Sgonico, Italy*
[2]*Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Catania, Catania, Italy*

The moment magnitude is closely related to the seismic moment, which quantifies the energy released by earthquakes, and is therefore important for understanding volcanic dynamics and assessing seismic hazard.

In this study, we calculate the moment-based magnitude (M_W) for selected seismic data sets, using different approaches in distinct magnitude ranges to cover the widest possible range of magnitude that characterizes Etna's seismicity. Specifically, we computed the M_W from a dataset of full moment tensor solutions of earthquakes that occurred in the magnitude range $3.4 \leq M_L \leq 4.8$ during 2005-2020; we created a dataset of seismic moment and associated M_W for earthquakes $2.0 \leq M_L < 3.4$ obtained by analyzing source spectra; we fine-tuned two relationships, for shallow and deep earthquakes, to obtain M_W from response spectra. Finally, we calibrated a specific relationship between M_W and M_L for the Etna area earthquakes in the range $2.0 \leq M_L \leq 4.8$ and for microseismicity ($M_L < 2.0$) using synthetic data. Our results show that the scaling between M_L and M_W is 1 for magnitude $2.0 \leq M_L \leq 4.8$, while it becomes 2/3 when we extend the relationships to $M_L < 2.0$.

All the empirical relationships obtained in this study can be applied in real-time analysis of the seismicity to provide fast and robust information on the released seismic energy.

The moment magnitude is closely related to the seismic moment, which quantifies the energy released by earthquakes, and is therefore important for understanding volcanic dynamics and assessing seismic hazard.

In this study, we calculate the moment-based magnitude (M_W) for selected seismic data sets, using different approaches in distinct magnitude ranges to cover the widest possible range of magnitude that characterizes Etna's seismicity. Specifically, we computed the M_W from a dataset of full moment tensor solutions of earthquakes that occurred in the magnitude range $3.4 \leq M_L \leq 4.8$ during 2005-2020; we created a dataset of seismic moment and associated M_W for earthquakes $2.0 \leq M_L < 3.4$ obtained by analyzing source spectra; we fine-tuned two relationships, for shallow and deep earthquakes, to obtain M_W from response spectra. Finally, we calibrated a specific relationship between M_W and M_L for the Etna area earthquakes in the range $2.0 \leq M_L \leq 4.8$ and for microseismicity ($M_L < 2.0$) using synthetic data. Our results show that the scaling between M_L and M_W is 1 for magnitude $2.0 \leq M_L \leq 4.8$, while it becomes 2/3 when we extend the relationships to $M_L < 2.0$.

All the empirical relationships obtained in this study can be applied in real-time analysis of the seismicity to provide fast and robust information on the released seismic energy.

Large basaltic volcanoes offer natural laboratories to study the fundamental processes of crustal deformation and seismogenesis. High rates of magma flux in to and/or out of shallow reservoirs can result in strain rates and stress regimes that seldom occur in purely tectonic settings. Eruption cycles at Sierra Negra, a basaltic caldera volcano in the western Galápagos Islands, Ecuador, are often associated with particularly high amplitudes and rates of deformation, and high rates of seismicity. Spatiotemporal patterns of surface deformation at Sierra Negra can largely be explained by magma flux in and out of a shallow sill within a laterally continuous viscoelastic medium. However, seismic strain is localized almost exclusively on an intra-caldera ‘trapdoor’ fault system. Here we describe the seismicity and deformation that occurred before, during, and after the 2018 eruption at Sierra Negra, documenting the activation and stress evolution of the trapdoor fault system. During the 13 years and 6.5 m of inflation before the eruption, increasing seismicity rates with both time and total uplift, and progressively degreasing Gutenberg-Richter b-values. The stress conditions on the trapdoor fault reversed during the co-eruptive deflation. On resumption of inflation, the number of earthquakes per unit of uplift was very low, and the b-value high, reflecting the newly relaxed stress state of the fault system.

Volcano monitoring and modelling using Distributed Acoustic Sensing (DAS) on a subglacial volcano: Grímsvötn, Iceland

DOI: 10.57757/IUGG23-1385 - LINK

Sara Klaasen[1], Solvi Thrastarson[1], Yesim Cubuk-Sabuncu[2], Kristín Jónsdóttir[2], Lars Gebraad[1], Sebastian Noe[1], Andreas Fichtner[1]

[2]Icelandic Meteorological Office, Warnings and forecasting, Reykjavik, Iceland

We present the results of an experiment with Distributed Acoustic Sensing (DAS) on Grímsvötn in Iceland, and the potential of Full Waveform Inversion with DAS.

We deployed a 12 km long fibre-optic cable for one month (May 2021) on Grímsvötn, Iceland's most active volcano, which is covered by the large Vatnajökull glacier. The cable was trenched 50 cm into the ice, following the caldera rim and ending near the central point of the caldera on top of a subglacial lake.

We have discovered previously undetected levels of seismicity using an automated earthquake detection algorithm that is based on image processing techniques. We identified first arrival times with an automated cross-correlation based algorithm, developed specifically for complex and local events recorded with DAS. The first arrival times, combined with a probabilistic interpretation and the Hamiltonian Monte Carlo algorithm, yield event locations, their respective uncertainties, and effective velocities along ray paths, even in the absence of a detailed velocity model. Finally, we complete our initial catalogue with local magnitudes, which reveals nearly 2000 events in total, of which ~1% was detected by the local network. This local microseismicity shows spatio-temporal clusters, with active parts of the caldera fault.

We use this catalogue as a starting point for simulations of the complex environment, with the aim of going towards Full Waveform Inversion with DAS data. We show the current challenges and progress towards inverting the data for both subsurface structures, and source characteristics.

The NASA InSight Lander on Mars includes the Heat Flow and Physical Properties Package HP^3 [1] to *in-situ* measure the surface heat flow. Temperature sensors were to be installed at a target depth of 3–5m by a small penetrator, nicknamed the mole. A radiometer to measure the surface temperature complements the package. The mole, requiring friction on its hull to balance remaining recoil from its hammer mechanism, did not penetrate to the targeted depth. Instead, it reached a depth of 40cm, bringing the mole back-end 2–3cm below the surface. Lessons learned from the penetration failure have been discussed by [2]. The root cause of the failure - as was determined through an almost two years long campaign - was a lack of friction in an unexpectedly thick cohesive near-surface duricrust. The mole was used as a penetrometer and a thermal probe [3,4] instead and the hammering signals were recorded by the InSight seismometer [5]. Accordingly, the soil is highly porous and layered with a density of 1200kg/m^3, thermal conductivity of 39mW/m K, cohesion between 4 and 25kPa, and s and p wave velocities of around 115 and 60m/s, respectively. The thermal conductivity varies with the season and the atmospheric pressure by +/-5% showing that gas in the pores contributes significantly to the heat transport.

On the Earth, with more than a century of seismology and on Mars, with the recent InSight seismic data, seismic signals generated through the coupling of the atmosphere with interior have been detected after atmospheric explosions, either due to coupling near the source or near the seismometer. Subsurface structure inversion have also been made on Mars and on the Earth from the joint recording by seismometer and pressure sensor of subsurface elastic deformation generated by atmospheric vortexes and the subsequent inversion of compliance.
On the opposite, gravito-acoustic signals in the Earth atmosphere have been also detected after earthquakes and tsunamis. While no such signal has been observed on Mars, their detection seems realistic on Venus, either with infrasound sensors in the atmosphere or with ionospheric sensors in orbit.
We present here a short comparative review of observations on Earth and Mars, with focus on coupling near the source due to atmospheric or surface explosion, on the detection at the station of atmospheric signal through compliance and on the subsurface inversion of compliance from atmospheric sources. We then extrapolate to Titan, for which we present synthetics illustrating how seismometer, such as those of the DragonFly mission, could also be used for detecting atmospheric infrasounds through compliance effect.
We finally compare Earth and Mars in terms of seismic atmospheric-interior coupling with two other terrestrial bodies of the solar system, Venus and Titan, here again, we illustrate with synthetics the strength of atmospheric signals generated by quakes and discuss perspectives, in terms of observation strategy.

Following its deployment at the surface of Mars, the SEIS seismometer of the NASA-InSight mission recorded tens of high-frequency Martian seismic events (> 1Hz) which we analyzed to characterize the attenuation properties of the Martian lithosphere from an Earth-Moon-Mars comparison perspective. The Martian waveforms are generally depolarized and show P and S arrivals with a gradual beginning, a broad maximum and a very long coda decay. These characteristics are reminiscent of the seismic wavefield in the terrestrial oceanic lithosphere at high frequency (Po and So above 2Hz). To constrain the attenuation properties on Mars, we modeled the energy envelopes of very-high frequency events (>2Hz) using a multiple-scattering approach, in which we considered a stratification of velocity and attenuation in the medium. We found that a simple model composed of a highly scattering crust overlying a weakly inhomogeneous mantle is sufficient to explain the main features of Martian events. We found that the Martian crustal diffusivity (10-12 km^2/s) is similar to the estimation obtained in the lithosphere of the Atlantic Ocean (15–60 km^2/s, Hannemann et al. 2022), but higher than the Lunar crust value (2 km^2/s). The absorption attenuation results indicate that the Martian crust is globally dry (Q_μ^{-1} ~ 10^{-4}) compared to the terrestrial crust (~ 10^{-3}). Our results suggest that the basaltic nature and the heterogeneities of the crust are the main source of the scattering in the Martian and oceanic lithospheres. By contrast, the extreme strength of the scattering on the Moon suggests a predominant role of fractures.

The InSight mission collected an astounding seismic dataset from Mars during more than four years of operation until it was retired in 12/2022. The Marsquake Service detected over 1300 seismic events. The largest marsquake reached magnitude 4.6. Two other significant events are distant impacts, with magnitudes M4.0 and 4.2 and crater diameters of 130 and 150 m respectively. We present the current understanding of the Martian seismicity and the different types of events observed on Mars.

Low Frequency (LF) family are the largest events and include energy predominantly below 1 Hz. They are similar to teleseismic events on Earth, with clear P and S waves. The epicenter is known for about half of the LF events, fewer have constrained back-azimuth. Seismicity occurs at only a few spots around Mars - a large number of LF events are located at 26–30° at the volcanic Cerberus Fossae region. Two events lie beyond the core shadow and have PP and SS phases. High-frequency (HF) family exhibit energy predominantly at and above the 2.4 Hz local subsurface resonance. HF events generally have magnitudes below M2.5 and originate from central Cerberus Fossae. Likely these are shallow events associated with volcanic dykes. HF events have inter and intra seasonal trends not yet understood. A small number of HF events have higher frequency content, up to 20–30 Hz with amplification on the horizontal components, and are termed Very High Frequency (VF) events. The closest VF events include a distinctive acoustic signal, and remote imaging confirms they are impacts.

No active volcanism has been ever observed on Mars, but the planet has many recent traces of volcanic activity and significant parts are covered by volcanic units (*1*). The InSight seismic dataset localizes more than half of the observed seismic activity in Cerberus Fossae (*2*), a young (<10 Ma (*3*)) graben structure in Elysium Planitia, previously interpreted as a result of dyke intrusion (*4*) or large-scale tectonic stress (*3*). While initial reports of volcanic tremor (*5*) could not be confirmed, spectral analysis of marsquakes observed in this region show a warm, elastically weakened source region (*6*), e.g. due to partial melting at lithospheric depths (*7*) or deformation due to a mantle plume (*8*). The significant contribution of this small region to Mars' global seismic budget *(9)* means that volcanism shapes the planet's surface at a higher rate than contraction. We discuss the mechanisms of Martian seismicity as they are currently understood and their relation to orbitally observed tectonics.

Silicate glasses represent an important component in volcanic products, and since volcanism occurred on all terrestrial planets in the solar system, they might influence the spectral response of portions of planetary sur-faces. However, their spectral characteristics are not always considered for the interpretation of planetary surfaces and terrains, giving their blurred spectral response and the supposed lack of information they can provide.
In this study, we used experimental petrology to produce glassy samples having a wide variety of chemical compositions, and we characterized them by means of reflectance and emissivity in different spectral ranges, to observe the variation of their spectral characteristics with changing chemical composition and with varying granulometric characteristics.
In the Mid-Infrared range, we observed a systematic shift of spectral features, both for reflectance and emissivity spectra, that can be modelled with SiO2 and SiO2 + Al2O3 + TiO2 content, whereas the shape of the spec-tra is determined by a complex interaction of chemical and granulometric characteristics. As for the Visible and Near Infrared spectral range, we observed a correlation between the spectral slope and the iron content and speciation. Our results suggest that accounting for the spectral properties of silicate glasses, when interpreting spectral data obtained from the surface of terrestrial planets, will help in the characterization of magmatic bodies and volcanoclastic materials.Thus, we offer an open-source database of collected spectra within the Space Sci-ence Data Center (SSDC), a facility of the Italian Space Agency (ASI) which includes data processing and data archiving center (www.ssdc.asi.it).

Silicate glasses represent an important component in volcanic products, and since volcanism occurred on all terrestrial planets in the solar system, they might influence the spectral response of portions of planetary sur-faces. However, their spectral characteristics are not always considered for the interpretation of planetary surfaces and terrains, giving their blurred spectral response and the supposed lack of information they can provide.
In this study, we used experimental petrology to produce glassy samples having a wide variety of chemical compositions, and we characterized them by means of reflectance and emissivity in different spectral ranges, to observe the variation of their spectral characteristics with

changing chemical composition and with varying granulometric characteristics. In the Mid-Infrared range, we observed a systematic shift of spectral features, both for reflectance and emissivity spectra, that can be modelled with SiO_2 and $SiO_2 + Al_2O_3 + TiO_2$ content, whereas the shape of the spec-tra is determined by a complex interaction of chemical and granulometric characteristics. As for the Visible and Near Infrared spectral range, we observed a correlation between the spectral slope and the iron content and speciation. Our results suggest that accounting for the spectral properties of silicate glasses, when interpreting spectral data obtained from the surface of terrestrial planets, will help in the characterization of magmatic bodies and volcanoclastic materials.Thus, we offer an open-source database of collected spectra within the Space Sci-ence Data Center (SSDC), a facility of the Italian Space Agency (ASI) which includes data processing and data archiving center (www.ssdc.asi.it).

A model for the angle of repose of dry cohesive granular materials on planetary surfaces

DOI: 10.57757/IUGG23-4541 - LINK

Eric Josef Ribeiro Parteli[1], *Filip Elekes*[2]
[1]*University of Duisburg-Essen, Faculty of Physics, Duisburg, Germany*

The surfaces of Earth, Moon, Mars and many other celestial bodies of our solar system are composed mainly of particulate materials, such as regolith, sand and dust. One of the most important observables characterizing the physics of these materials is the angle of repose, i.e., the angle of maximum stability of inclined granular surfaces such as heaps, crater walls and dune slip faces. However, this angle is affected by still poorly understood grain-scale processes. Attractive particle-particle interactions become more effective than particle weight the smaller the grains are, but the stability of granular landscapes on planetary surfaces has remained elusive. Therefore, a theoretical model for predicting the angle of repose as a function of particle size and gravity would have broad impact in the planetary, environmental and engineering sciences. Here we present such a model, which we have derived from grain-scale simulations under consideration of contact and van der Waals interactions. Our model reproduces quantitatively experimental data of the angle of repose, from gravel and rock particles to dust-sized grains, as well as simulation predictions with gravity from 0.06 to 100 times that of Earth. Based on our model, we present a method for estimating the angle of repose on a given planetary surface by suitably adapting the particle size in the laboratory, without the need for generating extra-terrestrial gravity. We also show how the angle of repose can be used as a proxy for grain attributes and the solid fraction of particulate materials on the surface of celestial bodies.

Jupiter's weather layer exhibits long-term and quasi-periodic cycles of meteorological activity. There are cycles with intervals from 4 to 9 years, dependent on the latitude, which were detected in 5µm radiation, which provides a window into the cloud-forming regions of the troposphere. However, the origin of these cycles has been a mystery. We propose that magnetic torsional oscillations/waves arising from the dynamo region could modulate the heat transport and hence be responsible for the variability of the tropospheric activity. These axisymmetric waves are magnetohydrodynamic waves influenced by the rapid rotation, which have been detected in Earth's core. Using the Juno magnetic field model, together with the density distribution model, we compute the expected speed of these waves. For the wave excited by variations in the zonal jet flows, their wavelength can be estimated from the width of the alternating jets, yielding waves with a half period of 3-5 years at mid latitudes, consistent with the intervals with the cycles of variability of Jupiter's North Equatorial/Temperate Belt identified in the visible and infrared observations. The nature of these waves is revealed by technique, dynamic mode decomposition, applied to the spatio-temporal data for 5µm emission. Our results imply that exploration of these magnetohydrodynamic waves may provide a new window to the origins of quasi-periodic patterns in Jupiter's tropospheric clouds and to the internal dynamics/dynamo of Jupiter.

How to understand volcanic processes on Jupiter's moon Io

DOI: 10.57757/IUGG23-2168 - [LINK]

Alfred McEwen[1]
[1]*University of Arizona, Planetary Sciences, Tucson, USA*

Jupiter's large moon Io is intensely tidally heated and is covered by >100 very active volcanic centers (greater than Kilauea's average heat flow). These are high-temperature eruptions that can be monitored remotely, even from Earth-based telescopes. However, there are multiple key questions that can only be answered by a spacecraft mission dedicated to Io: Is the magma dominantly mafic or ultramafic in composition? Are the eruptions sourced directly from the mantle or from shallow magma chambers? What is the role of sulfur and sulfur compounds in the volcanism? What is Io's total heat flow and how does it vary with latitude and longitude? How does the volcanism relate to the tectonics producing >10 km high mountains? What is the distribution of melt in Io's interior? Is there a magma ocean? Is the orbital resonance creating the tidal heat in equilibrium or does it vary periodically? How has Io evolved over time? A spacecraft mission with at least 10 close flybys of Io can address these questions, provided it carries the right science payload including visible cameras designed to measure liquid lava temperatures as well as map the surface topography and monitor activity, thermal-IR cameras sensitive from 1-50 microns, magnetometer and gravity science experiments to understand interior melt and lithospheric thickness, and a mass spectrometer to measure the composition of erupted gases. This is the basic concept of the Io Volcano Observer mission concept, which will be expanded for NASA's New Frontiers mission opportunity, with substantial European collaborations.

In 2019, Chang'E-4 (CE-4) landed on the eastern floor of Von Kármán crater on farside of the Moon. The Yutu-2 rover of CE-4 mission carries a Lunar Penetration Radar (LPR) that is equipped with one transmitting and one receiving dipole antenna for 60 MHz, and one transmitting and two bow-tie receiving antennas for 500 MHz. LPR data acquired onboard the Moon Chang'E 4 mission rover Yutu-2 is used to quantify the attenuation within the regolith-dominated shallow subsurface on the Moon. The signal attenuation is estimated using a recently developed approach, based on the downshift of the centroid-frequency of the transmitted pulse, which is assumed to be a Ricker wavelet. In particular, the intrinsic attenuation, which is described in terms of the medium's loss tangent, is retrieved from the back-scattered signals through a probabilistic inversion approach. In addition, the total energy loss (i.e., the sum of scattering and intrinsic losses), evaluated by the inverse quality factor is obtained from the linear fitting of the time amplitude decay. It is thus possible to separate the total loss to its composing components i.e., absorption and scattering terms. From the results, it appears that the intrinsic attenuation along the track is almost constant, while the total loss presents large variations, that are caused by both subsurface inhomogeneities and scatters. In addition, the average loss tangent and total loss are, and respectively.

The solar wind is a possible source of water and other volatile elements that may solve a puzzle of how did terrestrial planets (within the snow line) get a substantial amount of water during their formation. To understand the possible role of the solar wind, we conducted high-energy proton implantation experiments for olivine, orthopyroxene and quartz, and results were analyzed using nuclear resonance reaction analysis. We also conducted a numerical experiment on hydrogen implantation on small dusts and found that for not much hydrogen is trapped in small dusts whose size is comparable to or less than the mean free path of H in the mineral. Using these results, we conclude: (i) a large amount of H can be implanted into these minerals quickly, (ii) the amount of hydrogen implanted in dusts depends on the dust size with a peak at ~0.1 – 1 micron, and (iii) because the energy of D is ~twice higher than that of H in the solar wind, the D/H ratio of trapped H and D in the dusts will be higher than the D/H of the solar wind. For a plausible dust size in the nebular disk (~1 micron), one can get enough water to make a wet planet quickly (<1000 years). We also studied the nature of change in physical properties of mineral (olivine) by high-energy proton irradiation. Irradiation makes olivine mechanically weak and likely increases the dielectric constant. Possible effects on sticking of dusts will be discussed.

More mantle, more melt: modeling the mantle-derived causes of heterogeneity in volumetric magmatic flux at arcs

DOI: 10.57757/IUGG23-4482 - LINK

<u>Andrea Goltz</u>[1], Christy Till[1], Adam Kent[2]
[1]Arizona state University, School of Earth and Space Exploration, Tempe, USA
[2]Oregon State University, College of Earth- Ocean- and Atmospheric Sciences, Corvallis, USA

Estimates of volumetric magmatic flux vary significantly between arc volcanoes, both globally and between volcanoes in a given arc. A recent case study of the Cascades arc suggested that variation in basaltic flux from the mantle causes heterogeneity in surface volcanic flux. The root causes of such variations are poorly known, and could relate to along-arc variations in fluid flux from the subducting oceanic lithosphere, changes in mantle thermal structure or composition, or subduction geometry.

We model the volumetric flux of magma from the mantle using a simplified 3-D box model of a subduction zone to constrain the physical factors that most influence the volume of magma produced in the mantle over time. We evaluate the relative contributions of the extents and styles of melting at subduction zones and of the physical parameters of subduction to volumetric flux in a Monte Carlo calculation.

Our results suggest that the volume of mantle available to melt, the extent of wet (flux) melting, and convergence rate are the most important factors controlling volumetric flux. In cases where calculated volumetric flux closely approximates published estimates of volcanic flux, we predict that melting is not constrained to the mantle directly below volcanic edifices, suggesting that magma supplied to the lithosphere requires lateral transport to "feed" the central edifices of volcanoes.

Results from our model may aid in the interpretation of geochemical features like similarity of primitive magmas at adjacent volcanoes and support the idea that mantle magma supply may be an important control on volcano spacing.

Decisive role of lithosphere in the evolution of Deccan Traps, India and the "Bushe" conundrum

DOI: 10.57757/IUGG23-1343 - LINK

Tarun Khanna[1]
[1]*CSIR-National Geophysical Research Institute, Geochemistry, Hyderabad, India*

In the past, extensive studies were carried out in the peripheral regions of the Western Ghat Escarpment (WGE) to postulate the chemostratigraphy of the Deccan Traps, India. However, there remains a dearth of information in the knowledge of the petrogenesis and chemostratigraphy of the Deccan Traps in the Main Deccan Plateau, east of the WGE. Because the continental flood basalts (CFBs) are produced from voluminous melting of an asthenospheric mantle source, it is often difficult to discern the geochemical signatures sourced from the sub continental lithospheric mantle (SCLM). Interaction and contamination of the asthenospheric melts by the continental crust further adds to the complexity of geochemical fingerprinting of the lithospheric mantle. Recently, the basalt lavas recovered from the deep bore-hole well-cores drilled by CSIR-NGRI in the Koyna-Warna region, south-west Deccan Plateau, have yielded new high precision geochemistry and Nd-Sr isotopic information, elucidating the chemostratigraphy, which illustrates the decisive role of the lithospheric mantle in the genesis and evolution of the Deccan Traps. The trace and rare earth element systematics involving Ba, Ti, Nb, Th, Y, La, Gd and Yb in combination with initial $^{143}Nd/^{144}Nd_{(t=66My)}$ and $^{87}Sr/^{86}Sr_{(t=66My)}$ isotopic compositions of a 50 m thick eruptive phase, discovered at a depth of 100 meters below MSL, provided compelling evidence for the genesis of the Bushe-type lavas exclusively from partial melting of the lithospheric mantle and not from the asthenospheric sourced Reunion plume. This "Bushe" conundrum has far reaching implications for the overall processes of evolution of the Deccan Volcanic Province.

Evidence of fluid-triggered earthquakes and structural segmentation in the Kumaon-Garhwal Himalaya, India

DOI: 10.57757/IUGG23-0060 - LINK

Prantik Mandal[1], *R. Vijay Raghavan*[1], *Satish Saha*[1], *Raju Prathigadapa*[1], *Dakuri Srinivas*[1]
[1]*CSIR-National Geophysical Research Institute, Seismology, Hyderabad, India*

Using data from a 60-station network in Kumaon-Garhwal (2017-2022), we discovered a north dipping (2^o) low-velocity zone (10-20% drop in Vp and Vs, 10-15% increase in Vp/Vs) between 10 and 20 km depths that correlated with the main Himalayan thrust (MHT). It is worth noting that the rupture zones of the 1803 M_w7.6 Garhwal, 1991 M_w6.8 Uttarkashi, and 1999 M_w6.5 Chamoli earthquakes are all characterised by low-velocity zones, implying that the earthquakes were triggered by the presence of metamorphic or aqueous fluids within the MHT. Through the Common Conversion Point stacking of radial PRFs, we also detect a double Moho structure beneath the aforementioned rupture zones, which could be accumulating high crustal stresses favouring the moderate to large earthquake occurrences in the region.

Our H-K stacking of radial PRFs, as well as joint inversion of radial PRFs and Rayleigh wave group velocity dispersion, resulted in three NNE-SSW trending transverse crustal blocks with significant mafic crust thinning, which are projected to extend down to the lithosphere-asthenosphere boundary. These three transverse lithospheric characteristics correlate to the northward extension of the Delhi-Haridwar ridge, a presumed tectonic boundary (marked by the intersection zone of rupture zones associated with the 1505 M_w8.2 and 1803 M_w7.6 earthquakes), and the Great Boundary fault, in that order. As a result, we hypothesise that these transverse structures may have segmented the lithosphere (below the MHT) in the Uttarakhand Himalaya, reducing the potential rupture lengths and, as a result, the probability of future large earthquakes ($M \geq 8$) in the region.

[2]Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Roma, Roma, Italy
[3]Università Statale d Milano, Department of Earth Sciences, Milano, Italy

The crustal feeding systems of Toba caldera (Indonesia) remain largely unknown due to (1) the lack of seismic images resolving magmatic sills and fluid reservoirs and (2) our inability to translate seismic parameters into meaningful petrophysical quantities. Using data from available seismic arrays, we obtained thousands of dispersion curves sensitive to both the shallow crust and the upper mantle. The usual seismological approach is to invert them for phase-velocity maps at different periods and transform them into a shear-wave model. This model shows low-velocity sill-like structures at different depths under the northern and central Toba caldera; however, the uncertainty in their interpretation cannot be quantified just by looking at their shape, depths and correlation with surface features.

Therefore, we used a Gibbs energy-minimization solver that computes seismic velocities from phase petrology for the compositions relevant to Toba to forward phase velocities directly. A Bayesian Monte Carlo Markov chain inversion then inverts for temperature, composition, background host rock damage and melt content. As a result, every velocity value from our calculations is petrologically feasible. The results identify the portions of the crust where mafic sills are located, quantitatively defining their melt content, chemical composition, rock damage, temperature and associated uncertainty. Due to the low sensitivity of shear waves to temperature, there are still fundamental challenges in defining the thermal structure of the volcano; yet, seismo-petrological inversions are feasible today within one of the most complex crustal systems, a result few expected to achieve a decade ago.

Expert-based and data-driven gully and cliff erosion feature detection in New Zealand

DOI: 10.57757/IUGG23-0228 - LINK

Lorena Abad[1], *Daniel Hölbling*[1], *Hugh Smith*[2], *Andrew Neverman*[2], *Harley Betts*[2], *Raphael Spiekermann*[2]
[1]*University of Salzburg, Department of Geoinformatics - Z_GIS, Salzburg, Austria*
[2]*Manaaki Whenua – Landcare Research, Soils and Landscapes, Palmerston North, New Zealand*

Erosion in New Zealand is the result of its landscape, with steep slopes and weak rocks, climate, including high-intensity rainstorms, and its history of land clearing. Improved management of erosion requires better targeting of mitigation measures using data on the spatial distribution and dimensions of erosion features. For this, automated object detection approaches and the increased availability of remote sensing data can be exploited. In this study, we explore expert-based and data-driven object detection approaches to map gully and river cliff features in the Wairoa catchment in Hawke's Bay, New Zealand.
Aerial photographs and terrain derivatives obtained from a LiDAR digital elevation model were used as input data for object detection. Manual delineations of gully and cliff features were used as reference data. A knowledge-based object-based image analysis (OBIA) workflow constituted the expert approach. The integration of expert knowledge facilitated the differentiation of erosion types but resulted in the classification of a high proportion of false positives. The data-driven approach consisted of a region-based convolutional neural network (Mask-RCNN) deep learning (DL) model. The DL model showed good results in the delineation of erosion features and differentiated between gullies and cliffs reasonably well, although not all reference features were detected in the validation areas.
We showed that erosion feature detection can benefit from new data-driven techniques such as DL, however, expert knowledge remains an important aspect in such studies because any mapping task benefits from a certain understanding of erosion processes and the environmental characteristics of the study area.

Erosion in New Zealand is the result of its landscape, with steep slopes and weak rocks, climate, including high-intensity rainstorms, and its history of land clearing. Improved management of erosion requires better targeting of mitigation measures using data on the spatial distribution and dimensions of erosion features. For this, automated object detection approaches and the increased availability of remote sensing data can be exploited. In this study, we explore expert-based and data-driven object detection approaches to map gully and river cliff features in the Wairoa catchment in Hawke's Bay, New Zealand.
Aerial photographs and terrain derivatives obtained from a LiDAR digital elevation model were used as input data for object detection. Manual delineations of gully and cliff features were used as reference data. A knowledge-based object-based image analysis (OBIA) workflow constituted the expert approach. The integration of expert knowledge facilitated the differentiation of erosion types but resulted in the classification of a high proportion of false positives. The data-driven approach consisted of a region-based convolutional neural network (Mask-RCNN) deep learning (DL) model. The DL model showed good results in the delineation of erosion features and differentiated between gullies and cliffs reasonably well,

although not all reference features were detected in the validation areas. A variety of surface water indices have been developed in the past to detect and monitor water resources on regional, national to continental scal. Less attention has been given to exploiting surface water resources using machine learning algorithms (MLAs). This work compares surface water detection by MLA with surface water indices. Using high-resolution sentinel-1/2 data in the Google Earh Engine cloud computing system we quantify seven widely established surface water indices. Alternatively, we test various MLAs as an integrated approach for enhanced surface water detection complemented by surrogate spatial information like hydro-meteorological and topographic data as additional predictor variables. We establish four MLAs, namely support vector machine (SVM), random forest (RF), gradient tree boost (GTB), and classification and regression tree (CART). All surface water indices and results of MLAs are evaluated for their capability in surface water detection by an assessment of qualitative and quantitative accuracy indicators, including the producer's accuracy, user's accuracy, overall accuracy, and kappa coefficients. Most surface water indices generally provide very good results with kappa coefficients of more than 0.90. MLA-based assessment of surface water detection is not superior in this regard, but provide further insight to dominating predictor variables, and therefore contribute to an improved process understanding of why and where surface water resources occur.

Evaluating the impact of the 9€-ticket on air quality in Leipzig, Germany, through machine learning algorithms

DOI: 10.57757/IUGG23-4995 - LINK

Andrea Cuesta-Mosquera[1], Mira Poehlker[1], Thomas Mueller[1]
[1]Leibniz Institute for Tropospheric Research, Atmospheric Microphysics Department, Leipzig, Germany

To confront inflation and reduce private energy consumption, incentives to use public transport are becoming more common; this is the case of the 9€-ticket implemented in Germany during summer 2022 (June-August), which allowed passengers to commute and travel regionally using a reduced-price monthly ticket. However, there is still a lack of knowledge regarding the environmental impacts of the 9€-ticket, e.g., air quality (AQ) improvements derived from changes in private transport trends.

In this study, we aim to assess the influence of the 9€-ticket on air quality in Leipzig. Long-term (2018-2022) times series of atmospheric pollutants (PM, NOx, NO_2), aerosol concentrations (Black carbon), and meteorological variables have been collected. A random forest machine learning algorithm (RFA) is used for meteorological normalization of air pollution and aerosol data to "discount" the effect of meteorology on AQ. This process allows the robust comparison of the AQ time series from 2022 and normal years (2018-2019).

Preliminary use of the RFA successfully normalized NO_2 mass concentrations for 2018-2019. Slight reductions of 5% and 3% in the average NO_2 concentrations were observed in Summer 2018 and 2019 (compared to spring), respectively. The following steps include the meteorological normalization of 2022 AQ data (in preparation) and further pollutants (PM, NOx, BC). The normalized AQ time series from 2022 and normal years will be compared; the analysis will consider the reductions already observed in 2018-2019 and the school-holidays period effect. Additionally, we will assess traffic volume from permanent counting stations from 2018 to 2022.

Increasing demand for coastal and offshore marine applications calls for accurate forecast of instantaneous sea level, storm surges and better understanding of marine processes. Previously one of the major limitations in accomplishing this has been and incompatible vertical reference datum and access to a method that intelligently integrates and analyzes all the different sources. With respect to linking the different data sources the use a high-resolution geoid now allows the determination of dynamic topography which represents a more accurate term for sea level. Thus this study presents a proposed methodology, that uses machine learning strategies to forecast and better understand the marine dynamics.The methodology proposed shall utilize mathematical, statistical and machine learning strategies (e.g. neural networks and inter-technique solutions) along with various relevant data sources (e.g. marine geoid, tide gauges, hydrodynamic models, satellite altimetry etc.) to forecasts sea level in the absolute sense along with their uncertainties. The results is expected to: (i) forecast dynamic topography, storm surges up to 7 day ahead, (ii) identify and predict oceanographic patterns and processes (currents, eddies, etc.), and (ii) determine realistic under keel clearance. The developed method shall be performed in the study area of the Baltic Sea that has an intense activity of shipping and maritime activities.

Recently, there has been a surge in the utilization of machine learning algorithms in the field of reservoir characterization studies, reflecting a growing interest in the area. The development and application of novel machine-learning methods are crucial for optimizing production by addressing complex reservoir challenges. Here, an attempt is made to shed light on the application of novel machine learning algorithms to infer permeability, a vital property of reservoir rock. Case examples of a few different reservoir systems will be discussed to critically analyze the performance of machine learning tools and their predictability in petrophysical attribute characterization using wireline log data. Further, parametric sensitivity analysis is conducted to identify the influential predictor variable most relevant for the efficient predictive model. This study aims to benefit readers by highlighting existing gaps in reservoir characterization studies and the potential application of machine learning algorithms for reservoir rock property estimation with much accuracy.

A new deep learning tool to discriminate earthquakes and quarry blasts in Mainland France

DOI: 10.57757/IUGG23-1872 - LINK

Marc Grunberg[1], *Sophie Lambotte*[2], *Remi Dretzen*[1]

[2]*ITES, UMR7063 Université de Strasbourg / CNRS, Strasbourg, France*

Accurate seismic hazard assessment requires high quality and complete seismic catalogs. Anthropogenic events such as quarry blasts, rock bursts, explosions can introduce significant errors in statistical analyses, especially in areas with low background seismicity rates such as Mainland France.

The BCSF-Renass, a national service of observation in seismology, characterizes the seismicity of the Mainland France, and makes available to the scientific community its seismic catalog. Until 2012, only natural seismicity was localized but since 2012, other types of events are localized and manually discriminated, in particular quarry blasts, marine explosions (demining operation), induced seismicity.

These last years have seen a huge increase of new seismological stations installed in the Resif-EPOS framework. The main consequence is the location by the BCSF-Renass of many low magnitude events, most are quarry blasts (around half in 2022). The work of the analysts is considerably impacted, firstly by a huge increase of events to be processed and secondly by the difficulty of determining the events' origins with the issue of catalog contamination.

This is why the BCSF-Renass, in early 2022, has developed a Deep Convolutional Neural Network (DCNN) tool to automatically discriminate earthquakes from quarry blasts. The learning step was done on the 3 components seismogram spectra on the year 2021 events. The performances are more than 99% for precision and recall, and take well into account the different regions and geological contexts of France. Moreover, this discrimination also worked well for marine explosions, and allowed us to highlight landslides or rock falls.

Efficient Bayesian inversion of planetary structures based on normal mode analysis using generative neural networks

DOI: 10.57757/IUGG23-3163 - LINK

Binbin Liao[1], *Heping Sun*[1]

Bayesian inversion based on normal modes analysis is an essential approach to understanding the internal structure of the Earth and other planets. While the traditional Markov Chain Monte Carlo (MCMC) method provides a feasible approach to obtain the posterior probability density distributions of model parameters, it demands a considerable amount of forward calculation and is slow in terms of computational efficiency. In order to overcome the limitations of the MCMC method, a new approach to Bayesian inversion using generative neural networks has been proposed in this study, which can deliver outcomes equivalent in accuracy to those of the MCMC method with less sample learning. The study proposed three types of Bayesian inversion neural network models based on popular generative neural networks, including GAN, flow model, and energy model, and evaluated their accuracy and discreteness of inversion results. By using the generative neural network method based on actual lunar normal mode observation data, this study has provided posterior probability density distribution of one-dimensional density and velocity structure parameters of the Moon, along with the optimal parameter values.The results demonstrate the potential of using generative neural networks in Bayesian inversion and provide a new direction for future research in this field.

Increasing frequency of anomalous precipitation events in Japan detected by a deep learning autoencoder

DOI: 10.57757/IUGG23-0513 - LINK

Hiroyuki Murakami[1]
[1]*GFDL/UCAR, Seasonal-to-Decadal Variability and Predictability Division, Princeton, USA*

The frequency of large-scale anomalous precipitation events associated with heavy precipitation has been increasing in Japan. However, it is unclear if the increase is due to anthropogenic warming or internal variability. Also, it is challenging to develop an objective methodology to identify anomalous events because of the large variety of anomalous precipitation cases. In this study, we applied a deep learning technique to objectively detect anomalous precipitation events in Japan for both observations and simulations using high-resolution climate models. The results show that the observed increases in anomalous heavy precipitation events in Western Japan during 1977–2015 were not made only by internal variability but the increases in anthropogenic forcing played an important role. Such events will continue to increase in frequency this century. The increases are attributable to the increasing frequency of tropical cyclones and enhanced frontal rainbands near Japan. These results highlight the mitigation challenge posed by the increasing occurrence of unprecedented precipitation events in the future.

Fusing gridded satellite products and ground-based measurements is regularly made for producing precipitation datasets that: (a) cover large geographical regions with high density; and (b) are more accurate than pure gridded satellite products. Therefore, the respective procedures are commonly referred to as “correction” of satellite products. The same procedures often rely on the application of machine and statistical learning regression algorithms in spatial settings. Regression problems can be solved with high accuracy and low computational cost by applying tree-based ensemble learning algorithms. Despite this, information on which tree-based ensemble learning algorithm to select for the contiguous United States (US) and at the daily time scale was until recently missing from the literature of satellite precipitation product correction. Here, we present the first comparison of tree-based ensemble learning algorithms in this particular context. The algorithms compared are random forests, gradient boosting machines (gbm) and extreme gradient boosting (XGBoost). For the comparison, we extracted and utilized information from the PERSIANN (Precipitation Estimation from Remotely Sensed Information using Artificial Neural Networks) and the IMERG (Integrated Multi-satellitE Retrievals for GPM) gridded datasets. We also extracted and utilized earth-observed precipitation data from the Global Historical Climatology Network daily (GHCNd) database. XGBoost was found to perform better than random forests and gbm, and IMERG was found to be more useful than PERSIANN in the context investigated.

Acknowledgements: The research project was supported by the Hellenic Foundation for Research and Innovation (H.F.R.I.) under the “3rd Call for H.F.R.I. Research Projects to support Post-Doctoral Researchers” (Project Number: 7368).

Sea level forecasting that refers to a realistic and accurate vertical datum has became an important component for a variety of disciplines, particularly in coastal and marine disaster management, engineering and navigation. This is encouraged by recent advances in Artificial Intelligence (AI), especially that of encoder-decoder algorithms e.g. Convolutional Neural Network/ Long short-term memory (CNN/LSTM) that considers the nonlinearity have been used successfully to spatio-temporal forecast marine parameters. On the other hand, geoid-referred sea level or dynamic topography (DT), has the potential to be a beneficial alternative term with increased interpretability when compared to sea level anomaly fields, resulting in better ocean circulation and ocean state estimates. Despite its importance, it has received little attention in the literature thus far. As a result, this study develops a method that forecasts dynamic topography using a CNN/LSTM model in the Baltic Sea for the period 2019–2021, which is also validated using along track satellite altimetry sea level.

The methodology employed utilized a multi-source data-fusion strategy with a multivariate-multistep-ahead (1day, 3d, 5d, 7d ahead) framework to generate a new sea level product. Meteorological parameters such as wind speed, sea level pressure, and sea surface temperature, sea surface salinity, and sea surface height also need to be incorporated. The 1day forecast results show a spatial RMSE accuracy within ±4 cm for most of the Baltic Sea. External validation with along-track satellite altimetry data demonstrate differences between forecasted and SA being within 5 cm. The methodology can be applied to other sea areas.

Snow water equivalent forecasting in Sub-Arctic and Arctic regions with recurrent neural networks

DOI: 10.57757/IUGG23-2856 - LINK

Miika Malin[1], Jarkko Okkonen[2], Jaakko Suutala[1]

[2]Geological Survey of Finland, Hydrogeology and Modelling, Kokkola, Finland

Snow water equivalent (SWE) expresses amount of liquid water in the snow pack. This information is crucial in many hydrological models, but the actual measurement of SWE requires a lot of labor demanding manual work. Because these in situ measurements are labor demanding and often scarce, efficient, and accurate, forecasts of SWE are crucial to get reliable estimates from current and future state of the hydrological systems. In this work, we compare two different recurrent neural network (RNN) architectures: long short-term memory (LSTM) and gated recurrent unit (GRU). We show that GRU is as accurate as LSTM, but requires less computation and is thus preferred RNN architecture for SWE forecasting. We optimise the efficiency and accuracy of these RNNs with hyper parameter Bayesian optimisation, and comprehensive data preprocessing. We furthermore improve the accuracy of the forecasts by using time to vector representation of time in the RNN architecture. We also show that the RNNs have great generalisation capabilities in SWE forecast, outperforming the commonly used degree-day physical model in generalisation capabilities and forecast accuracy. All the results are demonstrated with real in situ measurements of SWE from Finland, which were carefully selected to present great variety in natural environments. As the outcome, we propose two models which can be efficiently applied to accurate forecasts of SWE: lightweight and heavy. Lightweight model has 321 trainable parameters in total, and has average NSE of 0.91. Heavy model has 51973 trainable parameters, and average NSE of 0.95.

Large-scale comparison of ensemble learners for merging satellite and earth-observed precipitation data

DOI: 10.57757/IUGG23-1002 - [LINK]()

Hristos Tyralis[1], Georgia Papacharalampous[1], Anastasios Doulamis[1], Nikolaos Doulamis[1]
[1]National Technical University of Athens,
Department of Topography- School of Rural- Surveying and Geoinformatics Engineering, Zografou, Greece

The accuracy of gridded satellite precipitation products is often improved by using ground-based precipitation measurements, together with machine and statistical learning algorithms. This is typically made in regression settings, where the ground-based measurements are the dependent variable and the gridded satellite data are predictor variables. Comparisons of various single machine and statistical learning algorithms in performing this regression task are regularly conducted in the respective literature. Also notably, some of these comparisons are of large scale, thereby providing generalizable findings. Still, a large-scale comparison of ensemble learners (i.e., methods for combining single machine and statistical learning algorithms towards obtaining further accuracy improvements with respect to selecting the best-performing one among these algorithms), such as simple averaging and stacking, was until recently missing from the same literature. Here, we present the first comparison of this kind in the context of interest.

The accuracy of gridded satellite precipitation products is often improved by using ground-based precipitation measurements, together with machine and statistical learning algorithms. This is typically made in regression settings, where the ground-based measurements are the dependent variable and the gridded satellite data are predictor variables. Comparisons of various single machine and statistical learning algorithms in performing this regression task are regularly conducted in the respective literature. Also notably, some of these comparisons are of large scale, thereby providing generalizable findings. Still, a large-scale comparison of ensemble learners (i.e., methods for combining single machine and statistical learning algorithms towards obtaining further accuracy improvements with respect to selecting the best-performing one among these algorithms), such as simple averaging and stacking, was until recently missing from the same literature. Here, we present the first comparison of this kind in the context of interest.

The problem of solving nonlinear inverse problems and related uncertainty quantification can be addressed by employing sampling strategies, i.e., Monte Carlo methods. Such approach can avoid linearizations and strives to explore regions of the model space where plausible models are located. Recent interest in such strategy has brought to attention the Hamiltonian Monte Carlo (HMC) method, thanks to its peculiar properties which permit tackling high-dimensional problems exploiting information from the gradient of the posterior probability density function. In this work we show how different geophysical problems can be solved with sampling strategies under a common framework, which facilitates experimenting with algorithms, tuning, forward models, etc.. This has been implemented in a software package named "HMCLab", a numerical laboratory which provides: 1) a set of sampling algorithms, particularly focusing on the HMC method, which can be combined with the 2) set of geophysical forward problems such as wave propagation, gravity and magnetic anomalies modelling, seismic traveltimes, etc. Each of the geophysical problems consists of routines to solve the forward problem and to compute the gradient of a misfit functional with respect to the model parameters. The sampling algorithms can thus be used to solve one of the implemented geophysical problems or combined with a user-provided problem. We show examples of the inverse problems that can be addressed with HMCLab and the kind of information that can be retrieved with a probabilistic (or Bayesian) approach.

The National Institute of Fisheries Science(NIFS) and Korea Hydrographic and Oceanographic Agency(KHOA) have been collecting temperature/salinity profile data for the marginal seas around Korea using CTD. NIFS collects data during even months, while KHOA collects data during odd months. According to Chang et al. (2023), assimilating data from the marginal seas around Korea improves the subsurface temperature/salinity structure in the East/Japan Sea, as well as in the Kuroshio–Kuroshio Extension region, by controlling the Kuroshio axis through improved Tsugaru Warm Current. Although they only used data obtained by NIFS on even month, it was shown that the regional observation data have a significant impact on the ocean analysis field in Northwest Pacific. We conducted a sensitivity experiment to quantify the impact of regional observation data for all months on the ocean prediction system by applying Ensemble Optimal Interpolation (EnOI) to Korea Operational Oceanographic System–Ocean Predictability Experiment for Marine environment(KOOS-OPEM), which was developed by Korea Institute of Ocean Science & Technology (KIOST). In this study, we demonstrate the importance of regional observing networks in improving ocean forecast skill by comparing physical properties of each experiment.

The radio occultation (RO) observations using multiple small satellites are expected not to be interrupted by a thick global cloud layer at about 48–70 km altitudes, and to enable frequent observations of the global vertical temperature distribution at 40–90 km altitudes. In this study, we focus on a phenomenon peculiar to Venus called “cold collar”, in which the polar region becomes warmer than the surrounding latitudes of 60–80 ° at 65 km altitude, and the Observation System Simulation Experiment (OSSE) is carried out assuming RO observation by satellites to be launched in the future. For the Venus assimilation system, “ALEDAS-V” (AFES LETKF Data Assimilation System for Venus) based on LETKF (Local Ensemble Transform Kalman Filter) is used. For the ensemble forecast, the Venus general circulation model “AFES-Venus” is used. For the pseudo-observation data, we use the temperature output of the IPSL Venus GCM (now called the Venus “Planetary Climate Model; PCM”) which represent ideal cold collar by radiative forcing. The temperature at 40–90 km altitudes corresponding to observation points obtained by orbit calculations is used as pseudo-observation data. As a result, while the experiment without assimilation (free run) cannot reproduce the cold collar at 67 km altitude, the RO OSSE reproduces it.

The recent global MHD simulation code (REPPU code by Tanaka [2015]) successfully reproduces even observed phenomena such as the auroral breakup of the substorm. We judge that the simulation code correctly reproduces the physical processes of the magnetosphere and ionosphere from the fact that the phenomenon is reproduced realistically.

REPPU code employs several empirical parameters expressing the non-MHD mechanisms. We tried to determine the optimal values of the parameters by using the data assimilation technique. For this purpose, we improve the REPPU code to include both the effect of the inclined rotation axis of the Earth and the effect of the discrepancy between the rotational axis and the magnetic axis.

Next, we apply the data assimilation technique to determine the ionospheric conductivity distribution which is given as empirical parameters in the original REPPU code. For this purpose, we use the ionospheric electric potential determined by SuperDARN and AE indices. We employed the ensemble variational method as the assimilation technique to obtain the optimal values of the parameters. As a result, we obtained that the ionospheric conductivities are enhanced compared with the empirical results. At the same time, modification of the ionospheric conductivity does not change significantly the magnetosphere. The simulation data become the “reanalysis data” of the space weather which is useful for space weather research. Our future goal is to provide a database of the reanalysis data for space weather.

The various probabilistic hydrological post-processing and forecasting tasks are receiving growing attention nowadays due to the larger degree of information that the probabilistic predictions and forecasts can offer to the practitioners compared to the best-guess predictions and forecasts. At the same time, several machine learning concepts and algorithms are remarkably relevant to dealing with these important tasks, and a pronounced intensification in the research efforts for benefitting from this specific relevance has recently emerged. This presentation will provide a practically-oriented synthesis of the most relevant machine learning concepts and algorithms for the above-outlined context of interest based on a recent forward-looking review. Key ideas and information that can lead to effective popularizations will be emphasized, as such an emphasis can support successful future implementations and scientific developments. In the same forward-looking direction, open research questions will be identified and ideas to be explored in the future will be proposed.

Developing prediction system for current structures in Yeosu Bay by assimilating Coastal Acoustic Tomography

DOI: 10.57757/IUGG23-2830 - LINK

Na Young Park[1], *Hyemin Lim*[1], *Young Ho Kim*[1]
[1]*Pukyong National University, Division of Earth Environmental System Sciences, Busan, Korea Republic of*

The importance of accurate coastal current prediction is becoming increasingly recognized for responding to maritime accidents and improving marine environments. The ocean model can overcome the limitation of an existing current observation, which is usually limited to pointwise or surface measurements, by providing extensive coastal current fields. However, since the model results are constrained not only by the numerical nonlinear problem, but also by the open boundary and initial conditions, it is essential to verify and update them through observational data assimilation.
Coastal Acoustic Tomography(CAT) is a remote sensing method that can infer physical variables such as temperature, salinity, and current by using ocean acoustic propagation speed. CAT is powerful to monitor ocean regions and has been shown to improve an ocean model's ability (*Park and Kaneko*, 2000).
In this study, we developed a data assimilation system to assimilate CAT data into a high-resolution ocean model in Yeosu Bay, Korea. We used the Regional Ocean Modeling System (ROMS) with a horizontal resolution of about 100m, and applied data assimilation of CAT applying the Ensemble Kalman filter(EnKF). We also modified the wind stress flux parameterization by introducing the concept of air stability which is associated with the temperature difference between the ocean surface and 2m atmosphere. This study aims to evaluate the effects of CAT data assimilation and wind stress parameterization.

The geology of Antarctica is formed from cratons, accreted terranes from multiple supercontinental cycles, and ongoing tectonism and glaciation. It would be a mistake to assume that the subglacial continent is geologically less complex than any other part of the world.

Geophysical data and the observed interaction between the solid Earth and the ice sheet suggest several distinct geological regions in the interior. Antarctica's margins have been affiliated with geological observations in adjoint Gondwana neighbours, and those projections identify Antarctica as a hub in the supercontinent cycle rather than a snowbank at the margin of the map. However, producing a robust tectonic map of the interior is challenging, as existing datasets and models are inconsistent and the interpretations ambiguous.

We map the tectonic domains of the Antarctic continent by applying a similarity approach. From multivariate observables in other continents, we calculate the most similar tectonic setting for each location in Antarctica and assign discreet distributions of tectonic classes. Observables include potential field data, seismic tomography, and, where applicable, geological observations. We use information entropy and cost function to optimise and evaluate the robustness of the model. Our results refine and redefine the tectonic map of the interior.

Impacts of radio occultation data assimilation on landfall and precipitation forecasts of low-predictability atmospheric rivers over the eastern North Pacific

DOI: 10.57757/IUGG23-2082 - LINK

Hsu-Feng Teng[1]
[1]*National Taiwan University, Department of Atmospheric Sciences, Taipei, Taiwan Province of China*

This study explores the potential impacts of global navigation satellite system radio occultation (RO) data assimilation on the forecast performance of low-predictability atmospheric rivers (ARs) over the eastern North Pacific through a regional model and sensitivity experiments. ARs with large forecast errors of landfall and precipitation in the global operational model are analyzed. To understand the contribution of RO data assimilation on forecast performance, sensitivity experiments are performed for selected AR cases that brought significant precipitation to the western US (stronger or equal to Category 3). Results show that, for weekly forecasts, assimilation of RO data can improve the location of high moisture and low pressure centers, resulting in better forecast performance of AR landfall. For 2-day forecasts, assimilation of RO data can improve the patterns of low-level jet and moisture flux, leading to more accurate precipitation forecasts. Although conventional observations, satellite retrievals, and radiances also have positive contributions to the AR forecasts, RO data can provide higher vertical resolution observations and mainly improve the forecasts of AR structure and precipitation areas.

Recovering far-field data for the 1883 eruption of Krakatau

DOI: 10.57757/IUGG23-1345 - LINK

Duncan Agnew[1]
[1]*University of California, Scripps Institution of Oceanography, La Jolla, USA*

The January 15 eruption of Hunga volcano in Tonga has provided an unprecedented volume of data on global air-pressure waves and volcanic tsunami. In order to apply the knowledge from these data to the only other example, the eruption of Krakatau (Indonesia) on August 27, 1883, I am assembling an openly accessible digital dataset of both the the air waves and the tsunami from this nineteenth-century example, the first for which any instrumental records (barograms and marigrams) were produced. Its narrow focus and range of sources makes this an unusual data rescue project. The 1888 report produced by the Royal Society of London does not show the air waves in a useful way; the report does contain reproductions of marigrams, though without describing their sources. In a few cases original records survive, but usually what is available is a journal article about some observations, with a foldout plate showing a photolithograph of the original or of a drawing of it. About half of the barograms listed in the 1888 report can be found in some form, and I have found a few new records both of air pressure and sea level; most pressure records come from a wide range of mercury barographs. Images of all records will be used to produce digital time series, relying on custom software. Two results already evident are that many barograms show similar waveforms, which differ from those of the 2022 eruption; and that tsunami were observed across the entire North Pacific ocean.

The seismicity of Romania is characterized by seismic events with magnitudes between $1 \leq Mw \leq 7.9$ (the largest earthquake produced in Vrancea in 1802) and depths from crustal to intermediate-depth domains. The Vrancea source generates a few significant earthquakes (magnitudes above 7.0) per century. The instrumental period of recording seismic activity in Romania started in 1888 when one of the first seismic stations from Europe was installed in Bucharest, at the Seismic Observatory from Cutitul de Argint. The seismicity recorded before the instrumental period is mostly based on macroseismic observations and early seismic instrumentation. Once the instrumental recording started to operate, over one million paper seismograms had been collected in the National Institute for Earth Physics archive. The archive includes records on smoked and photographic paper and ink recordings since 1900. The analog paper recordings are affected by continuous degradation which is followed by loss of data over time. Since the paper recordings are strongly affected by the passage of time and the storage conditions, currently, work is being done on the inventory of the existing seismograms, their evaluation, and scanning.

Evaluation and utilization of historical terrestrial gravimetric data over the Czech Republic territory

DOI: 10.57757/IUGG23-4934 - LINK

Martin Lederer[1], *Otakar Nesvadba*[2]
[1]*Land Survey Office, Geodetic control, Prague, Czech Republic*
[2]*Land Survey Office, Geodetic Control Section, Prague, Czech Republic*

In the presented project, we focus on the digitization and refinement of the terrestrial gravimetric data observed in 1940–1961 period on the territory of the present day Czech Republic. The project aims to utilize most of these older gravimetric observations by correcting and homogenizing them to the modern geodetic reference systems.

All available catalogues and data sources have been collected, digitized, and converted to the relational database. Also metadata are collected and converted to the database too. Besides, we digitized and georeferenced also the original analogue maps or schematic plots documenting the locations of the individual observations. All the digitized gravimetric data have been verified during the process. Data is transformed to modern geodetic reference systems with the aid of the acquired metadata. Finally, by applying geostatistical analysis techniques, data validity has been verified against later, more accurate terrestrial gravimetric data and new gravimetric observations.. As the later observed gravity field is often affected by gravity changes and variations, we need to address all known mass transports, primarily sourced in later anthropogenic interference, as mines, quarries, dam reservoirs, etc.The described process enabled us to significantly improve the reliability, accuracy and georeference of all available terrestrial gravimetric data in the Czech Republic.

The resulting homogenized gravimetric database can be used in any other project demanding accurate knowledge, or even time-differentiated knowledge, of the gravity field over the Czech Republic. Just as a geodetic applications, we can mention a quasigeoid modelling or realization of the normal heights geodetic reference system.

In the presented project, we focus on the digitization and refinement of the terrestrial gravimetric data observed in 1940–1961 period on the territory of the present day Czech Republic. The project aims to utilize most of these older gravimetric observations by correcting and homogenizing them to the modern geodetic reference systems.

All available catalogues and data sources have been collected, digitized, and converted to the relational database. Also metadata are collected and converted to the database too. Besides, we digitized and georeferenced also the original analogue maps or schematic plots documenting the locations of the individual observations. All the digitized gravimetric data have been verified during the process. Data is transformed to modern geodetic reference systems with the aid of the acquired metadata. Finally, by applying geostatistical analysis techniques, data validity has been verified against later, more accurate terrestrial gravimetric data and new gravimetric observations.. As the later observed gravity field is often affected by gravity

Baron Roland Eötvös (in Hungarian: Eötvös Loránd) as a scientist is known from (1) the Eötvös rule in capillarity, which has of equal importance as the universal gas laws; (2) from the Eötvös balance, by means of which he demonstrated the equivalence of gravitational and inertial masses, with a precision of 10^{-9}; (3) from the field version of his balance, which was the first geophysical field instrument. As a Public Man, he was founder and leader of scientific and sport organizations, a supporter of young talents, a sportsman, among others a mountaineer. In the Dolomites the Eötvös peak is named after him. He captured the landscape by his stereo camera. His photos were digitized on the occasion of the Eötvös 100 Commemorative Year, in two steps: (1) the already known photos in January 2019 (eotvos100.hu/en/page/tomorlatvany_kepek), (2) photos newly found in the Hungarian Museum of Science, Technology and Transport, in 2020 (virtualiskiallitas.kozlekedesimuzeum.hu/s/eotvos/page/dolomitok).

Recognizing the environmental significance of these documents, on the occasion of the 175th anniversary of his birth, we present several three-dimensional photos from this South Tyrol collection, as a part the complete oeuvre of one of the greatest pre-IUGG geoscientists, Baron Roland Eötvös. More photos (and an original Eötvös balance) can be seen in the booth of Institute of Earth Physics and Space Science (Sopron, Hungary), with the financial support of the Eötvös Loránd Research Network.

Evaluation of marine magnetotelluric responses to rugged bathymetry and coast effects simulated by three-dimensional forward modeling

DOI: 10.57757/IUGG23-1367 - LINK

Kiyoshi Baba[1]
[1]*The Universty of Tokyo, Earthquake Research Institute, Tokyo, Japan*

Marine magnetotelluric (MT) method is used to probe the crust and mantle beneath seafloor in terms of electrical conductivity. Rugged bathymetry and coast lines can distort MT responses significantly, and therefore, it is critical to simulate MT responses by incorporating such structure boundaries into an electrical conductivity model. Recent three-dimensional (3D) MT forward modeling methods can incorporate complex structure boundaries by computationally effective manners. However, it has not been deeply studied how stably or accurately the numerical modeling methods can synthesize the MT responses to practical complex structures. In this study, I propose a simple method to evaluate the random component of the uncertainty of MT forward modeling for 3D conductivity models, which includes rugged bathymetry and coast lines, in a Cartesian coordinate system. The method is based on the idea that the horizontal coordinate system can be selected arbitrarily for a general 3D structure. By synthesizing MT responses to the model in several different coordinate systems, the mean, standard deviation, and coefficient of variation can be calculated. The proposed method was applied to two practical situations of marine MT arrays in the northwestern Pacific and southern Atlantic. The results show that the uncertainty is comparable to real observation errors and is significantly dependent on the MT impedance element, period, site, structure model, and horizontal coordinate system. This method is also useful for testing the appropriate selection of the coordinate system and mesh design.

The rising demand for potable water in densely populated coastal regions has recently promoted growing research interest in detecting offshore freshened groundwater (OFG) worldwide. Recent geophysical studies along the continental margins offshore Israel, New Zealand, Malta, and the United States of America provide some examples of integrating geophysical and borehole data to constrain the spatial extent of OFGs and estimate their pore-water salinity. However, occurrences of OFGs and the interaction between terrestrial, carbonate-hosted groundwater systems with seawater are understudied in many coastal regions by complicated seafloor morphology. In this study, we investigate whether OFG can exist offshore a semi-arid carbonate coastline along the Maltese Islands and explore the possibility of sustainably exploiting these reservoirs as an unconventional source of potable water to relieve freshwater scarcity. We present an integration of 2-D resistivity models derived from marine controlled source electromagnetic (CSEM) measurements with 2-D and 3-D seismic data, core samples, borehole data, and geochemical measurements. Electrical resistivity models identify localized resistive anomalies (> 10 ohm-m) offshore the northeastern coast of Gozo (the second-largest island in the Maltese archipelago). Furthermore, a resistive body is observed at ~ 300 m below sea level close to the coast of Gozo which extends northeastwards and disappears at ~ 8 km offshore. If the anomalous resistive body is associated with pore-water salinity variations or, alternatively, caused by lithological changes, will be discussed through an integrative geological model developed along each profile.

The Calabrian Arc subduction-rollback system along the convergent Africa/Eurasia plate boundary is among the most active geological structures in the Mediterranean Sea. Single and composite landslides, volcanic features, seismogenic faults, erosive canyons, and fluid flow systems were imaged in this region as part of the recent 2021 Atlas of Marine Geohazards of the Italian Coast, and areas prone to hazards were intially assessed on the basis of their distance from the coast and their morphologiy. The Squillace submarine canyon is one of the most striking features imaged in the Atlas in this region. It is located at only a few hundred meters from the coast and is characterized by dendritic headwalls connected with prominent flash flood river systems onshore.

Here we present the design of new marine geophysical surveys planned for June 2023 within the EU EUROFLEETS+ programme that aims to collect a new multiparameter dataset (MBES and SBP from AUV, aero photogrammetry and sediment samples from ROV) to obtain very high-resolution imaging of the offshore Squillace canyon headwalls and derive lithological and geotechnical parameters indicative of instability, Additionally, we showcase initial work performed within two EU funded PNRR (National Recovery and Resilience Plan) initiatives. Over the coarse of the next three years we aim to generate a new geodatabase of submarine features, including landslides that will enable for example detailed intercompartative assessments of geohazards associated with he Calabrian, Ionian and Tyrrhenian continental margins, and to develop novel approaches for feature recognition based on machine learning and artificial intelligence approaches.

Investigations of Marine Hydrothermal Systems and Seafloor Massive Sulfides with Electromagnetic Methods

DOI: 10.57757/IUGG23-4684 - LINK

Sebastian Hölz[1], *Amir Haroon*[1], *Konstantin Reeck*[1], *Marion Jegen*[1]
[1]*GEOMAR Helmholtz Centre for Ocean Research Kiel, Geodynamics, Kiel, Germany*

The investigation of marine, hydrothermal systems requires the integration of multi-disciplinary approaches from e.g. biology, geochemistry, geodynamics, mineralogy and geophysics. Scientific research interfaces closely with economic and environmental interests, for which conflicts seem inevitable since exploration and potential exploitation of seafloor massive sulfides may pose a hazard to all biological activity surrounding hydrothermally active systems.

Past investigations have almost exclusively focused on identifying active hydrothermal sites due to the applied technologies: the discovery of sites of interests frequently relied on the detection of temperature or chemical anomalies in the water column, or the identification of characteristic, morphological structures like edifices on the seafloor. In contrast, very little is known about systems where activity has either ceased, is to low to be detected in the water column, or is shielded by sufficiently thick layers of sediment. For such inactive, extinct or buried systems, the use of electromagnetic methods can shed new insights. The sensitivity of electromagnetics towards conductive structures formed by the precipitated minerals is independent of the grade of hydrothermal activity and is able to see through potentially covering sediment layers, thus, providing a valuable constrain to the spatial extents of mineralizations.

At GEOMAR, we have built and applied electromagnetic instrumentation to investigate active and inactive hydrothermal sites in the Mediterranean Sea and at the Mid-Atlantic Ridge. Interpretations in some regions show hidden conductive anomalies in areas without current hydrothermal or relevant biological activity, which could be of interest for research exploration without the potential conflict with environmental sciences.

Shallow water navigation chart in multiple island coastal regions derived from ICESat-2 altimetry and Sentinel-2 imageries

DOI: 10.57757/IUGG23-4089 - LINK

Hsiao Jou Hsu[1], Pin-Chieh Pan[1], Kuo-Hsin Tseng[2], c.k. Shum[1]
[1]The Ohio State University, School of Earth Sciences, Columbus, USA
[2]National Central University, Center for Space and Remote Sensing Research, Taoyuan, Taiwan Province of China

Although the world's land digital elevation/surface model (DEM/DSM) has been well established through spaceborne and airborne sensors, high-resolution shallow clear water bathymetry remains poorly charted. Knowing the bathymetry in coastal zones is critical, especially for ocean navigation, environmental protection, mineral resources mining, and coastal management. However, surveys of bathymetry data in a traditional way relies heavily on humanpower and cost of equipment/vessels. National Aeronautics and Space Administration's (NASA's) Ice, Cloud, and land Elevation Satellite-2 (ICESat-2), launched in 2018, provides multi-beam georeferenced photon data every 70 centimeter along its ground tracks with a 91-day repeat orbit. The georeferenced photons can be utilized to derive water depth on coastal islands even without any on-site data. Here, we examine a synthesis of ICESat-2 ATL03 photon data and Sentinel-2 optical imagery to derive a bathymetry model based on Beer-Lambert law. Once the model is trained, the prediction of accuracy using goodness-of-fit (GoF) helps to select the most appropriate images. We select multiple islands in the South China Sea as testing sites, where the availability of coastal bathymetry models is scarce because it is costly and difficult to survey. The final bathymetry model is derived with a composite of multiple images, and the bathymetry accuracy via cross validation meets the requirement of category C in Zones of Confidence (ZOC) of the Electronic Navigational Chart (ENC) in 0-15m.

Measuring tectonic strain build-up on the seafloor with the GeoSEA array

DOI: 10.57757/IUGG23-0247 - LINK

Heidrun Kopp[1], Dietrich Lange[1], Morelia Urlaub[1]
[1]GEOMAR Helmholtz Centre for Ocean Research Kiel, Dynamics of the Ocean Floor, Kiel, Germany

The GeoSEA array is a network of seafloor transponders used in direct path measurements at water depths up to 6.000 m. Direct path acoustic ranging with baselines up to 2.500 m resolves seafloor deformation at high resolution (< 5mm repeatability). The array is configured for continuous interrogations to monitor the state of seafloor deformation, e.g. at volcanic flanks, active faults or continental slopes. Data retrieval may be conducted via an acoustic modem using a vessel or a surface vehicle (wave glider) as a platform. The GeoSEA array consists of 34 acoustic transponders, which have been deployed in various tectonic settings. One network monitored the stress build up along the North Anatolian Fault offshore Istanbul in the Sea of Marmara, indicating a potential slip deficit of up to 2.5 m. No right-lateral creep was detected, indicating a locked or very moderately creeping fault segment which is currently accumulating strain. Three networks consisting of 8, 10 and 5 transponders, respectively, were installed in 2015 on the continental slope and outer rise of the North Chilean subduction zone and were recovered in 2022. The arrays were positioned in water depths between 2.400 m to 5.200 m using the deep-sea cable of RV SONNE. A further scientific target was the instable eastern flank of Mt Etna volcano in Italy, where up to 6 transponders were installed in 2016 in recurrent campaigns. We provide an overview of the monitoring strategy for these different campaigns and the main results of the direct path ranging.

From December 2022 to January 2023, a geophysical survey of the RRS JAMES COOK in the Guatemala Basin collected two refraction and wide-angle seismic profiles, each with 11 Ocean-Bottom-Seismometers spaced at ~7.5 km intervals. Both two profiles have excellent data quality and recorded clear crustal refraction (Pg), upper mantle refraction (Pn), and very long-extended Moho reflection (PmP) phases. To utilize the data adequately, we use the layer-stripping top-down method to conduct joint refraction and reflection seismic tomography of these two profiles. The preliminary results show that the crustal thickness beneath line p300 is ~5 km, which is thinner than the global average thickness of the oceanic crust at ~6 km. This is in agreement with the result of down-hole logging and wide-angle seismic survey to the southwest at the ODP site 1256. In contrast, the seismic structure of profile p400, which is located to the northeast of profile p300, reveals ~6–7.5 km thick oceanic crust. Both two profiles present a high velocity gradient of oceanic layer 2 from ~4.5 km/s to ~6.5 km/s and a low velocity gradient of oceanic layer 3 from ~6.5 km/s to 7.2 km/s, which were interpreted as basaltic layer and gabbroic layer, respectively, showing typical oceanic structure. Our data present a very clear Moho reflection and our preliminary analyses suggest the area in the vicinity of line p300 fulfilled the requirements for future Moho drilling and thus may represent a site for the flagship drilling project MoHole of the International Ocean Discovery Program (IODP).

Japan Coast Guard's GNSS-A seafloor crustal deformation observation and the data strategy

DOI: 10.57757/IUGG23-1457 - LINK

Yuto Nakamura[1], Tadashi Ishikawa[1], Shun-ichi Watanabe[1], Koya Nagae[1], Yusuke Yokota[2]
[1]Japan Coast Guard, Hydrographic and Oceanographic Department, Tokyo, Japan
[2]University of Tokyo, Institute of Industrial Science, Tokyo, Japan

Around the Japanese Islands, major subduction zones along the plate boundaries of the Pacific Plate and the Philippine Sea Plate have repeatedly caused megathrust earthquakes. GNSS-Acoustic ranging combination technique (GNSS-A) is an effective tool to measure the absolute position on the seafloor, from which we can visualize the plate boundary conditions at these subduction zones. The Japan Coast Guard has been conducting GNSS-A observations at the sites deployed along the Japan Trench and the Nankai Trough, named the Seafloor Geodetic Observation Array (SGO-A).
At the SGO-A sites, we have been periodically conducting campaign observations for approximately 20 years. In these two decades, technological advancements in our observation and analysis techniques have enabled us to detect shallow slow slip events lasting for a year (Yokota and Ishikawa 2020). Our decadal observations have revealed the processes related to the 2011 Tohoku-oki Earthquake (Watanabe et al. 2021). We have also been developing a csv-based data format for GNSS-A observation data, which we have been discussing in a working group of the Inter-commission Committee on Marine Geodesy (ICCM) of the International Association of Geodesy (IAG).

At the SGO-A sites, we have been periodically conducting campaign observations for approximately 20 years. In these two decades, technological advancements in our observation and analysis techniques have enabled us to detect shallow slow slip events lasting for a year (Yokota and Ishikawa 2020). Our decadal observations have revealed the processes related to the 2011 Tohoku-oki Earthquake (Watanabe et al. 2021). We have also been developing a csv-based data format for GNSS-A observation data, which we have been discussing in a working group of the Inter-commission Committee on Marine Geodesy (ICCM) of the International Association of Geodesy (IAG).

Seismotectonics of oceanic transform plate boundaries in the Northeast Pacific: Constraints from ocean bottom observation

DOI: 10.57757/IUGG23-4397 - [LINK]

Yu Ren[1], *Dietrich Lange*[1], *Ingo Grevemeyer*[1]
[1]*GEOMAR Helmholtz Centre for Ocean Research Kiel, Marine Geodynamics, Kiel, Germany*

Among the recently evolving transform faults, the Blanco transform fault system (BTFS) in the northwest off the coast of Oregon, is strongly segmented and resembles other segmented oceanic transform systems, such as the Siqueiros in the East Pacific Rise, which developed from a pre-existing transform fault that was subjected to several extensional events due to a known shift in spreading direction. However, plate tectonic reconstructions suggested that the BTFS developed from at least two large ridge offsets rather than a single transform fault, emerging from a series of ridge propagation events after the plate reorientation at ~5 Ma.

We investigated the seismotectonic behavior and tectonic evolution of the BTFS using ocean-bottom seismometer data from the Blanco Transform OBS Experiment (2012–2013) as well as high-resolution multibeam bathymetry, aeromagnetic, and gravity datasets. Interestingly, we observed no evidence for the existence of either transform faults or fracture zones around the BTFS before 2 Ma, indicating that there were no pre-existing transform faults before the formation of the BTFS. Therefore, we propose that the BTFS developed from two broad transfer zones rather than pre-existing transform faults. Moreover, local seismicity shows significant along-strike variations, revealing different modes of slip in the eastern and western BTFS. Seismic slip vectors suggest that the western BTFS is an immature transform fault system since its reorganization is still taking place, but the eastern BTFS accommodating the plate motion is mature. The BTFS acts as a natural laboratory to understand the mechanisms controlling the development of oceanic transform plate boundaries.

Besides sea floor topography maps can be estimated by inversion of satellite-based gravity and/or geoid height anomalies, in particular in large oceanic provinces that are uncovered by ship tracks, it has been demonstrated that gravity gradiometry is a powerful technique to retrieve more details of regional bathymetry as gravity tensor is composed by the high frequency of the gravity field. Inversion of vertical gravity gradient data derived from the radar altimetry technique offers the possibility to reach greater resolutions (< 10 km). We propose an efficient approach based on Kalman filter to restore seafloor shape as well as lithospheric parameters, e.g. the crust and elastic thicknesses, for combining different types of geophysical information including mainly GG data. For validation, our estimated maps of bathymetry are confronted to existing data sets in areas well-covered by observation surveys.

Visuals like graphs, tables, and charts are frequently used by scientists as a way to communicate their findings or to make them more accessible to the general public. Some information or scientific ideas, however, are complex and challenging to understand. In contrast, art speaks to everyone. Collaborations between science and the arts are becoming more and more crucial in developing fresh strategies for promoting Earth science.
Here we present a current interactive immersive science-art work, concentrating on the deep marine realm where people cannot hear or see. In order to investigate how the deep sea is evolving as well as how mankind is hearing and comprehending the environment that supports us, our work breaks through the background noise of the ocean. The auralization and visualization of submarine seismic data have been the focus of our team's (Deep Sea Light, DSL) effort, and it provides a fantastic opportunity to learn more about the dynamic world of deep oceans. We have effectively detected the activities of earthquakes, volcano eruptions, and even fin whale sounds using seismic stations. We further employ the Audio Spectrum and the Touch Designer to visualize vast soundscapes in 3D perspective and physically convey various settings to the audience via artistic interactive devices. Our effort helps to reveal the ambient deep-sea world and demonstrate how people should listen to and comprehend it via the lens of the ocean soundscape.

Accurate bathymetry inversion through combining gravity-geological method and residual neural network: A case study over puerto Rico trench

DOI: 10.57757/IUGG23-4155 - LINK

Chen Xiaodong[1], *Min Zhong*[1], *Wei Feng*[1], *Meng Yang*[1]
[1]*Sun Yat-sen University, School of Geospatial Engineering and Science, Zhuhai, China*

The acquisition of accurate bathymetry is a challenging task in Marine Geodesy, especially for the area without sonar sounding data, the ocean gravity field is needed to realize the seabed topography inversion process. The gravity-geological method (GGM) is one of the most classic methods for seabed topography inversion. According to the approximate linear relationship between the seabed topography and the short-wave gravity anomaly, the GGM method constructs the regional bathymetry model. However, the correlation between seabed topography and gravity anomaly are non-lineardue to factors such as the geology of the seafloor.

To address this issue, based on the short-wave gravity anomaly obtained by the GGM method, residuals neural network (ResNet) is used by introducing a variety of prior geophysical attribute data information, such as vertical gradient, magnetic anomaly, and sediment thickness. The non-linear relationship between gravity anomaly and seabed topography is then obtained. In the Puerto Rico test area, the accuracy of the seabed topography over the inspection points is improved by ~10m compared with results using the GGM method.

The seabed topography inversion combined with GGM and neural network will provide a new idea for bathymetric survey based on satellite altimetry, which has high feasibility and important application value.

Scaling characteristics in ultra low frequency magnetotelluric signals: Investigating of possible earthquake precursors, northern Algeria

DOI: 10.57757/IUGG23-0117 - LINK

In the recent decade, earthquake-related electromagnetic phenomena have been considered one of the most promising candidates to achieve short-term earthquake prediction. Magnetotelluric measurements still remain one of the most challenging and debated questions in the scientific community regarding short-term earthquake prediction. Since 2018, a continuous recording magnetotelluric station has been installed at the Medea Observatory (Northern Algeria), whose main role is the assessment of seismo-electromagnetic signals. Using an MTU-A Phoenix system, we measure the five components of the telluric and magnetic fields. Multifractal detrended fluctuation analysis is a powerful method for capturing scaling behavior in non-stationary time series. Using an appropriate instability index, it is possible to identify and quantify deviations from uniform power-law scaling, which suggest the presence of changing dynamics in the system under study. In this context, the calculated scaling instability index β (defined as the range of the local scaling exponents) of magnetotelluric time series (in the frequency range below 1 Hz) were investigated. We considered only those seismic events that satisfy the Dobrovolsky rule ($r=10^{0.43M}$). Several significant scaling behaviors in the magnetotelluric temporal fluctuations were revealed, which could be linked with the occurrence of earthquakes in the northern part of Algeria, such as the 2021 Bejaïa earthquake (M = 6, epicentral distance 235 km) and the 2020 Blida earthquake (M = 4.5, epicentral distance 18 km). These results prove to be powerful for short-term earthquake prediction.

In this paper we try to identify changes of seismic propagation velocities in time, the seismic energy release and geomagnetic deviations from the normal trend before the occurrence of crustal and intermediate earthquakes from Vrancea zone, and to find the correlation in time between them.

In the crust, velocities change before, during and after earthquakes through several mechanisms related to, for example, fault deformations, pore pressure, changes in stress state and rebound processes. The seismic data used in this study consists in the seismic energy and seismic velocities vp/vs, computed from the seismic bulletins of NIEP, for the stations situated in the earthquake preparation area. Calculations are done automatically by the Phenomenal platform https://ph.infp.ro/seismicity/data. Seismic energy release in Vrancea zone was calculated for intermediate-depth earthquakes with Mw>3. The small earthquakes with Mw<3 were taken as background seismicity that releases almost constant the stress. The seismic energy was represented as a daily sum using a logarithmical scale. Then, the cumulative energy released during each identified anomaly was calculated and compared with the anomaly magnitude measured. The Geomagnetic data were taken from Muntele Rosu (MLR) Seismological Observatory of NIEP, situated inside Vrancea seismogenic zone as primary station, and from Surlari (SUA) Geomagnetic Observatory of Intermagnet, as remote station, unaffected by medium size earthquake preparedness processes. Geomagnetic indices taken from GFZ (https://www.gfz-potsdam.de/kp-index) were used to separate the global magnetic variation from possible local seismo-electromagnetic anomalies, that might appear in a seismic area like Vrancea zone.

On February 6, around 01:17 UTC, a magnitude 7.8 earthquake struck south-central Turkey near the Turkey/Syria border. Several aftershocks were registered in the following days, with the largest being a 7.5 magnitude earthquake that struck about 90 km north on the same day around 10:24 UTC.

This paper presents the ionospheric effects detected by ionosonde and GNSS networks covering the Mediterranean area and Europe, with the goal of trying to discriminate the different sources of perturbations affecting the ionosphere and to characterize the different ionospheric wave-like perturbations induced by the earthquake.

Specifically, earthquakes are responsible for different kinds of atmospheric perturbations, depending on the distance from the epicentre. In the near-field, acoustic-gravity waves are generated directly on-site by the strike-slip East Anatolian fault's movement. In the far field, upward propagating acoustic waves induced by surface Rayleigh Waves dominate the ionospheric response. Thanks to the multi-instrument approach, both mechanisms can be distinguished. In particular, thanks to the measurements nature, ionosondes are highly sensitive to acoustic waves, defined by small wavelengths and periods. On the other hand, GNSS-derived Total Electron Content is more suited for detecting waves defined by larger periods and longer wavelengths, such as the ones generated directly by the fault movement. The first results show a clear pattern of the ionospheric disturbances on the ionograms recorded at different distances from the epicentre propagating at a few km/s compatible with the hypothesis of Rayleigh waves related perturbations.

Phreatic eruptions are one of the eruption styles that are difficult to forecast and occasionally cause significant damage. Understanding the mechanisms of phreatic eruption is essential for minimizing damage. Mt. Motoshirane, one of the pyroclastic cones of the Kusatsu-Shirane Volcano located in central Japan, experienced a phreatic eruption in 2018 that resulted in casualties. The eruption was abrupt with no precursory phenomena. Mt. Motoshirane has been dormant for the last 1500 years, so it has been poorly monitored and studied. Studies conducted after the eruption suggested that the migration of hydrothermal fluids triggered the eruption, but those studies lacked information on shallow subsurface structure. In this paper, we report on the three-dimensional resistivity structure around the craters of the 2018 eruption, which was estimated from the audio-frequency magnetotelluric data obtained in 2020 and 2022. The inferred resistivity structure basically has a two-layer structure composed of a high-resistivity layer corresponding to the Quaternary lavas near the surface and low resistivities corresponding to the altered Neogene lavas below. Shallow moderately high resistivity regions in the low-resistivity layer are considered fluid reservoirs that have become infiltrated as a result of the eruption. Regions around the crack associated with the eruption showed relatively high resistivity, implying that the low resistivity zone is decoupled beneath the eruption site. We will discuss how the phreatic eruption occurred based on these interpretations in the presentation.

The shallow hydrothermal system of Mt. Usu imaged by electromagnetic survey

DOI: 10.57757/IUGG23-3004 - LINK

Tomohiro Inoue[1], *Takeshi Hashimoto*[2], *Atsuo Suzuki*[2]
[1]*Hokkaido University, Graduate School of Science, Sapporo, Japan*
[2]*Hokkaido University, Institute of Seismology and Volcanology- Faculty of Science, Sapporo, Japan*

We conducted electromagnetic survey at Mt. Usu, one of the active volcanoes in Hokkaido, northern Japan. We succeeded in the first three-dimensional imaging of the resistivity structure beneath the summit crater field of the volcano. This study revealed the geometrical relationship between the subsurface structure and the sources of micro-earthquakes, remagnetization, and ground deformation.

Mt. Usu is an active volcano that has repeatedly erupted about every 30 years since the 20th century. It is known from historical and geological records that the summit crater experienced repeated magmatic to phreatomagmatic eruptions in the past. Even in the present inter-eruptive period following the 2000 phreatomagmatic event on the western flank, remarkable ground deformation, micro-seismicity, and magnetic field changes have been observed in the summit crater field. Therefore, such geophysical monitoring is vital for evaluating the volcano's activity level. On the other hand, although several electromagnetic surveys (e.g., Matsushima et al., 2001) were previously conducted in the past, detailed three-dimensional imaging has been awaited. To this end, we conducted audio-frequency band magnetotelluric surveys in 2021 and 2022 to unveil the shallow three-dimensional electrical structure. Our model recognizes a low resistivity anomaly (1-10 Ωm) extending westward from the Ginuma crater at approximately 200-500 m below sea level. Current micro-seismicity and continuous remagnetization (Hashimoto, 2022) occur slightly above this low resistivity anomaly. On the other hand, the center of the long-term ground deflation (Wang and Aoki, 2019) is located on another low resistivity patch on the northeast side of the crater field.

Unravelling the internal structure of volcanoes is an essential step to understand the architecture of the magmatic system and advance hazard assessment. Electromagnetic (EM) measurements are particularly suited for this task due to the high contrast in resistivity between melts and solid rock. Due to this, EM surveys of active volcanoes have gained significant attention in recent years. However, many modelling and inversion algorithms only provide a rough approximation of the significant topography of the volcanoes. Currently it is not clear to which level the topography has to be incorporated to provide reliable and robust results. We use two modern finite-element modelling algorithms for magnetotelluric data to assess the impact of different approximations. Based on the geometry of a recent survey at Mt. St Helens we will compare the results of the two algorithms with different topography approximations. We will discuss different strategies for incorporating topography and how to ensure valid calculations of magnetotelluric forward responses.

Unravelling the internal structure of volcanoes is an essential step to understand the architecture of the magmatic system and advance hazard assessment. Electromagnetic (EM) measurements are particularly suited for this task due to the high contrast in resistivity between melts and solid rock. Due to this, EM surveys of active volcanoes have gained significant attention in recent years. However, many modelling and inversion algorithms only provide a rough approximation of the significant topography of the volcanoes. Currently it is not clear to which level the topography has to be incorporated to provide reliable and robust results. We use two modern finite-element modelling algorithms for magnetotelluric data to assess the impact of different approximations. Based on the geometry of a recent survey at Mt. St Helens we will compare the results of the two algorithms with different topography approximations. We will discuss different strategies for incorporating topography and how to ensure valid calculations of magnetotelluric forward responses.

Piezomagnetic fields associated with a dislocation source in a layered elastic medium

DOI: 10.57757/IUGG23-4836 - LINK

Ken'ichi Yamazaki[1]

The piezomagnetic effect is defined as a change in magnetization with applied stress. Changes in the geomagnetic field caused by the piezomagnetic effect, referred to as the piezomagnetic field, have been theoretically estimated and compared by previous studies to interpret observed variations in the geomagnetic field. However, the piezomagnetic field estimated in previous studies may not provide an accurate estimation because they ignored spatial variations in elasticity, leading to only a rough approximation of the properties of Earth's crust. In the present study, a semi-analytical procedure for calculating the piezomagnetic field arising from a point dislocation source embedded in a layered elastic medium is derived. Following a well-established method of the vector surface harmonic expansion, all of the governing equations written in partial differential equations in a real domain, together with the linear constitutive law of the piezomagnetic effect, are converted to a set of ordinary differential equations in a wavenumber domain. Equations in the wavenumber domain are solved analytically, and each component of the piezomagnetic field in the real domain is obtained after applying the Hankel transform. By using the derived procedure, the piezomagnetic and displacement fields due to a finite fault with strike-slip, dip-slip, and tensile-opening mechanisms are estimated for media with layered elasticity structures. In the presentation, I will also talk about an application to the calculation of the temporal variations of the piezomagnetic field, which will be essential when compared with the actual changes in the geomagnetic field just after the onset of earthquakes.

The formation of circular collapse craters are frequently observed on many receding tongues of formerly active glaciers. In absence of substantial ice flow dynamics, subglacial cavities formed by meltwater conduits are no longer closed down but continuously enlarge. A local depression will form at the surface due to creep with decreasing roof thickness. This process is accompanied by the formation of circular crevasses. Complete loss of stability eventually will lead to the collapse of the entire surface leaving a crater in the ice behind. Understanding the physical processes and conditions governing the collapse crater dynamics is essential to assess processes of rapid glacier retreat and hazards resulting from snout collapses and sudden blockage of subglacial drainage pathways.
On the glacier tongue of Rhonegletscher such an evolution was detected in spring 2022. A monitoring was carried out between June and October in bi-weekly to monthly intervals with drone surveys to document the surface topography, survey of network of ice flow markers and GPR surveys to estimate cavity size. After a successful drilling through the roof, direct measurements of roof thickness and cavity height were conducted in the evolving cavity. Preliminary ice flow modelling results show strain patterns that coincide with the observed low-angle circular crevasses. Although initiated by the presence of a subglacial drainage conduit, our results suggest the mechanical failure of ice lamellas from the cavity roof as main driver of the collapse crater, and subglacial melting by air flow or water drainage as minor influence.

In high mountains environments, permafrost degradation causes rockwall instabilities, sometimes leading to rock slope failures. These processes could be a threat for human lives and activities, it is therefore essential to improve our knowledge about their triggering and propagation mechanisms.

This study focuses on two rock slope failures which occured in the *Vallon d'Étache* (Maurienne Valley, France) and the *Crête des Grangettes* (Écrins massif, France) in 2020. These events have respectively volumes around 270 000 m^3 and 35 000 m^3. In both cases, ice in the rockfall scars suggests the presence of permafrost, but its local distribution and its role in the triggering of the events remain to be confirmed. The aims of this study are (i) to assess thermal conditions in which both events were triggered and (ii) to model their propagation. To do so, we first propose a method that combines rockwalls temperature monitoring, statistical modelling of permafrost distribution, geophysical surveys (Electrical Resistivity Tomography) and laboratory measurements (petrophysical model) to explain the thermal conditions under which the rockfalls occurred. Then, 3D models acquired by photogrammetry are used to obtain high-resolution DEMs in order to measure their volumes, and to provide consistent inputs for runout modelling.

This multi-method approach allows to understand the context and the processes leading to rockfall triggering of two events in the French Alps. We also propose depth-averaged flow simulations to model the runout characteristics of the *Vallon d'Étache* rock slope failure.

A machine-learning approach for estimating the snow avalanche danger level and avalanche activity

DOI: 10.57757/IUGG23-2854 - LINK

Christine Schönberger[1], *Reinhard Fromm*[2]
[1]*ÖBB-Infrastruktur AG, Strategy & Innovation, Vienna, Austria*

Snow avalanche danger level and avalanche activity are key metrics for describing the prevailing hazard situation of mountainous areas during winter. Avalanche warning services publish avalanche bulletins, which include the regional avalanche danger levels and descriptions of the snow cover properties. Physically-based snow cover models calculate the detailed stratigraphy of the snowpack using meteorological variables as input.

In this study the output of a snow cover model is used as input for machine learning algorithms to determine the local avalanche danger level and the avalanche activity at a ski resort. The avalanche activity is characterized by observations of avalanche releases by explosions or by snow groomers.

Two machine learning approaches using the modeled snow stratigraphy and meteorological variables were applied. An artificial neural network was designed to process the snow stratigraphy with convolutional layers and to treat the meteorological time series with recurrent layers. Support vector machines with radial basis functions as kernel functions were used for each output variable. The model results differ, but no model can be specified as best for all cases. This suggests the use of ensemble methodology. Logistic regressions handle ensemble learning and improve final outcomes.

The precision of the model reaches up to 0.73 for the local avalanche danger level, 0.75 for the artificial releases by explosives, and 0.94 for the artificial releases by snow groomers. The temporal evolution of the probabilities of the avalanche danger level provides additional information, which can be relevant for the operational work of the avalanche warning services.

The morphology of Askja caldera walls demonstrates features related to slope instability and permafrost variations that can be linked to each other. However, the causal link between mass wasting and cryosphere in active volcanic environments is poorly understood. Factors of permafrost degradation and associated slope instability at Askja may involve volcanic heat flow and atmospheric temperature increase. To investigate long-term morphological changes related to slope processes and permafrost activity, we performed photogrammetric processing and comparative analysis of archive aerial, recent Pleiades satellite, and drone data. We extracted DEMs and orthophotographs covering the period of 1970-2022 and revealed evidence of slope instability, previous mass wasting occurring on different scales, and permafrost degradation. The high-resolution multitemporal data allowed recognition of such surface features as emerging tensile cracks and multiple thermokarst sinkholes. Our photogrammetric dataset was complemented with SAR and infrared data processing, and historical ground-based photographs analysis. Our results show that landslides are common at Askja caldera, and considering the identified morphological features, a new mass wasting event can occur at any time. We outline unstable areas at the caldera walls and discuss the relevance of permafrost and instability that may have contributed to the Askja 2014 rockslide avalanche. We suggest that slope instability at Askja poses significant hazards and requires constant remote sensing and on-site monitoring.

Glacial Lake Inventory of Kinnaur District, Himachal Pradesh, India derived from Landsat Images

DOI: 10.57757/IUGG23-3790 - LINK

Divya Singh[1], *Varun Joshi*[1]
[1]*Guru Gobind Singh Indraprastha University,*
University School of Environment Management, Delhi, India

Climate change and associated glacier recession have led to the formation of new glacial lakes and the expansion of existing lakes across the Himalayas. Such lakes pose a potential glacial lake outburst floods (GLOFs) threat to downstream communities and infrastructure. The accelerated growth of glacial lakes has resulted in increased hazard and damage potential of GLOFs in Kinnaur district, Himachal Pradesh. To understand the spatiotemporal dynamism, a temporal inventory of glacial lakes in the study area for the years 2000, 2010, and 2022 is prepared at 30m resolution using Landsat satellite imagery. The study performed a three-step semi-automatic method for mapping glacial lakes based on geospatial techniques that included the use of the normalized difference water index (NDWI), elimination of mountain shadows using the Cartosat digital elevation model (DEM), and manual vectorization of lakes using Google Earth imagery. A total of 147 glacial lakes were identified having an area > 0.25 ha for the year 2022. This study presents an important database of glacial lakes and provides a basis for long-term monitoring and evaluation of outburst flood disasters primarily caused by glacial lakes in the study area.

The Antarctic Ice Sheet is the largest but also the most uncertain potential contributor to future sea level rise. Understanding involved feedback mechanisms require physically-based models. Confidence in future projections can be improved by models that reproduce past ice sheet changes and present change rates. The complex interaction between ice, bedrock and sea level plays an important role for the stability of marine ice sheets with characteristic response time scales varying regionally between years and thousands of years due to the heterogeneous Earth structure underneath Antarctica and the interacting ice sheet dynamics.

We have coupled the VIscoelastic Lithosphere and MAntle model (VILMA) to the Parallel Ice Sheet Model (PISM v2.0, www.pism.io) and have run simulations over the last two glacial cycles. In this framework, VILMA considers both, viscoelastic deformations of the solid Earth by considering a three-dimensional mantle-viscosity distribution and a gravitationally self-consistent mass redistribution in the ocean by solving for the sea-level equation. PISM solves for the stress balance for a changing bed topography, which can be updated with coupling intervals up to 1 year in view of fast changes in ice sheet flow and grounding line dynamics.

Here, we show results of coupled PISM-VILMA simulations scored against a database of geological constraints around Antarctica (AntICE2), including sea level index points and GPS uplift rates. We discuss the implications of a three-dimensional Earth structure over one-dimensional profiles for Antarctic ice sheet changes. This project is part of the German Climate Modeling Initiative PalMod.

30-year surface elevation changes over ice sheets of Greenland and Antarctica from multiple satellite radar altimeters

DOI: 10.57757/IUGG23-1617 - LINK

Baojun Zhang[1], Zemin Wang[1], Jiachun An[1], Mingliang Liu[1], Hong Geng[2]

[2]Wuhan University, School of Resource and Environmental Sciences, Wuhan, China

As the result of changes in ice dynamics and weather-driven changes on the surface, surface elevation changes over ice sheets are sensitive to climate forcing. Thus, long-term surface elevation changes over ice sheets of Greenland and Antarctica are of essential to assess the impact of climate change. Here, a dataset of monthly surface elevation time series over ice sheets of Greenland and Antarctica at 5km grid resolution using ERS-1, ERS-2, Envisat, and CryoSat-2 radar altimeter observations from August 1991 to December 2020. An updated plane-fitting least-squares regression strategy and Empirical orthogonal function (EOF) reconstruction were applied to ensure the accuracy and self-consistency of the merged elevation time series in the data processing. In addition, the cross-comparison with the IceBridge airborne laser altimeter observations confirmed that our merged dataset is reliable. Benefiting from its high temporal and spatial resolutions, the evolution processes on multiple temporal (up to 30 years) of ice loss from the main outflow glaciers in Greenland and Antarctica can be derived in detail. The spatiotemporal patterns of accelerating or decelerating surface elevation changes over ice sheet related to ENSO (for the Antarctic Ice sheet) and NAO (for the Greenland Ice sheet) indicated that climate forcing shifts oceanic forcing or atmospheric forcing in some way to affect ice sheet changes. Our merged time series provide a vital dataset for exploring the processes of climate forcing driving ice sheet change.

Approaches to constraining East Antarctic rheology using seismic measurements from isolated stations

DOI: 10.57757/IUGG23-0769 - LINK

Niam Askey-Doran[1], Ross Turner[1], Tobias Stål[1], Anya Reading[1]
[1]*University of Tasmania, Department of Physics, Hobart, Australia*

It is becoming apparent that the East Antarctic Ice Sheet may be more vulnerable to changing climate than previously thought. Tomographic studies have revealed significant lateral variations in mantle viscosity across Antarctica, which can strongly influence the results of glacial isostatic adjustment models. Glacial isostatic adjustment is an important consideration in sea-level and ice-sheet studies, necessitating improved constraints on rheology in East Antarctica.

Detailed studies of 3D rheology in East Antarctica are challenging due to the sparsity of seismic stations across this region. Stochastic Bayesian approaches to inversion naturally provide information on uncertainties and can be a powerful technique when data is sparse. The utility of such approaches has been demonstrated by the recent results of the Mars InSight mission, in which ensemble model approaches were used to invert for the seismic structure of Mars using recordings from a single seismic station.

We employ stochastic Bayesian approaches recently used on Mars to constrain the rheology of the lithosphere and asthenosphere in East Antarctica. These techniques will be used to develop new methodologies that can be used on data recorded at isolated stations to constrain possible bounds for rheology on a regional scale. In future work, seismic measurements may be used in combination with other techniques such as magnetotelluric measurements to provide additional constraints on solid Earth rheology.

Coupling cryosphere, hydrology, sea-level and solid-Earth processes within the ice sheet and sea-level system model

DOI: 10.57757/IUGG23-4637 - LINK

Lambert Caron[1], Eric Larour[1], Surendra Adhikari[1], Erik Ivins[1], Matthieu Morlighem[2]
[1]California Institute of Technology/Jet Propulsion Laboratory, Sea Level and Ice, Pasadena, USA
[2]Dartmouth College, Earth Science, Hanover, USA

Determining the multidecadal evolution of ice sheets and the associated sea-level change informs major decisions for coastal hazard mitigation and societal development at the global scale. Such systems involve physical processes occurring within and between ice sheets, terrestrial water, oceans, and the solid Earth. Important feedback loops have been identified in marine-terminating ice sheets between thickness change near the grounding line and the bedrock response.

We present a new framework for the Ice Sheet and Sea-level system Model that aims at coupling ice dynamics, hydrology, sea level, and solid-earth deformation. This framework features dynamic interactions between processes with support for multiscale resolution. For example, we are able to capture grounding line dynamics in West Antarctica at a kilometric and biweekly resolution, while global sea level is simultaneously computed on yearly timescales. This is achieved by combining spatial partitioning of physical processes, anisotropic meshing, subelemental geometry tracking, and an asynchronous mass transport approach.

Our solid-Earth model is based on high-degree (~10^4) love numbers and is able to account for viscoelastic response in the lithosphere and mantle to surface loading and rotational feedback. Rheology models supported include the Hookean, Maxwell, Burgers, and Extended Burgers models.

Our framework is fully parallelized and optimized to support ensemble modeling for uncertainty quantification purposes. Intended applications include the modeling of ice sheet retreat, sea-level projections, high-resolution coastline migration, Glacial Isostatic Adjustment, and hydrology fingerprints. These will affect the interpretation of numerous geodetic datasets, such as GRACE-FO, GPS, NISAR, ICESat-2, and SWOT.

Global mean sea level during the mid-Pliocene Epoch, when CO_2 and temperatures were above those of the present day, was significantly higher as a result of reduced global ice sheet coverage. However, the extent to which ice sheets responded to Pliocene warmth remains in question, owing to high levels of uncertainty in proxy-based sea-level reconstructions and solid Earth dynamic models that have been compared with only a limited set of data constraints. Here, we present a global dataset of 11 wavecut scarps that formed over successive Pliocene sea-level oscillations and occur today at elevations varying from ~6 to 109 m above sea level. The present-day elevations of these features have been identified using a combination of high-resolution digital elevation models and field mapping. Using the MATLAB interface, TerraceM, we project the cliff and platform surfaces to determine the elevation of the scarp toe, which often is buried under meters of talus. We correct the scarp elevations for glacial isostatic adjustment and find that this process alone cannot explain observed differences in paleoshoreline elevations. We next calculate the signal associated with mantle dynamic topography by back-advecting the present-day three-dimensional buoyancy structure of the mantle and calculating the difference in radial surface stresses over the last 3 Myr using the convection code ASPECT. We include a wide range of present-day mantle structures (temperature and viscosity) constrained by seismic tomography models, geodynamic observations, and laboratory experiments. Finally, we explore to what extent models can reproduce the different shoreline observations and deformation along them.

Degree dependence of Antarctic GIA correction for GRACE data

DOI: 10.57757/IUGG23-3943 - LINK

Yoshiya Irie[1], *Jun'ichi Okuno*[1]
[1]*National Institute of Polar Research, Geoscience Group, Tachikawa, Japan*

Ongoing mass changes in the Antarctic ice sheet have been observed as gravity changes by the Gravity Recovery and Climate Experiment (GRACE) satellites. The gravity signal also includes the component of the solid Earth's response to surface mass change (Glacial Isostatic Adjustment, GIA). Therefore, estimates of the ice mass change from GRACE data require subtraction of the gravity rates predicted by the GIA model (GIA correction). Previous studies imply that the long-wavelength components dominate the Antarctic GIA correction. To further understand the long-wavelength contributions, we compute the degree amplitude of Antarctic GIA correction in the spherical harmonic expansion. The degree dependence of Antarctic GIA correction is examined here using some typical ice history models. The Antarctic GIA corrections converge by degrees ~ 30 regardless of the choice of ice history models. When the GIA model includes Northern Hemisphere ice history, the degree amplitudes for degrees < 10 vary significantly at each degree. The degree-2 GIA component, due to the influence of the Northern Hemisphere ice history, accounts for 30% or more of the total Antarctic GIA correction. It will be necessary to pay attention to the treatment of the degree-2 component.

Vertical land motion (VLM) is an important component in relative sea-level (RSL) projections, while VLM is difficult to derive because of a lack of long-term instrumental records. Geological data offer an alternative, comparing RSL data with glacial isostatic adjustment (GIA) models to isolate VLM.

Here, we present a case study from the Oka estuary, northern Spain. We compare two GIA models (ICE-6G_C and ANU-ICE) with late Holocene RSL data along the Atlantic coast of Europe, showing good fit (misfit < 1.5) at all regions except the Oka estuary (misfit > 4.5), which indicates local subsidence. The nearby GPS (station SOPU, > 15 years) shows a VLM rate of -0.96 ±0.57 mm/yr (subsiding). The VLM rate of SOPU accounts for misfits between GIA models and RSL data, decreasing by ~90% from > 4.5 to ~0.5 after the subsidence correction of RSL data. The VLM rate incorporated in IPCC AR6 projections in Oka estuary is ~0.18 mm/yr (uplifting), which is contradictory in direction. Therefore, the projected sea-level rate is underestimated by 14 - 20% by 2050 and 9 - 26% by 2100 under the five Shared Socioeconomic Pathway (SSP) scenarios.

The sea-level projections of Spanish authorities were based on IPCC AR5. Under RCP4.5 scenario, the future RSL in Oka estuary will increase 0.38 m by 2081-2100, which is underestimated by ~71% (0.65 m) compared with the IPCC AR6 under the SSP2-4.5 scenario by 2100 after correction for local VLM. Our study indicates the importance of local VLM component in projections.

The deformation of the Earth's crust in Antarctica caused by Glacial Isostatic Adjustment (GIA) is highly dependent on the melting history of ice and the viscoelastic properties of the mantle. However, geodetic observations, including Global Navigation Satellite System (GNSS) measurements, are essential in constraining GIA model parameters.

The Japanese Antarctic Research Expedition has conducted GNSS observations and absolute gravity measurements for over 20 years along the coast of Lützow-Holm Bay in East Antarctica, mainly at Syowa Station. This study aims to examine the geodetic signals associated with GIA from the observations made along the coast of Lützow-Holm Bay. Furthermore, the study involves numerical simulations of the signals based on the recently reported rapid ice thinning in this region during the mid-Holocene (Kawamata et al., 2020, QSR).

According to Kawamata's paper, the target region underwent a rapid ice thinning of over 400 m from about 9 to 6 ka, as evidenced by geomorphological surveys and surface exposure ages. The representative deglaciation models, such as ICE-6G, do not incorporate this rapid thinning process. Therefore, the study examines the variability of the geodetic signals using the ice history, including rapid thinning. The predictions indicate that the modified ice history produces consistent results with the observations, thus supporting the occurrence of rapid ice melting during the Holocene. The results also suggest that geodetic observations can aid in constraining the ice sheet melting process in this region. Additionally, the study presents a similar analysis of gravity variations obtained from absolute gravity measurements at Syowa Station.

Glacial isostatic adjustment (GIA) models provide estimates for velocity, gravity and sea-level change based on ice loading scenarios of past glaciations. The input to GIA models is quite extensive and consists of ice histories and a variety of Earth model parameters that describe the three-dimensional (3D) structure and rheology. Here, we will show the effect of a range of lithospheric thickness models on vertical and horizontal velocities in Greenland using a 3D compressible GIA Earth model.
The lithospheric thickness beneath and around Greenland varies from a few tens of kilometres in offshore regions to several tens of kilometres (up to 200 – 250 km) in land areas. However, to date, no one has done an analysis of the impact of lateral lithospheric variation on the 3D velocity field for Greenland as horizontal velocities from incompressible GIA models, which are commonly used, are not suitable to be used due to the neglect of material parameter changes related to the dilatation. Compressible GIA models in turn can provide more accurate estimates of the horizontal and vertical viscoelastic deformations induced by ice-mass changes. We use various lithosphere models as input into a new 3D compressible GIA model code, which is constructed with the finite-element software *Abaqus.* We apply recent ice history models Huy3 and GLAC-GR2a for Greenland in combination with a Little Ice Age deglaciation model. The modelled 3D velocity field is compared against independent GNSS (Global Navigation Satellite System) observations as well as to previously modelled estimates using incompressible 3D GIA models.

Ice sheet – solid earth feedback during the last glacial cycle in Antarctica and Greenland

DOI: 10.57757/IUGG23-3121 - [LINK]

The solid earth influences ice sheet dynamics by controlling bedrock deformation and hence surface elevation and grounding line position. These in turn determine surface and basal melt. Ice-sheet models typically include models to compute bedrock deformation with a constant mantle viscosity (or similar parameter), whereas mantle viscosity can vary strongly underneath the ice sheets. Here we use a recently developed model that couples an ice-sheet model (ANICE) to a finite-element based GIA model that includes 3D variations in viscosity derived from seismic measurements. We investigate the effect of mantle viscosity variations on the evolution of the last glacial ice sheets in Antarctica and Greenland.

In Antarctica, the main feedback mechanism is the effect of bedrock elevation on local sea level and grounding line position. In particular, uplifting bedrock in marine ice sheets reduces ice sheet loss during deglaciation. Results show a grounding line position that is 500 km more outwards when including 3D variations in mantle viscosity compared to a homogeneous viscosity. In Greenland, the main feedback is the effect of bedrock elevation on the surface elevation and hence surface melt. We show that this feedback mainly manifests in north-west Greenland where the mantle viscosity is above average. The higher mantle viscosity leads to higher ice sheet elevation at last glacial maximum, which leads to less surface melt during deglaciation. The results underline the importance of including 3D viscosity in modeling ice sheet evolution.

We present a preliminary comparison between satellite and terrestrial gravity and GNSS data collected in a twenty-year period (2002-2022) at Mt. Etna volcano, with the aim of investigating the capabilities of this integrated approach to study the dynamics of volcanic phenomena over time-scales of months to years.

The terrestrial gravity data were collected through absolute and relative spring gravimeters in the framework of almost monthly campaigns. Instead, GNSS measurements are continuously collected for monitoring purposes.

Regarding satellite data, we used the Gravity Recovery and Climate Experiment (GRACE) data and GRACE Follow-On L3 solutions, that can provide high-quality information about mass distribution at regional and global scales in a long-term interval.

After being corrected for the known effects, reduced terrestrial gravity and GNSS height variations were compared with satellite data. The comparison reveals long-term correlations between the analyzed time series which could represent volcano-scale variations.

Shallow ocean/emergent basaltic phreatomagmatic volcanism observed on November 14, 1963 on the south-eastern end of the Vestmannaeyjar archipelago and the volcanic island of Surtsey appeared on the next day. Surtsey island is the only remaining subaerial part of the constructs from the 1963-1967 eruptions, has two tuff cones in its northern sector while the southern sector is a lava field mostly built on a lava delta. The SUSTAIN drilling in 2017 revealed the existence of an underlying diatreme, giving the island some of the characteristics of a maar volcano. Gravity data obtained on Surtsey in 2014 with a gravity station spacing of 100 m. Density measurements were obtained for surface samples of seafloor sedimentary rock bombs, and lava, tuff and tephra. With the best measured density value for gravity data correction, we use forward modeling to study the vent and surface lava characteristics by considering the four geological units defined for the island: tuffs above sea level, tuffs below sea level, lavas above sea level and a lava delta below sea level, composed of breccias over which lava advanced during the effusive eruption. The boundaries between the bodies defined from the eruption history and mapping done during the eruption. The data reveal low density of the vent areas within the lavas, best explained by cavities within the very shallow magma conduits. However, the small size of the island precludes accurate determination of the dimensions of the deeper diatremes, formed by excavation of the pre-eruption sea floor, through gravity data models.

Satellite gravimetry is a unique tool to monitor the Earth's mass variations. Satellite missions like GRACE and GRACE Follow-On provide insights into the time-variable gravity field on a global scale to further improve our understanding of climate change processes and geophysical phenomena on scales of a few hundreds of kilometres. The users of gravity field products, however, require higher accuracies and a better spatial and/or temporal resolution, which are not met yet. The current GRACE-FO mission is not only limited by its observational geometry but also by limitations of current instruments, like electrostatic accelerometers. These challenges are partly tackled by current ESA and NASA initiatives to realise satellite gravimetry missions with overlapping mission lifetimes at different orbits. The sensor issue is addressed by the Cold Atom Rubidium Interferometer in Orbit for Quantum Accelerometer – Pathfinder Mission Preparation (CARIOQA-PMP) project. The main goal of CARIOQA-PMP is the preparation of a pathfinder mission with view to demonstrating an atom-quantum accelerometer in space within this decade and to realise a technological and programmatic roadmap for a quantum space gravimetry mission meeting user demands from a wide range of applications.

This presentation will give an overview of the scientific activities within CARIOQA-PMP. These include the definition of the quantum pathfinder mission concept, the development of tools to simulate the quantum accelerometer and to estimate its performance, and to evaluate current end-user requirements, including the development of mission designs addressing these needs.

CARIOQA-PMP is funded by the European Union.

Managing and sharing volcanological data at the INGV - Osservatorio Etneo

DOI: 10.57757/IUGG23-1516 - LINK

Marco Antonio Aliotta[1], *Carmelo Cassisi*[1], *Placido Montalto*[1], *Fabrizio Pistagna*[1], *Michele Prestifilippo*[1], *Mario Torrisi*[1]
[1]*INGV - Istituto Nazionale di Geofisica e Vulcanologia, Osservatorio Etneo, Catania, Italy*

The study of volcanic activity requires monitoring a variety of data sources, including volcanological, geophysical, and geochemical data. With numerous research organizations and observatories collecting vast amounts of data from sensor networks, it's crucial to have a systematic way of organizing and sharing this information for volcano research and monitoring. This is where the INGV Osservatorio Etneo's TSDSystem framework comes in.TSDSystem is a framework that enables the acquisition and standardization of time series data from different sources within a relational database, and provides synchronized data visualization. The framework is integrated with the OEDataRep web data repository, which is based on the InvenioRDM research data management platform and follows an open access model.The proposed architecture of the system includes various features and services, such as a database optimized for time series data, a RESTful web service based on microservices pattern, near real-time data visualization through modern web technologies, data policy management, and an early warning module. These features help to efficiently manage and share time series data in a timely and accessible manner.

The study of volcanic activity requires monitoring a variety of data sources, including volcanological, geophysical, and geochemical data. Data Terra's main mission is to develop a structure for accessing and processing data, data-products and services geared towards observing, understanding and predicting in an integrated manner the history, mechanisms and evolution of the Earth system in response to global changes and extreme events.
Data Terra federates four data and services hubs dedicated to the four physical compartments of the Earth System: Aeris for the atmosphere, Odatis for the oceans, Theia for land surfaces and ForM@Ter for the solid Earth. While aimed chiefly at the scientific community, the unique research e-infrastructure also serves public and socio-economic stakeholders and its multi-source data are accessible via coherent, one-stop portals.

As a digital infrastructure in the field of earth and environmental science, Data Terra works closely with Earth-observation research infrastructures and space agencies. It is backed by a continuum of distributed and interconnected platforms, proposing services that span the full data cycle from access from repositories to value-added processing, thus enabling inter- and trans-disciplinarity studies as well as exploitation of large volumes of data. At national, European and international levels (EOSC Pillar, Fair impact, Phidias, Copernicus services, …), it is advancing the development of open science, implementation of FAIR approaches, contributing to space missions and applications and to the initiative to generate digital twins of the Earth.

Soil moisture is recognized as an Essential Climate Variable (ECV) because it is crucial for assessing water availability for plants and hence food production. Having long time series of freely available soil moisture data with global coverage enables scientists, farmers and decision makers to detect trends, assess the impacts of climate change, and develop adaptation strategies.

The collection, harmonization and archiving of in situ soil moisture data was the motivation to establish the International Soil Moisture Network (ISMN) at TU Wien, with the financial support of the European Space Agency (ESA), in 2009 as a community effort. The ISMN became an essential source for validating and improving global satellite products, and climate, land surface, and hydrological models. In 2021 permanent funding for the ISMN operations was secured through the German Government (Ministry of Digital and Transport).

The transfer of the ISMN to its new host, i.e., the International Centre for Water Resources and Global Change (ICWRGC)/German Federal Institute of Hydrology (BfG), took place during 2021/2022. Finally, the ISMN started serving data from its new host in December 2022 while keeping the service continuously running throughout the migration. In parallel the team in Vienna developed and launched a new dataviewer. This presentation aims at showcasing new ISMN features as well as recent data contributions as well as next evolution of the ISMN based on synergies and science outcome of the Research and Development activities performed by

ESA in the context of the Fiducial Reference Measurements for Soil Moisture (FRM4SM) project.

The Davos Dataset: An (un)fair backstory

DOI: 10.57757/IUGG23-4511 - LINK

Mathias Bavay[1], *Charles Fierz*[1]
[1]*SLF, Snow and Atmosphere, Davos Dorf, Switzerland*

The open data and FAIR data principles have seen widespread adoption in recent years. Unfortunately, the implementation of this vision often falls short of the original goals: seamless reuse is prevented by the reliance on undocumented and inconsistent file formats as well as the lack of metadata. Truly fulfilling the FAIR data vision requires standardization of the data formats and metadata. The necessary standardization efforts have been done, for example with the Climate and Forecast convention and the Attribute Convention for Data Discovery of the NetCDF ecosystem.

But this is only one part of the solution, the other part being that the published dataset must implement such standards. We present our efforts in publishing a dataset made of data from more than 50 Automatic Weather Stations with data extending over a period of 25 years, contributed by nine institutions. The raw data have been standardized into a common format with a common set of parameter names, units and metadata standard. This standardization process is described in a configuration file (one per station) that is used to dynamically generate the final dataset from the raw data.

The challenges in setting up such a dataset have ranged from finding the original data and parsing many different file formats, up to struggling to find the original measurement location or guessing which maintenance operations had been performed a long time ago. Preparing this dataset has therefore taken much longer than originally planned and our hope is that this could be improved in the future.

Making GeoNet Data FAIRer: lessons learnt from scoring a variety of natural hazard datasets (and how to improve them)

DOI: 10.57757/IUGG23-2199 - LINK

Jonathan Hanson[1], Steve Sherburn[2], Elisabetta D'Anastasio[1], Megan Madley[1], Mark Rattenbury[3], Maria Mavroeidi[4], Annemarie Christophersen[5], GeoNet Programme Team[1]

[4]IHC New Zealand, Business Analyst, Wellington, New Zealand
[5]GNS Science, Earthquake Physics and Statistics, Lower Hutt, New Zealand

The GeoNet programme at GNS Science, Aotearoa New Zealand is producer and custodian for datasets used for multi-hazard monitoring, assessment, and research. These datasets are of high national value and significance and range from highly sampled/highly automated to manual and ad-hoc datasets. FAIR is a cornerstone of GeoNet's and GNS Sciences' data principles and an area where we are always seeking to improve.

To understand and demonstrate improvements FAIRness of its datasets, all GeoNet datasets were assessed in 2019. Here we will discuss that scoring effort and the outcomes across our datasets, and show how subsequent targeted work has delivered improvements, using a few key examples:

- Our eruption history database was converted from unstructured document format (GNS report) to a csv format and made fully public; this significantly enhanced its FAIR score across the board.
- Our acoustic/infrasound dataset was made more discoverable by minting a DOI, creating a dataset description record that is based on international web standards and utilising community webservices, leading to significant increases in Findability and Interoperability.

FAIRness scoring is a powerful tool to guide dataset management improvements. It also revealed that some datasets have natural ceilings, particularly when there is a lack of clear international or community standards. More established and cross-peril datasets can achieve high compliance with FAIR data principles with relatively simple steps, while some key improvements generate nary a ripple in the score. FAIRness and open data are key policies for GeoNet, and will remain so for the foreseeable future.

New, open socio-hydrological data of paired events of floods and droughts

DOI: 10.57757/IUGG23-2098 - LINK

Heidi Kreibich[1], Kai Schröter[2], Giuliano Di Baldassarre[3], Anne F. Van Loon[4], Philip J. Ward[4]

[4]Vrije Universiteit Amsterdam, Institute for Environmental Studies, Amsterdam, Netherlands

A better understanding of the drivers of increasing impact trends is essential for effective flood and drought risk management. However, empirical data is lacking about the processes that result in flood and drought impacts. We present a benchmark dataset containing socio-hydrological data of paired events, which is unique in covering both floods and droughts, in the number of cases assessed, and in the quantity of socio-hydrological data. The advantages of the dataset are that it enables comparative analyses across all the paired events and allows for detailed context- and location-specific assessments. A first analysis of the dataset revealed the general pattern that risk management normally reduces the impacts of floods and droughts, but faces difficulties in reducing the impacts of unprecedented events of a magnitude not experienced before (Kreibich et al. 2022a). The dataset can be used by the scientific community for exploratory data analyses and for the development of socio-hydrological models. As such, the dataset can support solving one of the twenty-three unsolved problems in hydrology (Blöschl et al. 2019). The dataset is available to the public through the GFZ Data Services (Kreibich et al. 2022b).

[1]NASA - Goddard Space Flight Center, Code 61A, Greenbelt, USA
[2]Science Systems and Applications, Code 61A, Greenbelt, USA

The Crustal Dynamics Data Information System (CDDIS) is one of twelve NASA Earth Observing System Data and Information System (EOSDIS) Distributed Active Archive Centers (DAAC) and supports the space geodesy and geodynamics community through the International Association of Geodesy (IAG) services. As an EOSDIS DAAC, the CDDIS is required to meet best archival practices including the Findability, Accessibility, Interoperability, and Reuse (FAIR) Guiding Principles for scientific data management and stewardship which ultimately serves data and product providers and users. This poster will introduce some common tools to ensure clarity for users on how these best practices support their efforts and how to utilize and find the tools built to support them. These include ensuring data is findable via the use of Digital Object Identifiers (DOIs) and facilitating discovery using the Earthdata Search API and NASA's Earthdata Search. As the CDDIS continues to grow during NASA's year of open science, the CDDIS will start migrating to the cloud further ensuring clarity and accessibility of data.

Geo-Environmental Monitoring Station(GEMS):A real time monitoring network to evaluate the impact of anthropogenic activity on environmental conditions on urban areas

DOI: 10.57757/IUGG23-3091 - LINK

Alejandro Rodriguez-Trejo[1], Héctor Ibarra-Ortega[1], Harald Böhnel[1], Jorge Escalante González[2]
[1]Centro de Geociencias - Universidad Nacional Autónoma de México, Paleomagnetism, Querétaro, Mexico
[2]Centro de Geociencias - Universidad Nacional Autónoma de México, Geophysics, Querétaro, Mexico

Study of the impact of anthropogenic activity on environmental conditions from urban areas is one of the most important issues at a global level. Human activity on urban areas, such as commercial, industrial, transit, scholar and many-others, represents direct impact on the environmental conditions that influence directly on social and health issues. Monitoring and measure of variations on environmental conditions associated to human activity through time and space. In this work, a device was developed for real time monitoring of different geo-environmental conditions for urban areas: Geo Environmental Monitoring Station (GEMS), integrates different low-cost sensors and a web-based real time processing platform, for storage and visualization of the data. GEMS includes atmospheric sensors to measure particulate matter (PM2.5, PM1.0 and PM10), temperature(°C) , atmospheric-pressure and relative-humidity; noise(dB), ultraviolet-radiation, variations on the earth´s magnetic-field. GEMS can measure all those 9 different parameters and send them via Wi-Fi to the platform for real time processing and visualization The data is free and open access via internet. A dense network is installed on Queretaro,Mexico, a small city with up to 1 million habitants, located in central-Mexico, with an intense industrial activity. Up to 100 GEMS are projected to be installed at the end of 2023. With the data collected by the GEMS network, in combination with other parameters, such as micro-seismicity, magnetic-susceptibility, wind direction etc., a model for anthropogenic impact on environmental conditions is established. GEMS network is planned to be a very low-cost permanent monitoring-system, accessible to society, governments and private companies.

The Diploma in Seismology for high-school teachers a new version

DOI: 10.57757/IUGG23-3679 - [LINK]

Delia Bello[1], Xyoli Perez Campos[2], Jesus Antonio Perez Santana[1], Antonio de Jesús Mendoza Carvajal[1], Fernando Estrada Navarro[1], Miguel Ángel Sosa Jiménez[1], Iván Ruíz Vázquez[1], Adriana Gonzalez López[1]
[1]Universidad Nacional Autónoma de México- Instituto de Geofísica, Servicio Sismológico Nacional, Mexico City, Mexico
[2]Universidad Nacional Autónoma de México- Instituto de Geofísica, Seismology, Mexico City, Mexico

The Diploma in Seismology for high-school teachers is a 170-hour course, the first five generations started with examples of what they could offer their students in their classroom. The content seeks to apply some of the learning and concepts of the physics courses in high school through the analysis of the information recorded in seismograms. In addition to the material presented to the participant through an online platform, and during sessions, they worked on an integrating project, which objective is to prepare them for the use of seismographs and their data in their classes and begin scientific research themselves. We have excellent results; teachers learned and promoted to their students about seismology. Now the high school Physics programs include subjects based on seismology.
At the moment, the sixth generation is taking the new version of Diploma we added a new module, civil protection. The Diploma has reached professors of 20 high schools in Mexico City where also a Raspberry Shake has been installed to integrate the "Red Sísmica del Bachillerato" or the High-school seismic network. The participant teachers know how to extract the information from those instruments and they can work with their students. For the next stage we have support from the project DGAPA-PAPIME PE107023 for displaying the data from Raspberry Shakes installed in five high schools. We will install a screen and a bulletin board with information about basic subjects of seismology. The idea is to have profesors involved in the designed and content production of this board.

Brothers Volcano - virtual experience

DOI: 10.57757/IUGG23-0784 - LINK

Alexander Broadley[1], Veit Kakuschke[2], Jamie North[3], Angel King[4]
[1]Metaverse Engineering, Managing Director, Thames, New Zealand
[2]Metaverse Engineering, Software Engineering, Müncheberg, Germany
[3]Metaverse Engineering, Audio Engineering, Auckland, New Zealand
[4]Metaverse Engineering, Human Resources, Auckland, New Zealand

----

Keywords: VR, Social, Education, Virtual Classroom, Science, Exploration, Geology, Volcanology, Oceanography

----

Summary:

Brothers Volcano is a social VR experience for all standalone Meta Quest headsets, that allows users to explore a vast 20km² underwater landscape together while learning about geology, geophysics and oceanography.

The 3D terrain is based on real high-resolution scans of Brothers Volcano, located along the Pacific Ring of Fire, offering breathtaking hiking trails, many informative boards & slideshows along the way, and several scenic spots to read related scientific journals.

To help visualize depth below sea level we built the world's current tallest virtual tower on the volcano's summit, and placed inside a pair of magic shoes which enables faster flight, but to get them one must first find 2 missing keys along the educational hiking trails.

Additionally, the multiplayer experience supports synced lecture slides, laser pointers & Superman flying abilities, so anyone can join the marine adventure and zoom around as a fellow tuna fish.

(As a team we would bring 8 VR headsets for poster session demos)

Target Audience: Primary/Secondary/Tertiary Education and General Public

----

Learning Goals:

1. To understand the geology and geophysics of an underwater volcano

2. To learn about the oceanography and marine life surrounding an active undersea volcano
3. To explore virtual reality and its potential as a deeply immersive educational tool

----

Instructions:

1. To easy install, search ‘Brothers Volcano’ on the App Store within any standalone Meta VR headset (the experience is free)
2. Interactive tutorials and maps are included within (experience times can easily range from 2 minutes to 2 hours)
3. For pictures and/or sideloading visit : https://sidequestvr.com/app/10009/brothers-volcano-virtual-experience

----

Keywords: VR, Social, Education, Virtual Classroom, Science, Exploration, Geology, Volcanology, Oceanography

----

Summary:

Brothers Volcano is a social VR experience for all standalone Meta Quest headsets, that allows users to explore a vast 20km² underwater landscape together while learning about geology, geophysics and oceanography.

The 3D terrain is based on real high-resolution scans of Brothers Volcano, located along the Pacific Ring of Fire, offering breathtaking hiking trails, many informative boards & slideshows along the way, and several scenic spots to read related scientific journals.

To help visualize depth below sea level we built the world's current tallest virtual tower on the volcano's summit, and placed inside a pair of magic shoes which enables faster flight, but to get them one must first find 2 missing keys along the educational hiking trails.

Additionally, the multiplayer experience supports synced lecture slides, laser pointers & Superman flying abilities, so anyone can join the marine adventure and zoom around as a fellow tuna fish.

(As a team we would bring 8 VR headsets for poster session demos)

Target Audience: Primary/Secondary/Tertiary Education and General Public

----

Learning Goals:

1. To understand the geology and geophysics of an underwater volcano
2. To learn about the oceanography and marine life surrounding an active undersea volcano
3. To explore virtual reality and its potential as a deeply immersive educational tool

----

Instructions:

1. To easy install, search ‘Brothers Volcano’ on the App Store within any standalone Meta VR headset (the experience is free)
2. Interactive tutorials and maps are included within (experience times can easily range from 2 minutes to 2 hours)
3. For pictures and/or sideloading visit : https://sidequestvr.com/app/10009/brothers-volcano-virtual-experience

Boosting Space Weather research and applications in Africa: The NORISK project

DOI: 10.57757/IUGG23-3421 - LINK

Claudio Cesaroni[1], Giancarlo Santilli[2], Jahjah Munzer[2], Alessandra Di Cecco[2], Lucilla Alfonsi[1], Joseph Olwendo[3], Bruno Nava[4], Andrew Nyawade[5]
[1]Istituto Nazionale di Geofisica e Vulcanologia, Environment, Roma, Italy

It is well-known that among all the longitudinal sector of the low-latitude ionosphere, the African one is the less studied. This is mainly due to the difficulties in installing and managing long-lasting ionospheric observatories and instruments. Moreover, it is difficult for young people to establish a network of collaboration with scientists outside Africa.

Istituto Nazionale di Geofisica e Vulcanologia (INGV) and Italian Space Agency (ASI) established a framework agreement in 2017 on research activities for the study of Sun-Earth relations and development of Space Weather monitoring. In this context, the New Observatory for Real-time Ionospheric Sounding over Kenya (NORISK) project was funded. The general objective of the NORISK project is to make Broglio Space Centre in Malindi (Kenya) a point of reference in Africa and to contribute to the development of the knowledge supporting Space Weather in the Kenyan scientific community. NORISK specifically aims to:

1. a) Design and develop an ionospheric observatory in Kenya.
2. b) Develop models, algorithms and products for monitoring the low-latitude ionosphere in the African sector.
3. c) Train the new generation of experienced researchers and technicians in the field of research and technological development in support of Space Weather.

The paper shows a general overview of the project and the progress about the training activities.

Understanding earth materials is critical to foster technological and environmental development, as well as to advance in Earth-science disciplines, like mineral- and rock-physics, as well as material-oriented (bio)geochemistry. EXCITE, a large-scale infrastructure project supported by the European Union's Horizon-2020 program comprising 15 European institutions for electron and X-ray microscopy, enables free-of-charge Trans-National Access (TNA) to high-end microscopy and microanalysis facilities to develop community-driven technological advancements on Earth materials.

The WP5 of EXCITE aims to facilitate mechanisms and procedures to provide TNA to world-class facilities, specifically addressing new, non-expert or early career users worldwide. By definition, TNA involves a researcher conducting science at a research facility located in a country different from the one in which they are working. The EXCITE TNA programme provides access to 24 imaging facilities in 9 countries. Access is provided on a per-call basis, and is granted following a proposal review process. During the first two TNA calls, almost 150 scientific projects have been supported. Two more calls from both academia and industry users will allow access to facilities until April 2024. Analytical techniques and scientific expertise offered include X-ray micro- to nano-tomography, EPMA, FIB-SEM, TEM, as well as SEM-based imaging, element mapping, EBSD, cathodoluminescence and other specialized imaging tools. Our contribution will present the architecture of the EXCITE-TNA programme and outcomes of the user evaluations, which clearly demonstrate the success of Excellence-driven TNA programmes as a strategic asset of the European research scenario, allowing networking and collaboration and favoring education & outreach in geosciences.

Addressing the need for global standards for geochemical data – the OneGeochemistry initiative

DOI: 10.57757/IUGG23-2338 - LINK

Kirsten Elger[1], Rebecca Farrington[2], Dominik C. Hezel[3], Marthe Klöcking[4], Kerstin Lehnert[5], Alexander Prent[2], Geertje ter Maat[6], Lesley Wyborn[7]

The acquisition and analysis of geochemical data are pervasive in the Earth, environmental, and planetary sciences, but few of these data are FAIR (Findable, Accessible, Interoperable and Reusable) or ready to be mined for new knowledge using modern computational methods. The need for global standards and best practices for geochemical data is increasingly urgent so that scientists can better share and analyse geochemical data in a global context.

Standard protocols for exchanging geochemical data among distributed data systems, and for making software tools that support the management, publication, and preservation of interoperable geochemical data need to be developed and approved by a global community. Best practices need to be defined for researchers and laboratories to consistently and comprehensively describe samples, data acquisition procedures, and data quality, and these need to be endorsed and promoted.

OneGeochemistry is an international initiative which aims to support the development of data standards for geochemical data and approaches for their technical and organisational governance. Initially an informal network with representatives from AuScope (Australia), GEOROC, NFDI4Earth (Germany), EPOS Multi-scale Laboratories (Europe), EarthChem (US) and the Astromaterials Data System (US), OneGeochemistry is now funded as a use case of the WorldFAIR project (https://worldfair-project.eu/) and recognised as a CODATA Working Group (https://codata.org/initiatives/working-groups/)

Scientific discovery in many fields will benefit from this global geochemical data network: from the study of global climate change, to present and past biogeochemical cycles, to magmatic processes, to the origin and evolution of our solar system.

ORBYTS project: Predicting storm times with machine learning

DOI: 10.57757/IUGG23-4002 - [LINK]

Kendra Gilmore[1], Vishal Singh[1], Sarah Bentley[1]
[1]Northumbria University, Mathematics- Physics and Electrical Engineering, Newcastle Upon Tyne, United Kingdom

Historically there has been a lack of diversity in STEM subjects, including physics. Often to counteract this many outreach programs try and encourage young people, especially young girls, to pick up sciences. However, often these outreach programs are one-time events.

ORBYTS (Original Research By Young Twinkle Students) goes about this differently. Scientists are paired with local schools to work on a novel, scientific-relevant project over 3 months with weekly 1-1.5h sessions. This way students are introduced to what and how research works by conducting research themselves, thus hopefully solidifying their interest in STEM. To assess this, we ask them at the end of the project to fill out a questionary on how participating in this project impacted their likelihood to keep sciences in upper secondary school and to pursue a STEM-related career.

For this project, the students use machine learning to predict storm times, which is a problem that space weather scientists are trying to solve. Machine learning has proven to be successful in other fields and its use is becoming more frequent in the space weather community.

The students build a random forest on individual stations in the CARISMA magnetometer chain with magnetic field data and solar wind parameters to assess whether there is a geomagnetic storm or not. Each random forest is trained with the storm time list provided by Sandhu et al. 2021 and its performance is evaluated on a selection of unseen data. The different models are then compared to determine the impact of location on the prediction.

“JIGYASA” for Geoscience: Role of CSIR-NGRI, India

DOI: 10.57757/IUGG23-1407 - LINK

Sandeep Gupta[1], Tanvi Arora[1], T. Vijay Kumar[1], R Vijaya Raghavan[1], Devender Kumar[1], Prakash Kumar[1]
[1]CSIR-National Geophysical Research Institute, Seismology, HYDERABAD, India

CSIR-National Geophysical Research Institute (CSIR-NGRI; https://www.ngri.res.in), a premium institute of Earth Science research in India is actively involved in the outreach activities under the “JIGYASA” (a Hindi word which means curiosity), a flagship program of CSIR (Council of Scientific and Industrial Research, India). To tap and trigger the innate curiosity of the students and general public about the Earth, CSIR-NGRI conducts various outreach activities to explain about Earth’s evolution, its environment, natural resources and natural hazards etc. CSIR-NGRI welcomes students to visit its state-of-art laboratories and analytical facilities, conducts webinars for students and the general public, distribute booklets in various languages. CSIR-NGRI researchers and students also visit schools / colleges in different parts of India. Through lectures, models, Do-It-Yourself activities, quiz, conducting education camps, and print / electronic media; we spread awareness about rock types, exploration and exploitation of natural resources, phenomena of earthquakes and Tsunami, earthquake risks and precautions, extent and sustainability of groundwater etc. Further, CSIR-NGRI has open-air rock museum, first of its kind in the country, with large number of rock samples from different geological regions to educate students and general public about different types of rocks, their formation and information provided by these rocks. Since the initiation of “JIGYASA” program, CSIR-NGRI reached approximately 25,000 students and the general public through its outreach activities.

A study on satellite on-orbit conjunction assessment system by SaaS

DOI: 10.57757/IUGG23-0678 - LINK

Chih Chien Liu[1], *Yi-Shan Li*[2]
[1]*Chung Cheng Institute of Technology- National Defense University, Environmental Information and Engineering, Taoyuan, Taiwan Province of China*
[2]*Chung Cheng Institute of Technology- National Defense University, Environmental Information and Engineering, Taoyuan City, Taiwan Province of China*

Countries around the world are rapidly developing large number of Low Earth Orbit (LEO) projects which increase the number of satellites in the LEOs. Currently, there are still more than 14,000 man-made space objects and more than 35,000 space debris larger than 10 cm orbiting in orbit. Those space objects and debris will greatly increase the probability of satellite close approach or collision event now and future. This study established a Cloud On-Orbit Conjunction Assessment (COOCA) system, which analysis the short-term potential risk of collision events by a SaaS (Software as a Service). The system ingested the TLE data which is public provided by the 18th Space Defense Squadron of the U.S. Space Force. The Simplified General Perturbations (SGP4), earth gravity parameters and the simplified atmospheric model are adopted to determine the LEO positions and velocity. Then, the collision probability of the potential risk events can be estimated. The results of this research can analyze satellite collision probability by the operators in the satellite ground control center. In addition, general users (especially for students) can learn geodesy theory, geographic coordinate system, time system and Kepler orbital celestial mechanics through the intuitive website platform and automatic process in this COOCA system. It can contribute to the promotion of geoscience education and space science education.

Let's fire the passion for Geoscience! New geo-comic trilogy.

DOI: 10.57757/IUGG23-3469 - [LINK]

Matej Machek[1], Eden Kučera[2], Petr Brož[3], Lucie Lukačovičova[2], David Píša[4]
[1]Institute of Geophysics of the Czech Academy of Science,
Dynamics of orogens and rock deformation, Prague, Czech Republic
[2]freelance, xx, Prague, Czech Republic
[3]Institute of Geophysics of the Czech Academy of Science,
Surface Processes & Palaeoclimate, Prague, Czech Republic
[4]Institute of Atmospheric Physics of the Czech Academy of Science,
Department of Space Physics, Prague, Czech Republic

Communication of geosciences to the general public and students often runs into a lack of understanding of the fundamental processes of the inner Earth. We attempted to bring basic principles of Earth dynamics in an accessible way by creating three short comic books and board games. The structure of the Earth and earthquake mechanism is presented in the comic “When the Earth Quakes”. Origin and manifestation of the Earth’s magnetic field are introduced in the comic book “When the Earth Flares Up” and the danger and beauty of the volcano eruption is shown in the book “When the Earth melts”.

Our approach follows two basic strategies: i) the comics should not tell everything with a lot of explanatory text, but rather try to provoke the reader to look for additional information and it should give the readers some answers and hence start the passion for geoscience; ii) We believe that collaboration between artists and researchers needs to be founded on the equality of their views, discussions, and collective effort. The artists should be given creative freedom and the researchers should explain how the processes work inside the Earth rather than to try to push forward their views of artistic expression of them.

The creation of the trilogy has been funded by the Czech Academy of Science with the contribution of small donors on social media. Thus we decided to make the result of our work publicly available and publish it under the Creative Commons license: https://www.ig.cas.cz/en/comics/.

International Training Courses on „Seismology, Seismic Hazard Assessment and Risk Mitigation“

DOI: 10.57757/IUGG23-2629 - LINK

Claus Milkereit[1], *Torsten Dahm*[1], *Simone Cesca*[1], *Fabrice Cotton*[2], *Dino Bindi*[2], *Angelo Strollo*[3], *Frederik Tilmann*[3], *Training Course Participants*[4]
[1]*GFZ German Research Centre for Geosciences, 2.1 Physics of Earthquakes and Volcanoes, Potsdam, Germany*
[2]*GFZ German Research Centre for Geosciences, 2.6 Seismic Hazard and Risk Dynamics, Potsdam, Germany*
[3]*GFZ German Research Centre for Geosciences, 2.4 Seismology, Potsdam, Germany*
[4]*GFZ German Research Centre for Geosciences, International Training Course ITC 2023, Potsdam, Germany*

The GFZ organizes annually International Training Courses on “Seismology, Seismic Data Analysis, Hazard Assessment and Risk Mitigation”. They provide theoretical fundamentals and practical training for geo-scientists and engineers from countries in Asia, Africa, and Latin America. The courses are being supported by the German Federal Foreign Office and are a contribution to the global UN Sendai Framework for Disaster Risk Reduction (UNDRR).

In line with the growing demand by participants in former courses for mainly practice-oriented training and workshop discussions related to case studies, the course program comprises, besides introductory and state-of-the-art review lectures on the various subjects of earthquake seismology and risk assessment, extensive practical exercises, demonstrations, workshop discussions and scientific excursions. Generally, the course program aims at developing interdisciplinary problem understanding, acquaintance with the theoretical fundamentals and basic features of modern instrumentation, commonly used models and algorithms as well as developing practical skills in data evaluation and analysis. The courses are being announced through the GFZ website, the EMSC, and IRIS as well as printed information. Additional ad-hoc sponsors are mainly from the hosting institutions and governments in case of regional courses in Asia, Africa, or Latin America.

Since 1992 these 4-week courses are held alternately as world-wide open courses in Potsdam or as regional courses in earthquake-prone countries in Asia, Africa, or Latin America (2006 Kyrgyzstan, 2008 Costa Rica, 2010 Turkey, 2012 Morocco, 2014 Colombia, 2016 Myanmar, and 2018 Ghana). Many of the former course participants became project partner in ongoing research projects of German and European institutions.

Skills needed in work life: case study of Geoinformatics Master's program

DOI: 10.57757/IUGG23-3209 - [LINK]

Maaria Nordman[1,2], Pinja Lindgren[1], Miina Rautiainen[1]
[1]Aalto University, School of Engineering, Espoo, Finland
[2]Finnish Geospatial research Insitute, Geodesy and Geodynamics, Espoo, Finland

What are the skills that we are teaching in our Master's program in Geoinformatics? How useful those skills are for the new graduates and which skills do they end up using in their working life? What are the skills that the companies that are hiring the new graduates are looking for?

As part of renewing our Master's program we asked our alumni which skills they have found useful in the working life. We also asked a group of our stakeholders to evaluate the same skills for the people they might be hiring. We had a set of predefined skills, both general and field-specific, that we asked the answerers to rate based on their usefulness in the working life. There was also option for commenting the skill set and adding something that was missing.

The results show that both groups find the problem-solving skills the most important general skill. For the alumni the other two skills in top three were project management and team-work skills, whereas the people who might be hiring the graduates ranked programming and writing skills above them. From the field-specific skills understanding and implementing theories was the ranked as the most important. Other skills, such as data analysis or management of measuring process, were ranked in varying places depending on the duties of the person answering.

Based on the results we are going to critically evaluate our course contents and add components of problem solving and team working where possible.

The scientific community is well aware of the anthropogenic global warming and its consequences at regional level. However, the public is still not informed well enough, and may be confused especially due to the overwhelming, often contradictory social media environment. This is why we initiated a project with the aim to present and explain scientific results of regional climate change via a national platform (www.masfelfok.hu) established for climate awareness dissemination towards public, within this framework we also use a broad media platform and a large social media network as well. The message is formed as well-illustrated short studies focusing on various seasonally relevant climate indicators, mainly related to climatic extremes. The scientific background is based on calculations using reliable data: observation-based homogenized fine-resolution gridded data for Hungary (HUCLIM), outputs (i.e. CMIP6 data) from global climate model simulations with natural-only forcing as well as historical forcing (when anthropogenic concentration changes are also taken into account), regional climate model simulation outputs (i.e. EUROCORDEX data) for past decades (beginning from the last quarter of the 20th century) and future decades until the end of 21st century with strong mitigation, lighter mitigation, and non-mitigation scenarios. Studies are published in every 4-6 weeks, and online and traditional media connections are also used to outreach the public.

[4]NPO Dagik Earth Project, member, Kyoto, Japan

A three-dimensional digital globe system, Dagik Earth, has been developed by a group of geoscientists, software engineers, and educators for use in and out of school education and public outreach. The project aims to provide schools, science museums, and educators with the basic knowledge and recent progress in Earth and planetary sciences, and stimulate interest in them. The system is very simple and budget-friendly using a PC, a PC projector, and a spherical screen. The screen for this system is inexpensive, and any white sphere, such as a balance ball or balloon, can be used as the spherical screen. The three-dimensional presentation of the Earth and its data provides the audiences a view of looking down the Earth from space similar to large-scale three-dimensional globe systems, such as the Geo-cosmos of Mirai-kan, Japan, and Science On Sphere of the National Oceanic and Atmospheric Administration, USA. The software is provided free of charge for educational and scientific use. English and Chinese versions are also available although the majority of users are in Japan. A permanent exhibition of Dagik Earth is installed in 23 science museums, including one in Taiwan. As well as digital globe, the project is also developing analogue globes using global Earth and planetary science data. Students make their own handmade globes in classrooms and science events and take them home. In addition to introducing the software of Dagik Earth, we would like to introduce analogue craft materials in the presentation. International cooperation will also be discussed.

Seismic risk communication over the past 20 years: An overview on time, methods and tools

DOI: 10.57757/IUGG23-1546 - [LINK]

Angela Saraò[1], *Gemma Musacchio*[2], *Susanna Falsaperla*[3], *Anna Scolobig*[4]
[1]*Istituto Nazionale di Oceanografia e di Geofisica Sperimentale - OGS, Centro di Ricerche Sismologiche, Sgonico, Italy*

Risk communication has evolved significantly over the past two decades. In this study, we provide an overview of the timing, methods and tools we observed in a review study of earthquake risk communication in Europe.

Our study shows that communication occurs predominantly in the pre-event phase and that communication during the earthquake crisis is often limited to seismological information. Only one-fifth of the publications reviewed explicitly rely on theories of risk communication. There is an increasing convergence toward a two- or three-way communication model, i.e., the adoption of frameworks in which seismic risk experts promote proactive citizen participation; moreover, the goals of communication become more proactive than informative.

The goals of earthquake risk communication are to share information, raise awareness, change behaviors/beliefs, and increase preparedness. Students and citizens are the main target groups for communication activities. The involvement of schools is based on the idea of a 'domino effect," where students share and promote earthquake mitigation information and best practices within their families.

In an effort to reach an age-, culturally-, and educationally-diverse audience, traditional education/communication methods such as handouts and lesson plans are gradually giving way to exercises and hands-on activities, as well as more advanced communication tools such as infographics, video scribing, serious (video) games, and augmented reality applications. The results also show the growing role of social media as an information and dissemination channel.

KIDZ PAZ-NOWn - Increasing resilience to climate- and water-related natural hazards in Paznaun Valley via an inter- and transdisciplinary research-education-collaboration

DOI: 10.57757/IUGG23-4203 - LINK

[3]*Medical University of Innsbruck, Dep. of Psychiatrie II- Institut for Mental and Psychosomatic Illnesses, Innsbruck, Austria*

This poster presents the research framework of the transdisciplinary research project “KIDZ PAZ-NOWn”. The project aims to increase resilience to climate- and water-related natural hazards in Paznaun Valley (Tyrol, Austria), which looks back at a history of extreme weather events and natural hazards. Present-generation climate projections indicate that the region is expected to experience significant changes in temperature and precipitation with respective impacts on water-related natural hazards (e.g. the frequency and magnitude of floods). We apply the WRF-Hydro model, in conjunction with spatially and temporally refined climate scenarios from the CORDEX project, to simulate the impacts of climate change on the hydrosphere in Paznaun Valley. To account for glacier retreat in alpine environments, the new glacier mass balance model in WRF-Hydro will be expanded by a glacier flow routine. Model results will be discussed in a mutual learning alliance to promote a better understanding of the complex interaction between the climate and the water system in alpine regions as well as of the specific needs and vulnerabilities of mountain communities in the backlight of climate change. By strengthening the engagement between juveniles, hazard-relevant institutions from the local community and scientists from different disciplines, the project lays a solid foundation for lasting future resilience and the transformation of societies towards sustainability. As the valley represents a typical Alpine environment and is representative in terms of demographic and educational structure, the findings achieved in KIDZ PAZ-NOWn can be transferred to other alpine settings.

The phenomenon of Arctic Amplification is most evident in the rise of the near-surface air temperature observed in the last decades being at least twice as strong as the global average. The mechanisms behind that are widely discussed. Many processes and their feedback mechanisms are still poorly understood, especially considering the role of clouds. To increase the understanding of such processes and to improve their representation in models, direct observations are needed, but are barely available. Within the research initiative "Arctic Amplification: Climate relevant atmospheric and surface processes and feedback mechanisms (AC)3", several airborne campaigns aimed to provide observations of clouds and precipitation by state-of-the-art remote sensing instruments.

Within this contribution, we will present measurements and datasets from the remote sensing suite operated onboard the Polar 5 research aircraft of the Alfred-Wegener Institute for Polar and Marine Research (AWI) during four airborne campaigns over the Arctic ocean and sea ice out of Svalbard. The measurements provide unique opportunities for the evaluation of satellite products and atmospheric models, e.g., cloud vertical structure, liquid water path, and sea ice emissivity. We assess models and reanalysis with two approaches: (i) model-to-observation via the forward simulator PAMTRA and (ii) the development of products from the observations from the synergy of cloud radar, lidar, and microwave radiometer measurements.

Dome C is located on the high Antarctic plateau, at 3233m above sea level, and 1200km away from the coastline. At this location, the EPICA ice core was retrieved from the ice sheet and allowed the reconstruction of past climatic information 800,000 years back in time. Amongst several atmospheric parameters, the past local temperature was inferred from the stable water isotope record measured in the ice.

To interpret this record, it is necessary to understand how it was formed in such a dry and cold environment. This includes understanding the water cycle dynamics in Antarctica, from evaporation to precipitation and moisture pathways, as well as the processes affecting the record after deposition of the precipitation, such as snow-atmosphere exchanges.

During the austral summer 2018-2019, a Picarro laser spectrometer was installed on site to monitor continuously the isotopic composition of the atmosphere. It provided measurements for all austral summers since then and allowed the detection of two major atmospheric river events, including a rare event during the onset of the cold Antarctic winter. To go beyond the limitations of the Picarro instrument when measuring at very low humidity levels, as encountered during the wintertime at Dome C, a new laser spectrometer dedicated to low humidity measurements has been developed and installed it in parallel to the Picarro instrument during the summer season 2022-2023. Here we present the results of the atmospheric isotopic composition during four consecutive austral summers and the comparison of the two laser instruments during the most recent period.

[3]CNRS, Liphy, Grenoble, France

Water isotopes measurements in polar ice cores are key to reconstruct past climatic variations. However, the relationship between surface temperature and water isotopic composition is not straightforward because snow isotopic composition is influenced by many factors in addition to local temperature of condensation (evaporation origin, trajectory of moist air, post deposition effects). In order to refine this interpretation, parallel observation of water vapor and surface snow isotopic composition in polar regions is essential.

Measuring atmospheric water isotopic composition is however an important challenge, especially in dry places like the East Antarctic plateau, where water mixing ratio can be as low as 10 ppmv. Laser spectrometers based on the cavity ring-down spectroscopy (CRDS), commonly used for field measurement, fail to precisely measure water vapor isotopic composition for the lower range of water mixing ratios recorded in East Antarctica.

The optical feedback cavity enhanced absorption spectroscopy (OF-CEAS) technique offers an interesting alternative for low humidity detection. During the austral summer 2022 – 2023, two OF-CEAS spectrometers were respectively installed at Dumont-d'Urville, situated along the coast, and Dome C, situated on the plateau, at 3230 m above sea level. We present here results obtained with this OF-CEAS technique, which shows an improved limit of detection, while keeping a low humidity dependence.

This work is part of the AWACA ERC project, in which we intend to install several OF-CEAS instruments, in three remote sites situated along the Dumont-d'Urville – Dome C transect, in addition to the two permanent polar stations.

Airborne remote sensing observations of Arctic low-level clouds and precipitation during cold air outbreaks

DOI: 10.57757/IUGG23-4355 - LINK

Imke Schirmacher[1], Susanne Crewell[1], Mario Mech[1], Sabrina Schnitt[1], Manfred Wendisch[2]
[1]Universität zu Köln, Institut für Geophysik und Meteorologie, Köln, Germany
[2]Universität Leipzig, Institut für Meteorologie, Leipzig, Germany

In cold air outbreaks (CAOs), cold and dry air flows from the central Arctic southward often leading to extreme weather at mid-latitudes. Roll convection in the boundary layer is triggered within the marginal sea ice zone. During the air-mass transformation, this roll convection leads to cloud formation within several 100 km away from the sea ice edge. Mixed-phase processes and extreme surface heat fluxes play an important role in the transformation. Understanding air-mass transformation is very important for weather and climate modelling. However, only few observations of cloud macro- and microphysical characteristics during CAOs along their trajectory exist yet.

Our study investigates cloud rolls over the open ocean and sea ice west of Spitsbergen using airborne remote sensing measurements obtained by the Microwave Radar/radiometerfor Arctic Clouds (MiRAC) and Airborne Mobile Aerosol Lidar for Arctic research (AMALi). We focus on two CAO events that took place during the HALO–(AC)3 campaign conducted in March/April 2021. The POLAR 5 aircraft flew several legs along the same track perpendicular to the cloud streets crossing the sea ice edge. This allows an investigation of the air masses with time and distance to sea ice edge. Hence, our analysis resolves the development of the roll convection. Dropsondes serve information of the thermodynamic state of the atmosphere, whereas remote sensing observations allow for a geometrical and microphysical analysis of clouds. In-situ measurements from the POLAR 6 aircraft, which flew collocated with P5 but inside the clouds, resolve aerosol number concentrations and droplet size distributions.

Antarctica and the Southern Ocean are important parts of the Earth system. The physical and biological properties here to a large degree control and shape other parts of the Earth through atmospheric, cryospheric and oceanic connections.

The Troll Observing Network – TONe - is a new comprehensive infrastructure centered around the Norwegian Troll Research Station in Dronning Maud Land. It will be an important contribution to global research efforts in this part of Antarctica, closing data gaps in Antarctic environmental observations and providing key data required to respond to the fundamental societal challenges and uncertainties facing the world today.

The Norwegian and international partner consortium in TONe is in the process to develop the state-of-the-art, multi-platform, multi-disciplinary observatory network for environmental observations, and a remotely piloted aerial system (RPAS) services to collect data for studying and monitoring the atmosphere, terrestrial and marine environment. The observatory network consists of 8 observatories: an integrated cloud observatory, an atmosphere composition observatory, an infrasound array, an ionospheric observatory, a seismic array, an ice-shelf observatory, a multidisciplinary open ocean moored observatory and a sea-bird observatory.

The key aspect of TONe is to ensure wide and free access to the data from the observatories and the RPAS services to the entire national and international research community.

TONe as a whole will be implemented and fully operational from 2027, while single parts of the infrastructure will be available before that.

The AWACA (Atmospheric WAter Cycle over Antarctica) project aims to deploy 4 OPUs (Observation Platform Units) along a 1100km transect from coastal Terre Adélie to the interior of the high-elevated antarctic plateau. They will perform condensed water measurements throughout the atmospheric column. Surface meteorological conditions near the OPUs will be monitored with a 7m tower mast, the first prototype of which was deployed during the last summer campaign 2022-23.

This setup includes a sonic anemometer, which gives access to turbulent momentum and heat fluxes near the snow surface. The collected measurements will enable the investigation of those fluxes which remain scarcely studied especially in the winter season and in the interior of the continent due to harsh meteorological conditions.

The context of the AWACA Project and the meteorological tower's design will be illustrated, and the first results from the summer campaign depicted and analyzed.

JP01 - Posters - Tides (IAPSO, IAHS, IAGA, IASPEI, IAG)

Temporal stability of strain tides in southern California, 1971-2021

DOI: 10.57757/IUGG23-4348 - LINK

Duncan Agnew[1]
[1]*University of California, Scripps Institution of Oceanography, La Jolla, USA*

Tidal forces, by providing a well-known, though narrowband, input to the Earth and ocean, are very useful for detecting temporal changes in the response of these systems. Strain tides provide the most sensitive tidal measurement of local changes in the elastic behavior of the solid Earth for two reasons. First, unlike tilt and gravity, strain tides have no component from the direct attraction. Second, measuring the derivative of displacement makes strain measurements more sensitive to nearby changes than displacement measurements would be; changes in elastic constants are more likely at shallow depths. We report on temporal variations in strain tides observed on long-base laser strainmeters at five locations in Southern California. Since the overall data span is almost fifty years at some locations, and mostly more than a decade, these data provide an unmatched dataset for examining the stability of strain tides. The calibrations depend mostly on instrument length and the wavelength of light, both invariant with time, along with two electronic systems of high stability. A first look at a portion of the data from a few sites shows high stability for the semidiurnal tides; the diurnal tides show seasonal patterns driven by unavoidable thermal effects on the instrument systems, which produce a spurious S1 tide. Results from a fuller analysis will be compared with postseismic inelastic effects from large earthquakes in 1992, 1999, and 2010, along with water-well tides at one site, which have shown temporal variations.

Tidal forces, by providing a well-known, though narrowband, input to the Earth and ocean, are very useful for detecting temporal changes in the response of these systems. Strain tides provide the most sensitive tidal measurement of local changes in the elastic behavior of the solid Earth for two reasons. First, unlike tilt and gravity, strain tides have no component from the direct attraction. Second, measuring the derivative of displacement makes strain measurements more sensitive to nearby changes than displacement measurements would be; changes in elastic constants are more likely at shallow depths. We report on temporal variations in strain tides observed on long-base laser strainmeters at five locations in Southern California. Since the overall data span is almost fifty years at some locations, and mostly more than a decade, these data provide an unmatched dataset for examining the stability of strain tides. Ocean tides are a vital component of global ocean circulation, with their role in the Arctic Ocean being crucial for ocean and sea ice dynamics. Recently, significant advances have been made in global ocean tide models, however, difficulties remain in the coastal regions as well as in the higher latitudes. The latter is related to the poorly resolved bottom topography, the influence of sea ice and limited regular satellite altimetry measurements. Although modelling efforts are attempting to improve our ocean tide estimates in the Arctic Ocean, the tidal in-situ network is an additional limiting factor in this region. In-situ measurements from tide gauges or ocean bottom pressure sensors are crucial sources of information that can be used to understand the spatial variability of tides as well as validate the advances made in modelled estimates. However, globally in-situ tidal constituent databases contain a limited number of observations with, for example, TICON-3 containing 111 above 60°N and 21 above 70°N with the distribution of these measurements mainly being around North America. This abstract presents the results of a concerted effort to produce a harmonised dataset of tidal constituents in the Arctic region. This dataset combines in-situ measurements from tide gauges, ocean bottom pressure sensors and GNSS reflectometry, which results in approximately 691 measurements above 60°N and 313 above 70°N with a much greater spatial distribution across the full Arctic ocean. The resultant dataset is quality assessed and compared to recent tide models to determine the reliability of the different data sources used.

In the UK, Coastal Flood Forecasting procedures rely on forecasts of still water level generated by combining predicted tide and storm surge components. The tide component of this system is often termed the 'astronomic tide'. However, the predicted tide is derived from a harmonic analysis of the full water level time-series (tide plus surge) observed at tide gauges – typically from the last 19 years. Therefore, the tidal predictions will include radiational tides particularly those that occur with tidal frequencies such as S_2 and Sa.

We have previously shown that the current forecasting system double-counts several cm of tides from these sources, since the radiational tides are also generated by the surge model. Now we investigate further, to see whether removing a modelled surge prior to tidal analysis and prediction can improve total water level forecasting.

Comparisons of a revised tidal Response Method with modern Harmonic Analysis

DOI: 10.57757/IUGG23-3989 - LINK

Thomas Monahan[1], *Tianning Tang*[1], *Thomas A. A. Adock*[1]

While tidal Harmonic Analysis (HA) has seen considerable development in the past 50 years, the Response Method, as described in the seminal paper of Munk and Cartwright, has remained relatively stagnant. The principal advantage of the response method is the inclusion of Kepler-Newtonian mechanics which avoids the need to split species into discrete spectral clusters. Additionally, the physical basis of the response framework allows for the systematic study of non-linear processes which are not well understood and play a significant role in shallow-water regions. Despite these advantages, HA remained and remains the tool of choice for tidal analysis due to the non-trivial burden of selecting realistic input functions. As such, a data-driven response analysis procedure is proposed for the automatic selection of input functions. We present comparisons between the proposed method and the state-of-the-art harmonic analysis. Additionally, a framework for the study of non-linear processes using response analysis is presented, and a Python implementation is provided.

The Antarctic continental shelf plays a critical role in global climate system as a buffer zone of the heat and material exchange between Southern Ocean and Antarctica. To investigate the response of physical properties for Antarctic shelf waters in response to increasing atmospheric greenhouse gases, we present a comparison of a fully coupled global climate model, Community Earth System Model version 1.2.2, results between present-day climate run (PC, atmospheric CO_2 is fixed to 367 ppm) and future climate run (FC, atmospheric CO_2 is double to 734 ppm). The latter experiment was branched from 71 year of the control run for 140 years and was integrated for another 100 years. The last 20 years of both simulations were analyzed. The resulting physical properties of Antarctic shelf waters reproduced by PC are generally consistent with what has been known by previous studies except for the Prydz Bay where the considerably warm (T>0.5C) water was simulated and the Cape Darnley where the outflows of dense shelf water were vanished. The FC results demonstrate significant warming (T>0.5°C) on the shelves in Amundsen Sea, Bellingshausen Sea, and eastern Ross Sea, and off the Adelie and Budd coasts, and freshening all over the Antarctic shelves, suppressing the Antarctic bottom water formation. The results suggest weakening of deep and abyssal circulation by suppressed bottom water formation due to increased atmospheric CO_2 concentration along with the potential for more rapid melting of Antarctic ice sheets.

Here we present initial results from a coupled configuration of the BISICLES ice sheet and NEMO ocean models for the Amundsen Sea Embayment. We use NEMO 4.2 with ice shelf cavity circulation enabled on a 0.25 degree horizontal grid with 75 vertical levels. Our initial focus is on producing a credible simulation of recent changes in the oceanography of the area before comparing the patterns of ice shelf melt predicted by NEMO with those required by BISICLES to generate patterns of ice thinning and grounding line retreat similar to observations. Forcing for these experiments comes from the UKESM CMIP6 simulations, currently for the historical period but with the intention of producing projections to 2100 of ice loss from the area.

The November 2016 Mw 6.9 Fukushima earthquake tsunami was a fresh call for potential large and long duration of tsunamis in Sendai Bay associated with the normal-faulting earthquake. The maximum tsunami height of 1.4 m and duration for more than 34 h was observed at Sendai port. Here, we conducted spectral analyses to sea level records at five tide gauges and tsunami simulation to shed light on the source characteristics and various coastal and shelf features such as reflections, trapped edge waves, as well as resonance of the wave on the shelves. We reproduced the tsunami source spectrum by calculating the ratio of tsunami and background spectra. Based on the source spectrum, the short-axis source dimension was identified as 30 km, which is consistent with the source models proposed by Gusman et al., 2017 and Adiano et al., 2018. In addition, we identified the main oscillation periods of the 2016 Fukushima earthquake tsunami at 9-38 min. Based on those periods, we performed spectral analyses of simulated tsunami wavefield in the region of interest, including Sendai Bay, Oshika Peninsula, and southern part of Sanriku coast. Tsunami resonance is a coastal process that occurs when the tsunami periods match the natural periods of Bays or continental shelves. Our analyses showed significant energy amplification inside the Sendai Bay at certain periods owing to resonant oscillation. Our findings have implication for tsunami warnings and disaster risk reduction for future tsunamis.

Numerical simulation and experiment on Tsunami of high viscosity and density fluid containing sediment

DOI: 10.57757/IUGG23-3463 - LINK

Yota Enomoto[1], *Taro Arikawa*[1]
[1]*Chuo University, Coastal Engineering Lab, Tokyo, Japan*

It has been observed that huge tsunamis such as the Great East Japan Earthquake cause black, muddy water to overflow and run upstream. This is presumably due to the large amount of sediment carried by the tsunami. Although many studies have been conducted on such sediment-containing flows, the effects of sediment on tsunamis have not been dealt with much. A tsunami containing sediment may become a non-Newtonian fluid due to its increased density and viscosity. In fact, Nakamura et al. confirmed that a tsunami containing a certain amount of silica sand becomes a Bingham fluid. In this study, numerical simulations of a tsunami inundation flow containing sediment are conducted to investigate the effect of the viscosity change on the tsunami wave force. In the numerical simulations, the Bingham model was applied to the CADMAS-surf3D/2f fluid analysis model to reproduce the spatiotemporal changes in viscosity. Coupled calculations with a sediment transport model were also used to calculate sediment roll-up and reproduce changes in density. The validity of the simulations was verified by comparison with experiments. The model was then used to perform numerical simulations under local conditions to verify the change in tsunami behavior due to sediment roll-up. The results showed that the viscous effect increased the tsunami overtopping height, and coupled with the density effect, the quasi-steady sustained wave pressure was larger than that of pure water. Furthermore, the increase in tsunami density due to sediment roll-up was found to be larger for finer particles.

Since tsunamis generated by submarine and subaerial landslides occur less frequently than tsunamis generated by fault movement, the actual behavior of landslide tsunamis is not well understood. Experimental and analytical studies have been conducted on submarine and subaerial landslide tsunamis, but there are fewer research examples than tsunamis generated by fault movement. In addition, experiments using two-dimensional flume have been mainly conducted, and there are few examples of examinations of submarine and subaerial landslide tsunamis under the same conditions. In this study, granular and solid slide models were used as models of landslide bodies, and hydraulic model experiments of submarine and subaerial landslide tsunamis were conducted by three-dimensional landslides. The 12.0m long, 12.0m wide, and 1.5m high experimental water tank was constructed, and landslide models were installed on the top of the slope. As the shape of the landslide model, three kinds of solid slide models were used as non-deformable landslide bodies, and granular bodies were used as deformable landslide bodies. We investigated the tsunami water level generated by the difference between granular material and solid slide model, and the difference between submarine and subaerial landslides, and its propagation process. The experimental data obtained in this study are useful for verification of the landslide tsunami numerical simulation model.

Examining the reliability of historical teletsunamis reaching Japan using literature review

DOI: 10.57757/IUGG23-0802 - LINK

Yutaka Hayashi[1]
[1]*Japan Meteorological Agency, Meteorological Research Institute, Tsukuba, Japan*

The NGDC/WDS Global Historical Tsunami Database (GHTD; NCEI) includes thirteen tsunami cases recorded in Japan, accompanied by foreign earthquakes until 1900. Following a literature review, false tsunami information based on errors in Japanese documents and historical interpretations was found in GHTD; five out of thirteen cases were false teletsunamis. Therefore, the reliability of historical tsunami data cannot be ensured without collaboration among researchers with different nationalities.

List of false teletsunamis to Japan found through literature review:
(1) The earthquake in Chile on 6 September 1420: Both earthquake and tsunami occurrence in Chile or Peru on 6 September 1420, and teletsunami occurrence in Ibaraki Prefecture on that date are groundless [1].
(2) The earthquake in Peru on 10 July 1586: This earthquake and an oral tradition in Japan are unrelated [2].
(3) The Philippines earthquake on 14 September 1627: This earthquake and the historical material on tsunamis in Japan are unrelated, and the date of the earthquake can be identified only by the month [1].
(4) The earthquake in Peru in 1651: No evidence of a tsunami caused by the 1651 earthquake in Peru. No reliable document on the event found in Japan [1].
(5) Earthquake along the Kuril Islands on 29 September 1780: The only economic impact on Japan was from the tsunami [3].

The saturated suspended sediment concentration in tsunami flow was experimentally investigated in this study. The large-scale tsunami physical simulator of Central Research Institute of Electric Power Industry was used for the experiments. The flume was composed of 5m long flat and non-movable bed at the upstream side and 20m long initially flat movable bed with a sand layer at the downstream side. Fast inundation flows with the velocities of approximately 3 m/s and inundation depths of approximately 0.4m passed over the bed and entrained suspended sediment from the sand layer. As going to the downstream side, the suspended sediment concentrations increased and appeared to approach equilibrium/saturation states. The saturated suspended sediment concentration which were measured were compared with the classical theory of Bagnold (1966), and good agreement among them was confirmed.

Fujii et al. conducted three-dimensional experiments to investigate the generation and propagation of tsunamis caused by landslides. They used granular materials or solid slide models as the landslides and switched between submarine and subaerial landslides by changing the initial water level. In this study, the two-layer model was validated using the results of their granular subaerial landslide experiments. Although calculated water levels using the original two-layer model based on the nonlinear shallow water equations significantly differed from the measurements, the addition of the dispersion term to the upper-layer equation resulted good agreement. The dispersive two-layer flow model can predict the water level of tsunamis caused by subaerial landslides comparable to the three-dimensional model, and is advantageous in terms of computational cost.

In this study, three-dimensional numerical simulations using OpenFOAM for tsunamis generated by submarine and subaerial landslides, were verified by comparison with the results of hydraulic model experiments conducted by Fujii et al. MultiphaseInterFoam was used for the solver and the landslide was modeled as a dilatant fluid. It was clarified that the grid size must be appropriately set to reproduce the short wave propagating to the shallow water area in the case of submarine landslide. The calculated thickness of the landslide at the start of the movement was consistent with that of the experiment, but the spread in the direction orthogonal to the slope was narrower than in the experiment. By examining the validity of the analysis for three-dimensional experiments rather than two-dimensional experiments, the issue of reproducibility of the flow shape and depositional area of the landslide body was clarified.

The impact of tsunamis on buildings, infrastructures and human losses has been globally studied. However, the relationship tsunami waves-marine ecosystems remains unclear. For example, during the 2004 Indian Ocean Tsunami (IOT), damage to living corals and reefs were surveyed all over the archipelago. Given that coral reef system is essential for fisheries, tourism and represent a natural coastal protection against large waves events, it is urgent to better understand how the IOT damaged such an ecosystem. Using TUNAMI-N2 model, we propose to reproduce the maximum amplitude and flow velocity of the IOT along the Maldivian shores with 10-m resolution. From statistical analysis, we developed tsunami fragility curves, with their 95 % confidence interval, for damaged coral reefs based on the maximum tsunami amplitude and the maximum flow velocity of the IOT. The flow velocity is found to be the best descriptor of tsunami damage. Based on the results, when the tsunami amplitude and flow velocity attain 4 meters and 4 m/s respectively, the probability that reefs endure damage is about 80 %. This founding may have implications for the development of long-term reef monitoring and planning to strengthen the resilience of reef resources after large wave events in the Maldives.

The population at risk of tsunami varies according to the season, day of the week, time, etc. Thus, even the same tsunami hazard may pose different levels of risk for an area with high mobility of residents and tourists. In the context of the efforts to develop the Tsunami Digital Twin (TDT) (Koshimura et al., 2023) for Japan, we investigated the application of human mobility data for real-time population exposure estimation. We selected two target areas prone to the anticipated Nankai Trough Earthquake, Katsurahama beach and Tanezaki district in Kochi Prefecture. The areas near Katsurahama correspond to a low residency but highly touristic zone, while Tanezaki is a highly residential area with low tourist activity. The size of both sites is similar for comparison, and the expected tsunami runup is in the same order of magnitude. The tsunami inundation is based on the scenarios proposed by the Cabinet Office of Japan. As the human mobility data, we used "Mobile Spatial Statistics" (DOCOMO InsightMarketing) containing estimated hourly population counts based on mobile phone networks. We found significant variations in the expected number of people at risk of tsunami during a year. Population dynamics affect the necessary levels of response and assistance. Furthermore, we show a prototype of our newly developed Population Exposure Mapping System (PoEMS) applied to real-time tsunami risk assessment.

Since the 2011 Tohoku earthquake and tsunami, each municipality in coastal areas has constructed and designated a lot of Tsunami Evacuation Buildings (TEB), the sites for secure physical safety under tsunami threat. The total number of them in Japan is more than 15,000 at present. The municipalities have concurrently developed tsunami hazard maps and evacuation signs to inform people of their locations. However, previous surveys point out the low awareness of their locations among people, especially visitors. Therefore, those who should quickly evacuate from the tsunami cannot decide their destination smoothly. In particular, the popular touristic sites along the coastal area require a solution to guide visitors who are not familiar with the TEB. It is necessary to highlight their locations intuitively to complete evacuation as soon as possible. For this reason, this study examines the use of balloon-type evacuation signs as visual information to lead people within a wide area to the sites before the tsunami arrives. This study consists of experiments in real space and virtual space. In real space, we set up balloon-type evacuation signs with different design and delimit the area for which the balloons can be seen. On the other hand, in the virtual space, we measure the evacuation time and the people trajectory with and without the presence of these signs. Through these experiments, we could evaluate the social implementation value of tsunami evacuation guidance with balloon-type evacuation signs.

The Kuril Islands trench has produced major tsunami events that have propagated towards different coastal areas in the Pacific Ocean basin. A tsunami wave inversion is performed to characterize the initial sea surface distribution triggered by the 2020 Kuril Islands earthquake (Mw 7.5). The tsunami generated by the earthquake caused a small appreciable tsunami wave at stations 21415, 21416 and 21419 of the DART network. To calculate the elementary waveforms (Green's functions) associated with each subfault and station, tsunami simulations are performed using the EasyWave code (Babeyko, 2012). This formulation solves the shallow water linear equations on a grid in spherical coordinates. A GEBCO bathymetry with a resolution of 30 arc-sec (~900 m) is used and a 90-minute propagation period of the tsunami is simulated. Once the Green's functions have been calculated, we proceed to solve the linear system using the algorithm of least squares following the method developed by Tsushima et al. (2009). Tsunami waves on DART buoys are adequately reproduced. The results are compared with the waveforms based on the finite fault solution obtained by the United States Geological Survey.

The accurate estimate of the tsunami forecast is crucial in Tsunami Early Warning Systems (TEWS) framework. However, the inherent uncertainties associated with the tsunami source estimation in real-time make tsunami forecasting challenging.

In this study, we consider the South American subduction zone, one of the most seismically active regions in the world, where in the last 15 years occurred, three M8+ tsunamigenic earthquakes; in particular, we focus on the 2014 Mw 8.1 Iquique event.

Here, we compare the tsunami forecasting for the Chilean coast as resulting *i)* from the coseismic slip model obtained by geophysical data inversion and *ii)* from an expeditious method for the tsunami source estimation, based on an extension of the well-known spectral approach.

In the former method, we estimate the slip distribution of the 2014 Iquique earthquake by jointly inverting tsunami waveforms and GPS data; on the other hand, a set of stochastic slip models in the latter is generated through a Phase Variation Method (PVM), where realizations are obtained from both the wavenumber and phase spectra of the source.

We also evaluate how the different physics complexity included in the tsunami modelling (e.g. by including dispersion or not) can be mapped into the tsunami forecasting uncertainty. Finally, as an independent check, we compare the predicted deformation field from the slip models (inverted or by PVM) with the RADARSAT-2 InSAR data.

A tsunami triggered by the eruption of an undersea volcano off the coast of Tonga in January 2022 caused damage to aquaculture facilities along the Japanese coast. Since damage to aquaculture facilities by non-seismic tsunamis, which have a shorter period than seismic tsunamis, is unprecedented, it is important to elucidate the damage mechanism. In this study, drifting simulations of aquaculture facilities in Yamada Bay were conducted to clarify the damage process of aquaculture facilities caused by this event.

The tsunami propagation was based on the nonlinear shallow water equations, and the water level waveforms observed by GPS wave gauges were input from the boundary. The drift of the aquaculture facility was represented by a rigid body model, and the hydrodynamic forces caused by the tsunami were applied to the model. The location of the aquaculture facilities was obtained from Google Earth satellite images of Yamada Bay, and the weight and size of the aquaculture products were given as parameters based on information obtained from field surveys conducted by the authors.

Numerical results indicated that the water level tended to rise at the back of the bay and the flow velocity tended to increase at the mouth of the bay and on topographic features such as capes. There was a positive correlation between the flow velocity and the drift distance of aquaculture facilities, which was especially significant in the affected areas. Even small tsunamis may have a significant impact on the location of aquaculture facilities in the bay.

An appropriate tsunami evacuation behavior is effective in reducing human casualties from tsunamis. One of the ways to promote their behaviors is learning about disaster risk reduction especially preparedness before a disaster occurs. Thus, many elementary schools and junior high schools in Japan have been conducting disaster education programs to learn about disaster risks in their community. In this study, we incorporate interview survey into disaster education program and study the learning effects of interviewing residents who experienced disaster about their experiences at the time of a disaster to be shared for the future. By concentrating on the residents' experiences during the disaster, it is expected that the interviewer will be able to relive the residents' behavior during the disaster. Furthermore, the interviewed residents' experiences of disasters are expected to provide lessons on what actions to take and how to prepare for disasters, and to improve individual disaster preparedness. In addition to learning disaster risk reduction, it is expected that students will acquire abilities necessary for living, such as the ability to understand people's stories and the ability to communicate with others, through interviews. By conducting a questionnaire survey before and after the disaster education and statistically analyzing, we will clarify the effects of the disaster education including interviews on the ability to cope with disasters and on other abilities necessary for students' life.

The U.S. National Oceanic and Atmospheric Administration (NOAA) National Centers for Environmental Information (NCEI) archives analog and high-resolution digital coastal water level data and ocean-bottom pressure data, digitizes select analog data, and performs quality-control and tidal analysis of these data. The analog tide gauge records (marigrams) cover selected tsunami events between 1854 and 1994 observed at stations across the globe. The digital tide gauge data, primarily U.S. stations, have been collected at 1-minute sampling since 2008. The ocean-bottom pressure data have been collected since 1983. These time-series data are complementary to the maximum wave heights recorded in the NCEI/World Data Service Global Historical Tsunami Database. All water level data and products are converted to standardized file formats to reduce barriers to re-use. We provide quality-controlled water level data, computed astronomical tides, details on the harmonic tidal analysis results, and spectra to assess the quality of the de-tiding. Researchers use the quality-controlled data to validate tsunami propagation and storm surge models. In the event of a tsunami, we augment our holdings by collecting and processing data from the National Hydrographic Services in the affected regions and from the United Nations Education, Scientific and Cultural Organization Intergovernmental Oceanographic Commission (UNESCO IOC) Sea Level Stations Monitoring Facility. These data products are then made available via Tsunami Event Pages. This presentation will provide an overview of NCEI's water level data availability and processes.

Effect of water density on wave pressure due to bore-like tsunamis

DOI: 10.57757/IUGG23-4923 - LINK

Naoki Taniguchi[1], *Taro Arikawa*[1], *Riku Takakura*[1], *Enomoto Yota*[1]
[1]*Chuo University, Civil and Environment Engineering, Bunkyo-ku, Japan*

The tsunami caused by the Great East Japan Earthquake of 2011 was called a black tsunami, and it was mixed with sediments, which was observed in many areas. Most of the previous studies on tsunami loading have been based on experimental and numerical calculations using fresh water, and the effects of sediment contamination have rarely been investigated. This study conducted bore-like tsunami pressure experiments with various densities to clarify the mechanism of impulsive wave pressure due to density changes. For validation, numerical calculations were performed on the same model used in the experiment, followed by calculations on local conditions. The average impulsive wave pressures of silt-mixed water, sand-mixed water, and freshwater were compared in terms of the Froude number. Under these conditions, the impulsive wave pressure due to sediment-mixed water was found to be in some cases greater than that with fresh water. The relationship between the water surface angle and wave pressure at impact was also investigated. The results revealed large variations. In silt-mixed water, the impulsive wave pressure tended to increase as the water surface angle at impact increased. Numerical results show that a 4% increase in density results in a 15% increase in maximum wave pressure. Additionally, an increase in the water surface angle was also observed. Numerical calculations performed under local conditions confirmed the increase in wave pressure due to sediment-mixed water. Wave pressure against the wall surface of the sediment mixture tends to increase but can be evaluated by the freshwater wave pressure rating index.

Capability of inversion of dense offshore tsunami measurements to constrain spatio-temporal evolution of tsunami source process

DOI: 10.57757/IUGG23-3548 - LINK

Hiroaki Tsushima[1]
[1]*Meteorological Research Institute- Japan Meteorological Agency, Department of Seismology and Tsunami Research, Tsukuba, Japan*

This study discusses the spatio-temporal evolution of tsunami source process in real-time tsunami forecasting. Previously, we developed a tsunami forecasting method based on the real-time source inversion using offshore tsunami waveforms. In the method, the source process is assumed to finish instantaneously at the time of an earthquake, whereas the source process of actual huge earthquakes is spatio-temporally complex. The offshore tsunami data from the dense seafloor observation networks around Japan may enhance to constrain the spatio-temporal evolution. To design the improved forecasting method that is versatile for tsunamigenic earthquakes with various spatio-temporal source processes, this study conducted synthetic tests of tsunami forecasting, focusing on how well the offshore tsunami waveforms can constrain the time evolution of the source process. Synthetic data for ~170 offshore tsunami-meters along the Japan trench were produced by numerical tsunami simulation assuming the fault model of the 2011 Mw 9.0 Tohoku earthquake. Synthetic tests were conducted under various conditions by independently varying the source duration assumed in production of the synthetic data and the that used in the inversion. The results showed two suggestions for accurate forecasting of coastal tsunami heights. The first suggestion is that it is important to avoid situations that source duration used in the inversion is much shorter than that of the targeted earthquake. The second suggestion is that using a very long source duration for the inversion is effective for both the long- and short-source-duration earthquakes.

This work was partially supported by JSPS KAKENHI Grant Numbers JP21K04621.

Hydraulic Experiments on Sediment Trapping Capacity by Types of Coastal Vegetation in Chiba Pref.

DOI: 10.57757/IUGG23-2205 - LINK

Ako Yamamoto[1], *Yoshinori Shigihara*[1]
[1]*National Defense Academy, Department of Civil and Environmental Engineering, Yokosuka, Japan*

Coastal forests have disaster-prevention effects such as reducing the force of tsunami waves and trapping drifting debris. On the other hand, sediment runoff from the coastal forest floor can cause the forest to driftwood, increasing the damage. The forest floor environment is composed of a wide variety of coastal vegetation. Although these vegetations have the effect of preventing blowing sand, their sediment trapping effect against tsunamis is unknown. The objective of this study is to elucidate the sediment trapping effect of coastal vegetation through hydraulic experiments. The samples were collected from coastal vegetation from the front edge of coastal forests in Chiba Prefecture, Japan.

The vegetation samples were placed in a sand box in a two-dimensional water channel, and waves were generated to measure the amount of sediment transported from the sand box. The generated waves were a bore wave simulating the tip of a tsunami and a steady flow simulating the passage of a tsunami. The water level and velocity in the channel were measured in a fixed-bed experiment. The flow conditions were checked during the experiment by video recording from above and from the side of the sand-bed box.

The results showed that sediment transport decreased with increasing vegetation coverage. In the case of multiple bore wave events, it was suggested that the type of vegetation and the amount of rhizomes may also affect the amount of sediment transport.

Coastal forests have disaster-prevention effects such as reducing the force of tsunami waves and trapping drifting debris. On the other hand, sediment runoff from the coastal forest floor can cause the forest to driftwood, increasing the damage. The forest floor environment is composed of a wide variety of coastal vegetation. Although these vegetations have the effect of preventing blowing sand, their sediment trapping effect against tsunamis is unknown. The objective of this study is to elucidate the sediment trapping effect of coastal vegetation through hydraulic experiments. Children’s awareness and the effects of disaster prevention education: Impact of the great east Japan earthquake tsunami

DOI: 10.57757/IUGG23-1423 - LINK

Mari Yasuda[1], *Ryo Saito*[1], *Toshiaki Muramoto*[1]
[1]*Tohoku University, International Research Institute of Disaster Science, Sendai, Japan*

This study investigated trends in disaster preparedness awareness among elementary school children in Miyagi and Fukushima prefectures. Questionnaire surveys conducted before, immediately after, and one month after the delivery classes revealed regional differences in children's disaster awareness.Compared to coastal areas, inland areas had relatively lower disaster awareness. Children in the coastal area of Fukushima were highly motivated to learn about disaster prevention, and their disaster risk assessment increased even after the on-site class, and remained high one month later, indicating the influence of the earthquake off the coast of Fukushima Prefecture, which occurred frequently from the Great East Japan Earthquake to the present and continued to occur even after the delivery classes. The Miyagi coastal area has a high awareness of evacuation behavior in the event of a disaster, suggesting that the importance of evacuation behavior may be shared within the family due to the many past tsunami disasters. The Fukushima inland area showed a high fear of natural hazards and a tendency to lack confidence in their actions in the event of a disaster, while the Miyagi inland area showed low fear of disasters, assessed low disaster frequency, and showed low interest in family commitments. Finally, this study suggests the factors that influence the effectiveness and sustainability of disaster prevention education for children including the geographical characteristics of the region, past disaster experiences, and the number of local disaster training programs.

Reproduction of tsunami attenuation effects by coastal vegetation using three-dimensional numerical calculations

DOI: 10.57757/IUGG23-2287 - LINK

Mei Yoshida[1], *Taro Arikawa*[1]
[1]*Chuo University, Civil and Environmental Engineering, Bunkyo-ku, Japan*

The tsunami attenuation effect by coastal vegetation, such as mangroves, called green infrastructure, is widely known through field surveys of disasters and has been studied experimentally and numerically. Previous studies have investigated wave attenuation effects using two-dimensional numerical calculations. However, three-dimensional numerical calculations are necessary to model various wave conditions, including surf zones. Moreover, mangrove prop root shapes are complex and require small grid sizes for detailed reproduction. In addition, the resistance calculation depends on the grid size in the previous method, and applying this method to field calculations incurs high computational costs. Therefore, CADMAS-SURF/3D was employed in this study to reproduce and model mangrove forests as porous structures, and the Dupuit-Forchheimer (DF) law, whose resistance calculation is independent of grid size, was used to establish a low-cost numerical modeling method for mangrove forests. The coefficients and , which depend on the constituent materials of the porous structure, were obtained by sensitivity analysis. When =1000 and =1.0, the wave height attenuation effect is replicated with relatively good accuracy, regardless of the grid size resolution, by a calculation process reproducing the physical experiment. The relationship between the mangrove shore width and the attenuation effect was verified by three-dimensional numerical field calculations to confirm the validity and generality of the model. Upon establishment, this modeling method can evaluate the effects by of coastal vegetation on disaster attenuation in detail on a large scale.

We analyze seismic time series collected during experimental campaigns in the area of the David Glacier, South Victoria Land, Antarctica, between 2003 and 2016. We observe hundreds of repeating seismic events, characterized by highly correlated waveforms (cross-correlation > 0.95), which mainly occur in the floating area between the grounding and the floating line of the ice stream. The joint analysis of seismic occurrences and observed local tide measurements shows that seismicity is not triggered by a seasonal, periodic forcing such as the ocean tide, but more likely by transient irregular impulses. We consider possible environmental processes and their impact on the coupling between the glacier flow and the brittle bedrock failure. Our results suggest that clustered and repeated seismic events may be correlated with transient episodes of mass ice discharge (observed by satellite GRACE and GRACE-FO experiments) through the subglacial hydrographic system that originates upstream of the glacier and extends to the grounding zone, lubricating the interface with the bedrock. The GRACE data reveal a mass transfer from the David Glacier catchment area towards the coast which could be consistent with an emptying/refilling of the regional subglacial hydrographic network and the subsequent acceleration of the glacier flow. Basal lubrication conditions are correlated with seismic occurrences that we locate in correspondence with the main flows toward the David Cauldron.

Glacier often generates similar icequakes due to their common seismogenesis. Therefore, finding clusters of icequakes is critical to investigate the mechanisms of ice fracturing and glacier dynamics. We monitored icequakes near the ice-shelf front of Langhovde Glacier in East Antarctica in the summer of 2017/18 and up the grounding line of the glacier in the summer of 2021/22. The hierarchical clustering method was applied to the seismic records, which is based on the correlation coefficient among the icequakes. Seven and six clusters were generated for the seismic records in 2017/18 and 2021/22, respectively. For example, in 2017/18, clusters 1 and 2, with a center frequency of around 10 Hz, coincided with the lowering tide when the horizontal speed of the glacier increased. Clusters 3 and 4, with center frequency ranges from 20 to 50 Hz, coincided with the rising tide when the ice shelf lifted in pace with the tide. Other clusters 5-7, dominated by frequencies higher than 100 Hz, showed a relation with meteorological records. When air temperature dropped below zero, the frequencies of clusters 5 and 7 increased up to 200 events/hour. Noise generation due to high wind speed is expected to cause cluster 6. In the presentation, we will discuss the clustering method, temporal variation of the clustered events and their possible mechanisms.

Questions addressing Arctic change span earthquakes, meteorology, climate, sea ice, glaciers, permafrost, and wildfire. Many change-based research questions require consistent and continuous long-term data. By co-locating a wide variety of geophysical instruments, the Alaska Geophysics Network lends itself to enhancing cross-disciplinary research. Our stations co-locate: a 3-component broadband seismometer (Nanometrics T120PH or Kinemetrics STS-4B/5A); a Vaisala WXT weather station; a MEMS state-of-health barometer; a NCPA infrasound sensor; a SETRA microbarograph; and an Onset HOBO soil temperature profile. The stations were originally part of 192 multi-sensor platforms installed across Alaska between 2014 and 2017 by the USArray seismic project, managed by the Incorporated Research Institutions for Seismology (IRIS) as part of the NSF EarthScope program. These stations vastly expanded the amount of data available in Alaska and marked the first time seismic instruments were installed in some remote locations. Following the commencement of the USArray project, the Alaska Earthquake Center adopted the best-performing stations to become part of our permanent monitoring network. Data collected by the Alaska Geophysics Network can help explore questions related to climate, earthquakes, landslides, glaciers, sea ice, weather, wildfire, and more. All data is available for public use. In this presentation, we show the extent of the network and data and examples of cross-disciplinary cryoseismology findings from the Alaska Earthquake Center using this data.

Iceberg Calving in Greenland: Understanding the Dynamics through Seismic Data Analysis and Machine Learning

DOI: 10.57757/IUGG23-2510 - LINK

Selina Wetter[1], Emilie Pirot[1], Clément Hibert[2], Mangeney Anne[1], Eléonore Stutzmann[1]
[1]Université Paris Cité, Institut de Physique de Globe de Paris, Paris, France

The Greenland ice sheet is a critical component of the global climate system, and its significant mass loss due to iceberg-calving has greatly contributed to sea-level rise.

Through the quantification of the spatio-temporal changes in Greenland's ice mass loss resulting from iceberg calving, we gain a deeper understanding of the impact of climate change.

The mass loss related to calving icebergs can be estimated by combining mechanical simulation of iceberg calving and inversion of seismic data. Indeed, seismic signals are generated by the time-varying force produced during iceberg calving on marine-terminating glacier termini. Those events, known as glacial earthquakes, are recorded by the Greenland Ice Sheet Monitoring Network at tens of km from the source. However, differentiating these signals from tectonic events, anthropogenic noise, and other natural noise is challenging due to their wide frequency range. To overcome this challenge, we use a detection algorithm based on the STA/LTA method and machine learning (Random Forests) trained on catalogues with known events. This algorithm will be applied to continuous data to detect new and possibly smaller events. As a result, we will present a comprehensive catalogue spanning several years and discuss its relevance and reliability. Finally, we will examine the correlations between events in the catalogue and external factors, such as climatic and meteorological events. The catalogue and machine learning approach can be used in the future to extract properties of the source from the generated seismic signals, such as the volume or the shape of the iceberg.

Seasonal oscillations in GNSS time series are a major source of noise for the interpretation of tectonic signals. While some success in isolating the seasonal signals has been demonstrated with Kalman filters and matrix factorization, seasonal signals are still generally difficult to remove, especially for time series with interannually varying amplitudes.
We develop a deep learning model with the aim of predicting seasonal oscillations in GNSS time series from Earth system models describing geophysical fluid loading on the Earth's surface (developed at ESM-GFZ) and that consist of hydrological loading, and non-tidal atmospheric and oceanic loading. For our algorithm, we use globally distributed daily PPP GNSS displacement time series from Nevada Geodetic Laboratory (NGL) and isolate the seasonal displacement signals as our learning targets. We pair each target sample with a sequence of loading grids within a set time window around the sample time and spatially constrain the grids to a small area around the respective station. We test different architectures: a 3D U-Net (also called V-Net) and a time distributed LSTM-2D-ConvNet.
Finally, we evaluate the performance of our model on a hold-out data set not used during training to assess the effectiveness of our deep learning method for removing annual and semi-annual oscillations from GNSS displacement time series. We also demonstrate the effect of removing seasonals on the identification of tectonic transients, using time series from active fault zones.

Deformation in the Cerro Prieto pull apart basin (CP) located between Cerro Prieto and Imperial faults on the Mexican part of San Andreas System was studied for years. Leveling was realized in the basin by different agencies since 60’s, DInSAR analisis and GPS observations were realized many times since 1997. Since the subsidence caused by geothermal water extraction in the Cerro Prieto Geothermal Field affected the faults in the basin subsequently geotechnical instruments were installed for continuous monitoring.

The creep and episodic slip were observed on the basin faults before the 2010 earthquake. When the M7.2 EMC strikes all the geotechnical instruments, installed on the CP faults, recorded displacements triggered by the earthquake. However, the post-seismic behavior of the records varies, and 3 typical behaviors can be distinguished: 1) the creeping has similar magnitude before and after the earthquake, 2) the deformation rate after the earthquake increases and 3) the cessation of creep on the fault for up to 6 years after which the creep reactivated with a magnitude similar to that before the earthquake.

Applying an empirical relationship between magnitude and stress, the accelerometer data and Coulomb 3 modeling, we found that the dynamic stress is responsible for the triggering.

For post-seismic behavior, the Coulomb static stress changes caused by the EMC earthquake, by tectonic stresses and by fluid extraction in the Cerro Prieto geothermal field are analyzed. It can be concluded that the EMC shadow is causing creeping cessation on the faults closest to the epicenter.

Data assimilation (DA) is the technique to combine the observations and physics-based simulations. DA has now been widely adopted in the field of meteorology and oceanology, especially in its practical use such as weather forecast. It has recently been applied to the problem of fault slip estimation. For example, Kano et al. (2020) developed an adjoint DA method and applied to the postseismic crustal deformation data following the 2003 Tokachi-oki earthquake. They assimilated GNSS data for 15 days following the mainshock to optimize frictional properties of the afterslip area, and then examined the short-term predictability of GNSS data for the following 15 days. Hirahara and Nishikiori (2019, hereafter, HN19) proposed Ensemble Kalman Filter method and investigated the feasibility for estimating the fault slips during slow slip events (SSEs) through numerical experiments.

Following these studies, we attempt to assimilate GNSS data including long-term SSE (LSSE) in the Bungo Channel, southwest Japan, occurred during 2009-2011.We used the same fault model as HN19 covering the Bungo Channel LSSE area, consisting of one large circular patch allowing for the occurrence of SSE within the surrounding stable sliding region. By assigning the conditionally stable frictional properties, HN19 reproduced recurrent LSSEs with a similar recurrence interval, duration, and maximum slip velocity observed in the Bungo Channel LSSEs. Assuming these frictional properties as the initial model, we attempt to optimize the frictional properties in the LSSE patch by DA, and discuss the reproducibility and predictability of GNSS data.

Slow-slip events (SSEs), although widely recorded in various convergent margins globally, only recently have been reported in the Eastern Mediterranean, with one of them triggering the 2018 ~M7 Zakynthos Earthquake along the western Hellenic Subduction System (HSS). Here, we explore the distribution, size and duration of SSEs along the HSS and assess their importance in subduction-related strain accumulation and release. To achieve this, we analyse geodetic timeseries from a dense network of permanent GNSS stations on Western Peloponnese, Crete and surrounding islands that collectively span a time-period of ~10 years. We use greedy linear regression techniques to estimate displacement trajectory models for each station and thus we identify transient displacement signals, associated with aseismic processes at depth. To further constrain the spatial extent and size of the SSEs we invert the GNSS transient displacements for variable distributed slip at depth and we, therefore, discuss likely scenarios of aseismic and seismic strain distribution (and partitioning) within the HSS's complex plate-interface zone.

We use greedy linear regression techniques to estimate displacement trajectory models for each station and thus we identify transient displacement signals, associated with aseismic processes at depth. To further constrain the spatial extent and size of the SSEs we invert the GNSS transient displacements for variable distributed slip at depth and we, therefore, discuss likely scenarios of aseismic and seismic strain distribution (and partitioning) within the HSS's complex plate-interface zone.

Interseismic deformation in a plate subduction zone is attributed to not only slip and coupling on the plate boundary but also strain partitioning on overriding plates. The latter is often modeled by rigid motion of small tectonic blocks and slip on their boundary faults. Although many deformation analyses for southwest Japan have revealed spatio-temporal distribution of these phenomena, their interaction and the effect on the total slip budget is a remaining important topic. This is because previous studies individually analyzed different areas and periods using different estimation methods, making us difficult to combine their results. Therefore, we attempt a comprehensive estimation of the spatio-temporal evolution of interplate slip and block motion around southwest Japan based on state space modeling, using GNSS time series for about 25 years. Toward this final goal, we first evaluated separation precision between fault slip and block motion by numerical experiment. We generated synthetic displacement time series for 770 GNSS sites around southwest Japan assuming various contribution ratios for interplate back slip and block motion of the forearc region. Then, we applied the formulation of block modeling suggested by Meade and Loveless (2009) to Kalman filtering. As a result, cumulative back slip on the plate interface always showed underestimation of about 10 to 40 % for known strongly coupled regions beneath the Tonankai and Shikoku regions. Correspondingly, block motion showed slight overestimation. In the presentation, we will discuss the detailed structure and mechanism of the trade-off between unknown parameters through covariance matrix estimated by Kalman filtering.

The relationship between background seismicity rate and strain rate in and around the strain concentration zones in Japan

DOI: 10.57757/IUGG23-2221 - LINK

Taku Ueda[1], Takuya Nishimura[1]
[1]Disaster Prevention Research Institute- Kyoto Univerisity, Research Center for Earthquake Hazards, Uji, Japan

Earthquakes are caused by the stress accumulation in the earth's interior due to the relative plate motion. Therefore, it is considered that the geodetically-estimated strain rate may correlate with seismicity, and this relationship has been discussed in several areas in the world (e.g., Zeng et al., 2018). In this study, we investigate the spatial correlation between the strain rate and the background seismicity for crustal seismicity in Japan.

We applied the Hierarchical Space-Time Epidemic Type Aftershock Sequence (HIST-ETAS) model (e.g., Ogata, 2004) to the M > 3.0 crustal earthquakes (JMA catalog, 1980-2010, depth < 25km). We evaluated background seismicity using the estimated HIST-ETAS parameters and compared it with the strain rate estimated using the GNSS data (1997-1999 and 2006-2009) by Fukahata et al. (2022). The study regions are in and around the four strain concentration zones: the Niigata Kobe Tectonic Zone (NKTZ), the Ou Backbone Range (OBR), the San-in shear zone (SSZ), and the Beppu-Shimabara graben (BSG).

We found spatial variations in background seismicity in and around the NKTZ and the OBR positively correlate with that in the strain rate. No significant correlation was found in and around the SSZ and the BSG. It is possible that the results could be improved by appropriately removing deformations attributed to interplate coupling and non-tectonic local deformations.

Acknowledgements: The JMA catalog was used; the code of Ogata et al. (2021) was used to estimate parameters of the HIST-ETAS model. I thank T. Okazaki for providing strain rate data (Fukahata et al., 2022).

Digital broad-band seismic recordings from station HLG on the small island of Heligoland in the German Bight in the North Sea are available since 2001. Since July 2017, an additional local network of six broad-band seismometers is operational on Heligoland with a focus on investigations of local microseism in the North Sea.
In this study, we combine information gathered by passive seismic registration and gravity measurements from a superconducting gravimeter on Heligoland. We utilize 20 years of passive seismic data for long period spectral investigations spanning periods of tens of seconds up to several years. In the period band between 70 to 100 s, H/V ratios reveal strong noise on the horizontal components occurring contemporaneously with strong storms. In addition, distinct peaks in the spectral data are observed at periods of 6, 12 and 24 hours, which can be related to ocean tides and atmospheric pressure variations that are affecting the amplitude of local microseism. We compare the spectral seismic data with three years of gravity spectra from a collocated superconducting gravimeter. They are highly comparable with the seismic spectra and show distinct differences between local tides in the North Sea and solid Earth tides.
At even longer periods up to several years, the spectral seismic data reveal a strong signal at one year, accompanied by peaks at 0.5, 2, 3 and 8 years. These variations seem to affect mostly the secondary microseism of the Northern Atlantic recorded at station HLG.

As one of the most populous regions, Central Java in Indonesia is prone to high seismic and volcanic hazards, primarily due to the progressive northward subduction of the Australian plate beneath the Sunda plate. Detailed velocity structure of the crust and uppermost mantle beneath Central Java is critical for an improved understanding of the subduction processes and the associated seismicity and volcanism. Despite several independent isotropic velocity models proposed for the region, crustal-scale anisotropic structure, which reflects past and ongoing deformation, has rarely been investigated. Our goal is to image the crustal-scale P-wave azimuthally anisotropic structure beneath Central Java. Seismic data used were recorded by > 200 seismic stations from multiple projects. To make full use of the open access data, machine learning phase picking and subsequent event association and location were applied to build a local earthquake catalog. The machine-learning-based workflow detects > 1000 events, roughly triple the amount from previous manual picking. Notably, the preliminary catalog includes a large number of earthquakes that were located in the offshore areas but were recorded by land stations to the north, resulting in huge back azimuthal gaps and potential bias in earthquake relocation. The ongoing study attempts to involve depth phases, such as sPn and sPg, for more accurate earthquake locations and thus more reliable tomographic images. With the expanded and refined seismicity catalog, a ray-free adjoint-state traveltime tomography package called TomoATT will be used for the 3-D velocity heterogeneity and azimuthal anisotropy beneath Central Java.

Multiscale analysis of the GOCE signal in the subduction zones

DOI: 10.57757/IUGG23-2420 - LINK

Cécilia Cadio[1], *Xavier Vergeron*[1], *Fanny Garel*[1]
[1]*Université de Montpellier - Géosciences Montpellier - CNRS, Géosciences Montpellier, Montpellier, France*

Owing to space gravity missions, unprecedented high-quality data are now available on the entire Earth surface. In particular, the GOCE mission allows the study of features as small as 80 km in subduction systems, often characterized by a sparse spatial coverage of available ground gravity data. Providing unique information on the mass distribution, these data coupled with seismological and topographic measurements can allow a major advance in the characterization of the geometry and thermal structure of the subducting plate which play an essential role in the distribution of seismicity. The analysis of the associated signal will, however, highly depend on our ability to separate the components related to the superficial structures (< 200 km depth) from the ones at depth in the total signal. In this work, we attempt to evaluate the crust and lithosphere contributions at the surface in the GOCE data by calculating the gravity signature (geoid, gravity disturbance and gravity gradients) of synthetic slabs derived from geodynamical models varying lithospheric plate ages and crust characteristics. A continuous wavelet transform (CWT) is then applied to the synthetic and observed signals. Such analysis allows us to unfold their components and finely characterize their local features at different spatial scales. We will show that this approach, combining different gravity signal components and CWT, is particularly well suited to estimate the different signal contributions in the subduction zones, which are characterized by a superimposition of structures on a broad range of scales.

Determination of the seismic structure of the Earth's mantle based on joint analysis of gravimetric and seismometric data

DOI: 10.57757/IUGG23-3564 - LINK

Monika Wilde-Piorko[1], Kamila Karkowska[2], Przemyslaw Dykowski[1], Marcin Sękowski[1], Marcin Polkowski[3]

This study presents a new concept of joint analysis of the gravimetric and seismometric recordings of earthquakes for determining the seismic structure of the Earth's mantle. The proposed method allows using gravimetric data without the known full transfer function of the instrument. Group and phase velocity dispersion curves of the fundamental mode of Rayleigh waves are measured from recordings of superconducting gravimeter and broad-band seismometers operating at the same location, allowing for exploration of a broader response for incoming seismic waves. The analysed sites, the Yebes, Larzac, Wettzell, Pecny and Borowa Góra Observatories, are located along the profile going from central Spain to central Poland and crossing the main tectonic unite of Europe – the Trans-European Suture Zone. Calculated dispersion curves are inverted by the weighted linear inversion and Monte Carlo methods to estimate a distribution of shear-wave seismic velocity in the Earth's mantle. A comparison of the deterministic and probabilistic inversion methods can excellently demonstrate surface waves' ability to determine the Earth's mantle structure.

This work was done within the research project No. 2017/27/B/ST10/01600 financed from the Polish National Science Centre funds.

The electromagnetic signature of the Moldanubian-Saxothuringian boundary

DOI: 10.57757/IUGG23-2502 - [LINK]

The Moldanubian-Saxothuringian boundary is one of the major suture zones within the Variscan orogen. It formed in the Paleozoic during the collision of Laurentia and Gondwana and the two distinct units have been either interpreted as remnants of microcontinents or as a sequence of large-scale nappes. The Moldanubian-Saxothuringian boundary has been studied and identified in exposed parts of the Variscan in the Bohemian Massif and Schwarzwald-Voges area. However, its exact location below Mesozoic cover in other areas is still enigmatic. Due to the lack of outcrop and well data magnetic and gravity data have been utilized in locating this interface in the subsurface.

Previous magnetotelluric experiments have largely concentrated on the Bohemian Massif around the KTB and the Eger Rift. This region has also been the target of seismological investigations. Further south-west in central Bavaria only potential field data and scattered magnetotelluric measurements are currently available. However, even in combination these are not sufficient to clarify the geometry of the suture, the depth extent of boundary faults and other first order parameters. To provide further constraints on this, we collected long-period magnetotelluric measurements across the suspected boundary region. Here we show first results from remote-reference data processing of these new data and how they agree with the inferred resistivity structure from a large-scale 3D resistivity model of Germany.

Detailed imaging of subsurface crustal structures requires inverse modeling from massive amounts of waveform data, including regional and/or local seismic events of lower magnitudes and high frequencies, aspects not conventionally used in Full-Waveform Inversion (FWI). The use of higher frequency signals notably boosts spatial model resolution but increases the computational cost of inversion, affordable only with HPC infrastructures. Preliminary tomographic models for the Eastern Pyrenees region have been constrained through a visco-elastic FWI using seismic data. Three-component recordings were provided by over 120 stations from a high-density seismic deployment. To optimize coverage, in addition to the far-field waveforms from M>4.5 events, data from 23 smaller magnitude earthquakes were included from a temporary broad-band seismic network deployed between September 2019 and November 2020. Moment tensor solutions of these additional seismic data were determined, and the seismograms were bandpass filtered. Through this computationally intensive workflow, multiple iterations resulted in a better fit with the observed seismograms, and point to improved spatial resolution of shallow structures. This contribution, aims to disclose and discuss the difficulties and challenges faced when using relatively high frequency seismic recordings in visco-elastic FWI applications, as well as addressing the benefits of the resulting models. Improved tomographic models could be the basis for more accurate waveform modeling and we hope that they will contribute to improve ground-motion simulations on a regional scale. This research is funded and contributes to the objectives of the Horizon Europe Project DT-GEO: A Digital Twin for GEOphysical extremes (ID 101058129).

Magnetic properties of Precambrian rocks from the Denman Glacier area and the Obruchev Hills

DOI: 10.57757/IUGG23-1629 - LINK

Dmitry Golynsky[1], Nikita Borovkov[1], Alexander Golynsky[1], Hyung Rae Kim[2]
[1]VNIIOkeangeologia, Antarctic Geology, Saint-Petersburg, Russian Federation
[2]Kongju National University, Department of Geoenvironmental Science, Gongju, Korea Democratic People's Republic

This study covered an area on the western side of the Denman Glacier and the Obruchev Hills, where the predominantly granulite-facies metamorphic rocks exposed of rather different composition. They are intruded by a wide variety of plutonic rocks, including a major batholith of syenitic to granitic composition at David Island.

A variety of intrusive rocks (gabbrodiorite, granite-aplite and Bt-granite) of 500 m.a. batholith, exposed at Cape Delay Point, are characterized by high values of magnetic susceptibility $(13\div22)\times10^{-3}$ SI units. However, biotite gabbro has low values. The granosyenites and granodiorites of Hippo Island mainly have high values of magnetic susceptibility $(40\div50)\times10^{-3}$ SI units. The Batholith dyke complex in the area of Cape Kennedy is mainly composed by non-magnetic rocks, with the exception of Bt leucogranite 64×10^{-3} SI units. Also, the aplite of Gilles Island has high values of magnetic susceptibility $(55\div70)\times10^{-3}$ SI units.

The Archean Cape Charcot metamorphic rocks include weakly magnetic paragneisses $(4\div5)\times10^{-3}$ SI units and non-magnetic orthogneisses $\sim0.3\times10^{-3}$ SI units. Metamorphic rocks of the Davis Peninsula basement are characterized by values of $(0.05\div9)\times10^{-3}$ SI units and are represented by Amf-Bt orthogneisses and banded gneisses. Thus, the main sources of anomalies in the studied area are intrusive rocks of batholith, while Archean crystalline basement only forms a common magnetic background. The magnetic rocks of the Obruchev Hills and Cape Jones are represented by (±Px)-Amf-Bt orthogneisses $(30\div90)\times10^{-3}$ SI units, which form the main anomaly magnetic field pattern. Magnetic susceptibility values for Sill-Bt and Grt-Bt paragneisses do not exceed 0.4×10^{-3} SI units.

A dense network of long-period magnetotelluric and magnetovariational data in the period range of 3-16 to 2500-3600s made it possible to explore the geoelectrical structure of the western part of the Ukrainian Shield limited by coordinates 26°-30°E and 48°- 51,7°N. 3D inversion resulted in the creation of spatial models of electrical conductivity for the territory of investigation. The local character of the conductors and their position indicate their connection with recently activated fault zones, their junctions and with metallogeny. The Precambrian age of crystalline rocks of the investigated area refers mainly to the electronic-type graphite-sulphite origin of increased conductivity, however the depth of conductive features, their vertical extent and their link to rejuvenated fault systems may indicate the genetic connection of various minerals and their subsequent precipitation with deep fluid migration. The obtained results correlated with heat flow data are aimed at clarifying the deep structure and linking the geoelectric features of the earth's crust and upper mantle with fault systems and deposits of various natural mineral sources and can serve as evidence of tectonic processes in the studied area.

We study the present-day thermomechanical state of the Alpine Himalayan Collision Zone lithosphere using data-driven modelling, to understand the physics controlling the observed crustal differentiation and the underlying continental dynamics. We found that there exists thermodynamically (internal energy, chemical composition) controlled critical crustal thickness, which is close to the global average of the continental crust. The regions with thickness higher than the critical thickness, i.e. orogenic lithospheres, have higher potential energy acquired from the tectonic forces and are rendered weak by the internal energy from the heat-producing elements, compared to the continental interior lithospheres that have crustal thickness close to the critical crustal thickness. The weaker orogenic lithospheres are deforming in dissipative mode to release the acquired potential energy, which manifests as zones of diffused deformation. Further, we find that the energy dissipation path taken by orogenic lithosphere to either attain critical crustal thickness or not, depends on the feedback between thermal and mechanical relaxation of the lithosphere and the internal energy in the crust. The internal energy stored in the crust from heat-producing elements helps the dissipation of the acquired potential energy to attain the critical crustal thickness.

Southern Indian Shield is a mosaic of several cratonic blocks which include the Western Dharwar cratons (WDC), Eastern Dharwar cratons (EDC), Southern Granulite Terrain (SGT) and Deccan Volcanic Province (DVP). We investigated the shear wave velocity structure of the shield using joint modelling of teleseismic receiver functions and surface wave dispersion data recorded at 56 seismological stations. We analysed the data comprising waveforms of the teleseismic (epicentral distance 30–95º) earthquakes of magnitude >5.5 recorded at broadband seismic station. P-wave Receiver Functions were computed at Gaussian of width 1.0.

We estimated thickness of lithosphere in the DVP, EDC and WDC using the joint modelling of the teleseismic receiver functions and surface wave dispersion data along with teleseismic relative residuals data. The thicknesses of lithosphere are found in range of 210, 160-130 and 125 km beneath the WDC, EDC and DVP, respectively. The variation in lithospheric thickness under these different geological blocks shows different type of tectonic evaluation regime. The lithosphere, under the DVP, is modified due to Deccan volcanic event while in the WDC cratonic root is preserved and prevented from deformation due to its distinct composition. The EDC indicates modification in lithospheric thickness due to evolution of Cuddapah basin.

Three-dimensional potential fields models are being tested in the Brazilian pre-salt region of the Campos Basin, where a noticeable magnetic anomaly with oval outline was identified. The study area is relevant for tests, as 3 abandoned pioneer wells with depths varying between 5500 and 7100m were re-drilled and marked the presence of oil, one of which is a commercial producer. These wells cut through several sedimentary formations of the basin, including shales with intercalations of carbonates and sandstones. Thick layers of salt were crossed, and intercalations of volcanic and carbonates are present below the salt. Oil samples were identified at the top of a volcanic sheet at 7100m depth. Some 3D inversion models of both the magnetic susceptibility distribution and density contrast fit the observed data. To reduce the non-uniqueness of potential field models, inversions were constrained by well logs, geological and other existing geophysical data. Several parameters were considered during the inversion procedure including cell dimensions, data quantity, reference models, assigned uncertainties, depth weighting, wavelet compression of sensitivity matrix, choice of regularization parameter. A Multiphysics approach was found to facilitate the selection of the best models. The results evidenced anomalies of density and magnetic susceptibility associated with the volcanic rocks that display variations laterally and in depth and satisfactorily explains the oval magnetic anomaly.

In early 2023, 25 broadband ocean bottom seismometers (OBSs) were recovered in the northeast Pacific Ocean, about halfway between Hawaii and the North American west coast. These instruments had collected seismic data continuously for nearly 15 months.

The OHANA project is an integrative seismic study to explore the crust, lithosphere and asthenosphere in a 600~km wide region west of the Moonless Mountains. The new data will enhance seismic imaging in a regional as well as in a global context: regionally, the analysis of surface waves and receiver functions as well as surface wave azimuthal anisotropy and shear-wave splitting will provide insight into the seismic structure within the OBS network and mantle deformation fabric of 40-to-50 Myr old Pacific lithosphere. A fundamental question to be addressed is whether this particular area has the signature of a normal plate cooling history or if there is evidence for a previously proposed reheating process, e.g. resulting from small-scale shallow-mantle convection.

Within a global framework, the new surface wave data will profoundly improve current global dispersion maps, allowing researchers to reduce imaging biases caused by trade-offs between lateral isotropic heterogeneity and azimuthal anisotropy that result from uneven data coverage, in the study area as well as far outside of it.

The ONAHA network occupied one of the the long-envisioned locations of the Pacific Array and thereby contributes to this larger international community initiative.

The Triassic collision between the North China Craton (NCC) and Yangtze Craton (YC) created the world's largest ultrahigh-pressure (UHP) metamorphic belt (the Dabie-Sulu Orogen). Although abundant in the associated geologic records, geophysical fingerprints from oceanic subduction to continental collision and deep subduction remain largely unveiled. In 2019, broadband and long-period magnetotelluric (MT) data were collected along two parallel profiles that extend from the Subei Basin in YC, across the Sulu Orogenic Belt (SOB), and onto the eastern NCC. These data, together with available legacy MT data throughout the region, were inverted using a regularized nonlinear inversion algorithm to produce a three-dimensional electrical resistivity model. The model reveals three prominent features in the crust and upper mantle: (1) A highly resistive column extends from the surface to a depth of >100 km directly beneath the SOB, with a width closely matches the outcrop width of the UHP metamorphic rocks; (2) A narrow, elongated crustal conductor at 25–40 km depth that lies along the western edge of the SOB, which we interpreted as graphite/sulfide that was emplaced into the crust during the orogeny; and (3) A broad zone (~200 km wide) of enhanced conductivity that is centered in the middle-lower crust to upper mantle beneath the rifted eastern NCC, which is likely associated with partial melting of volatile-bearing peridotite formed by subduction-related metasomatism. These observations provide insights into the assembly of the NCC and YC, and demonstrate the promise of using the MT method to study ancient subduction/collision activities.

The role of inheritance and kinematics in shaping the West Antarctica Rift System (WARS): A parametric study

DOI: 10.57757/IUGG23-2599 - LINK

Alberto Pastorutti[1], Magdala Tesauro[1], Carla Braitenberg[1], Florence Colleoni[2], Laura De Santis[2], Martina Busetti[2]

[2]National Institute of Oceanography and Applied Geophysics, Sgonico, Italy

Extensional tectonics in continental settings usually results in lithospheric stretching of narrow (e.g. Upper Rhine Graben), as well as wide regions (e.g. Basin and Range). Some rift systems bear evidence of a transition between the two styles: the West Antarctica Rift System (WARS) have likely progressed from diffuse to focused rifting (Cretaceous - Middle Neogene). The system currently covers a length of 1000 km, at the boundary between East and West Antarctica and is composed of four main basins (Victoria Land Basin, Central Trough, Northern Basin and Eastern Basin). The deformation pattern and available geological reconstructions suggest that, at least for some part of the rifting, the extension occurred concurrently in multiple sections.

Inheritance of prior structural, thermal, and rheological heterogeneities is likely a controlling factor in this evolution [1]. Consequently, with the goal of identifying the most likely initial conditions, we designed a series of 2-D numerical models, analysing the effect of variations in the temperature field, rheology, accumulated strain, distribution of extensional pulses on the basins' geometry. To this aim, we used the open source Underworld2 [2] and BGR-02 and ACRUP2 profiles [3], as 2-D analogue of the WARS structures in the Southern Ross Sea.

The results show that the models most consistent with the observations are those that include inherited weakness zones at the cratonic boundary. Early onset of focused extension often occurs, with high sensitivity to the pattern of inherited weakening.

Effective elastic thickness over North East India and the Bay of Bengal using joint analysis of gravity and topography data

DOI: 10.57757/IUGG23-3107 - LINK

Priyank Pathak[1], Prakash Kumar[1], William Kumar Mohanty[1]
[1]Indian Institute of Technology- Kharagpur - West Bengal-721302- India, Department of Geology & Geophysics, Kharagpur, India

The geodynamic structure of the continental Northeast India (NEI) is shaped by the collision of the Indian and the Eurasian plate in the north and subduction of the Indian plate underneath the Burmese plate in the eastward direction. The oceanic lithosphere of the Bay of Bengal (BOB) is evolved due to rifting of India and Antarctica, has been mainly affected by two aseismic ridges emplacement: Ninetyeast and 85° ridges. Effective elastic thickness (Te) of the lithosphere is an important parameter for mechanical strength which provides information about the rheology of the deformation and evolution of the lithosphere. In this study region, we have calculated Te, by applying joint inversion of the real admittance and coherency between topographic and gravity anomaly data by using PlateFlex software. Load ratio (F) has also been determined to understand the mass distribution of surface and subsurface, where low F (< 0.2) in the Northeast India and the northernmost part of BOB represent surface loads is dominated in comparison to subsurface loads, while high F in the BOB region is dominated by subsurface loading. The spatial variation of Te varies ranging between 3–55 km. Low values of Te (9–16 km) over the 85° ridge correspond mainly to high thermal structure and weak lithosphere strength while slightly high in the activated Shillong Plateau (Te ~ 30 km) which indicates high seismic activity. High Te > 40 km in the Northeastern part of the Indian shield correlates mainly with low heat flow shows strong lithospheric strength.

The Archean cratons are the key to understand the crust formation, the early Earth geodynamics, and the subsequent transition to the present-day plate tectonics. Dharwar craton is a granite-gneiss-greenstone terrain, situated in the south India bounded by Deccan traps, Southern Granulite Terrain (SGT), Eastern Ghat Mobile Belts (EGMB) and Arabian Sea in north, south, east, and west respectively. The subduction-accretion (plate tectonic) models and plume-plate tectonic mixed models are proposed by various authors for the crustal evolution of the Dharwar craton. In this study, we present the 3D inversion results of magnetotelluric (MT) data from the Dharwar craton using the long period MT (LMT) measurements. The LMT data is acquired in a 3D grid fashion, covering the entire Dharwar craton. This study delivers the lateral and vertical variations in electrical resistivity of the Dharwar subsurface. The crust beneath the Dharwar craton is highly resistive in nature with few conductive zones. The conductive zones in the crust subsequently join with the upper mantle which is observed as a broad and interconnected conductive zone. Highly resistive segments that extend to the upper mantle indicates the locations of preserved lithosphere in the Dharwar craton. An anomalous conductive body is seen in the upper mantle in the north-western part of the craton. Its relations to the evolution of Dharwar craton will be discussed.

Deformation in the continental interior, far from tectonic plate boundaries, is not fully understood. Due to its location, Mongolia is a prime natural laboratory for studying effects such as intracontinental deformation and intraplate volcanism. A previous regional magnetotelluric (MT) study, including three (2016-2018) field campaigns, identified a localized asthenospheric upwelling with a correspondingly thin lithosphere underneath the Hangai Dome (Central Mongolia).

Compared with Central Mongolia, Eastern Mongolia is less studied with geophysical methods; consequently, its underlying lithospheric and asthenospheric properties are less constrained. At the same time, this region is of economic and scientific interest, as it hosts several mineral zones and relevant geological features, such as the Mongolia-Okhotsk suture zone. Furthermore, it is unknown to what extent the identified electrical conductivity anomalies in Central Mongolia extend to the east and how the crust and mantle differ in this region.

This work presents the first results of a new MT field study covering Central-Eastern Mongolia. 64 broadband MT stations were deployed between 2020 and 2022 along five profiles east of the Hangai. The data were processed using a two-step multi-taper processing approach, simultaneously improving the quality at short and long periods, providing credible MT responses up to 2048 seconds. The previously acquired and new data were jointly inverted regarding 3-D conductivity variations. Furthermore, data from an 880 km long 2-D profile extending from the Selenga Basin to Gobi Desert were inverted independently. This study is part of a broader project aiming to constrain the electrical conductivity of entire Mongolia.

In the framework of the Pannon LitH_2Oscope Lendület project in Hungary, we investigated the lithosphere structure of the Pannonian Basin. Besides seismological and geochemical methods, a large-scale grid of MT stations was used for an in-depth investigation of the sedimentary basins. The aim of the group is to explain how the thinner-than-average continental lithosphere could have formed and what is the role of fluids. The theory that discusses the effect of fluids on the melting relations and rheology of the lithosphere and upper mantle is called the pargasosphere hypothesis. For the MT part of the study, aimed at imaging the well conductive layer at the base of the lithosphere, 38 soundings were implemented close to the broad-band seismological stations, achieving a nearly uniform MT coverage in the Pannonian Basin.

Our goal was to achieve as accurate as possible mapping of the lithosphere-asthenosphere boundary (LAB) from the MT data. In the MT modeling and inversion, we have considered resistivity profiles calculated from geochemical data, providing an estimate for the rock compositions and fluid contents assumed to be present in the lower crust and upper mantle. Therefore, MT modeling provides a simple approach to test these geochemical assumptions. Furthermore, the new MT data were also suitable for mapping the resistivity distribution of the deep structure of the Pannonian Basin more accurately than ever before. In the 1D and 3D MT modeling, we also incorporated some available a priori datasets into the models. In this work, we present some selected preliminary MT results.

Understanding the arc parallel variation on the geometry of the Main Himalayan Thrust (MHT) is as much important as the arc perpendicular variation in the collision tectonics such as Himalayas. Geometrical variation of the MHT has a significant role on the occurrence of major/great earthquake. The lateral variation in the geometry of the MHT beneath the north-western Himalayas is studied to understand the crustal structure from the magnetotelluric (MT) 3D forward modelling. We computed MT impedance tensors from 3D forward modelling algorithm MTD3FWD, which computes magnetic and electric fields at the surface of a 3D electrical resistivity model illuminated by electromagnetic plane waves. The previous resistivity and velocity models in different sectors of the north-western Himalayas are utilized as inputs to create a 3D model. The mapped MHT shows a lateral ramp on the Garhwal and Kumaun sectors of north-western Himalayas. The crustal structure of this region has segmented by nearly vertical resistive and conductive tectonic features beneath the Himachal and Garhwal-Kumaun region. These tectonic features are interpreted as the continuation of Delhi Haridwar Ridge and Great Boundary fault, respectively. These subsurface structures plays major role on controlling ongoing seismicity in this region.

We attempted a comparison of the crustal electrical conductivity structure deduced by two-dimensional (2-D) and three-dimensional (3-D) magnetotelluric inversion for data obtained at 19 stations spanning a profile length of about 150 km. Station spacing is 10-15 km. A non-linear conjugate gradient scheme is used for 2-D inversion for both apparent resistivity and phase. Several conductive features are mapped in the 2-D model. This study shows the upper crust is highly resistive (>10,000 ohm-m) all along the profile. It suggests the presence of the tonalite-trondhjemite-granodiorite (TTG) crust. The conductor mapped on the NW part of the profile is considered a deep-seated fault representing a boundary or a rift-related feature beneath the Deccan Volcanic Province and the western Dharwar craton. This conducting feature can be interpreted as an extension of the Kaladgi basin further west. On the central and SE sides of the profile, the mid-crust shows a highly resistive nature. The sensitivity analyses confirm the robustness of the conductive features obtained in the 2-D models. 3-D inversion was carried out by ModEM code with data of the diagonal and off-diagonal components. 2-D and 3-D resistivity models are compared. Finally, the electrical resistivity nature of the crust is compared with other shield and rift regions of the world.

In this study, we use P wave receiver functions from teleseismic events recorded at 24 permanent stations in the Corinth Rift and the surrounding regions to determine the crustal structures (thickness and Vp/Vs ratio) and the African slab geometry. Stations are operated by the National Network of Greece and are equipped with broadband seismometers. We selected events recorded between 2011 and 2021 with magnitude > 6.0 and epicentral distances between 30 and 95 degrees. We computed the receiver functions for each station using iterative time deconvolution and used Zhu and Kanamori's stacking method (2000) to estimate crustal thickness and Vp/Vs ratio. The results show that Moho depth varies from 28 km (Eastern Corinth rift) to 45 km in the western studied area. The deeper Moho values are correlated with the Hellenides mountain range (western part) and an isostatic behaviour. Some stations at the eastern Corinth rift (LOUT, LTK, PROD, KLV, GUR, VILL) display a clear signature from the subducting African crust, allowing for a better estimate of its thickness variation and lateral geometry changes. Arrival times and polarities of P to S converted waves at dipping structures are sensitive to the incident angle of the teleseismic P wave. For stations having good azimuthal coverage, the geometry (dip direction and dip value) of the slab crust and/or of the Aegean Moho beneath the stations will thus be inferred by inversion of the data through a grid search.

Gravimetric signature of subduction zones deep thermal structures.

DOI: 10.57757/IUGG23-1939 - LINK

Xavier Vergeron[1], Cadio Cécilia[1], Garel Fanny[1]
[1]Geosciences Montpellier CNRS - Université de Montpellier, Géosciences Montpellier, Montpellier, France

At subduction zones, cold lithospheric plates dive deep into the hotter Earth's mantle. Earthquakes can occur at depths of hundreds of kilometers in these cold subducted slabs, apparently related to their thermal structures. Seismic tomography provides a first-order information on slab morphology but cannot discriminate « cold » from « warm » slabs due to the inhomogeneous repartition of seismic sources and surface sensors. This study investigates the potential of the gravity data from the GOCE mission to infer slabs' inner thermal structures. Deep thermal structures (> 200 km depth) are derived from dynamic subduction zones models or from simplified analytical structures (ellipsoidal shape). Our parametric study considers various dip angles, morphologies, slab core temperatures, radial and axial thermal gradients. We convert temperature field into density and use the freeware DynG3 (Cadio et al. 2011) to predict surface and CMB deflections due to slab dynamic sinking, depending on the radial mantle viscosity, and calculate the corresponding synthetic signals (geoid, gravity disturbance, gravity gradients). As expected, they are sensitive to density anomalies at different depth ranges. Geoid anomalies reflect deep anomalies (> 600 km depth), whereas gradiometric anomalies mostly represent anomalies in the upper mantle. We also perform a sensitivity study of gravimetic signals for the same realistic slab morphology (e.g. piled, deflected) exhibiting various slab core temperatures. Variations between different inner thermal structures are greater than the detection threshold of the GOCE sensors. These preliminary results are encouraging to later infer subduction zones deep thermal structures from GOCE data.

The Northern Zagros orogenic belt tectonics examined by Magnetotellurics

DOI: 10.57757/IUGG23-5031 - LINK

Sharare Zhian[1], Andreas Junge[1], Oskooi Behrooz[2]

[2]University of Tehran, Department of Geomagnetism, Tehran, Iran Islamic Republic of

The collision of the Arabian and Eurasian plates during the early Miocene resulted in the formation of the Zagros mountain belt, which extends from northwest to southeast across the western half of Iran. This area is of significant geological and tectonic interest due to its complex history and ongoing deformation. Recently, Magnetotelluric (MT) data has been collected along two 400 km profiles in the northern part of the Zagros belt to create the first image of the area's electrical conductivity distribution and to gain insight into how the collision between the two plates is accommodated within the lithosphere and upper asthenosphere. The MT data, measured at 22 long-period sites, was processed using a robust processing technique based on the eigenvalue decomposition method by Egbert (1997) to obtain estimates of the electrical resistivity structure beneath the study area. The phase tensor inversion results indicate the presence of a well-conducting zone at a depth of about 100 km, which may indicate the presence of the asthenosphere. Additionally, the inversion reveals a mid-crustal layer with low resistivity increasing beneath the Arabian plate and probably correlating with the locations of seismic low velocity zones in that region. The result coming from the sites close to the plate's suture shows complications and is probably biased by 3D phenomena. Therefore, the existing 2D studies will be followed by 3D investigations to obtain a meaningful subsurface model of electrical conductivity.

After almost 50 years of quiescence, the Cumbre Vieja rift in La Palma underwent a reactivation process that culminated in a volcanic eruption from September 19 to December 13, 2021, preceded by a seismic swarm that started just eight days before the eruption onset. Seismic unrest started in October 2017 and comprised ten seismic swarms in five years, with the last one in August 2021. In July 2021, a magnetic station (CFU) was deployed in Cumbre Vieja, 2 km away from the site where the eruptive vents would open two months later. In September 2021, a second magnetic station (SAN) was installed near the southern end of the Cumbre Vieja rift. Both stations are still in operation today and acquire the total geomagnetic field intensity (F) with a sampling rate of 1 measurement/minute with two Overhauser magnetometers. In this work, we present the results of the analysis of these geomagnetic time series, which led to the identification of several signals of presumed volcanomagnetic origin. Our data revealed a magnetic signal at CFU station with an amplitude of 10 nT and a duration of 10 days by mid-August, one month before the eruption onset. During the eruption, the SAN magnetic station registered a magnetic signal with an amplitude of 17 nT in the second half of October. We analysed possible correlations with other physical parameters and concluded that these signals are the result of changes in the magnetization of rocks beneath the volcanic edifice related with volcanic activity.

To better understand the shallow structure of El Hierro island, we determined a 3D S-wave velocity model using Ambient Noise Tomography (ANT). We exploited a dataset recorded by 21 broadband seismic stations deployed at El Hierro island in two surveys realized in 2015 and 2021. This dataset allowed us to obtain empirical Green's functions by cross-correlating seismic ambient noise signals and retrieving 105 dispersion curves using the frequency-time analysis (FTAN). Then we obtained 2-D Rayleigh wave group velocity maps for periods between 0.6 s and 2.6 s through a non-linear multiscale inversion (Cabrera-Pérez et al, 2021). Finally, we performed depth inversion through a Bayesian transdimensional approach to obtain a 3-D S-wave velocity model. The obtained ANT model is merged with a local earthquake tomography model (García-Yeguas et al, 2014). Our study highlights six relevant seismic velocity anomalies. We observed the presence of three high-velocity zones located in the eastern, western and northern parts of the island, which could be related to intrusive bodies possibly associated with the formation of El Hierro island. We also observed three low-velocity anomalies in the northern and southern parts. The anomaly in the North of the island could be related to loose deposits generated by the El Golfo valley megalandslide. The anomalies in the South could be related to porous and highly fractured materials produced during the more recent volcanic episodes.

Hydrothermal alteration of volcanic rocks is considered a driving factor in volcano instability by altering their strength and permeability. La Fossa of Vulcano Island (Italy), the most southern exposure of the Aeolian volcanic archipelago, is known for its intermittent hydrothermal activity, fumarole locations and volcanic unrest. Here we explore if events such as the 1988 landslide on the northeastern flank, causing a small-scale tsunami, may be facilitated by hydrothermal activity. Due to La Fossa's location, accessibility, altered flanks and periods of escalating fumarole activity, such as the most recent 2021 crisis, La Fossa acts as a great natural laboratory to monitor and observe the effects of hydrothermal alteration. We used remote sensing methods and field-based rock physical property measurements to assess areas that preserve different degrees of hydrothermal alteration. In detail, we (1) acquired close-range photogrammetric data using unmanned aerial surveys and performed a structure-from-motion and classification approach to map alteration areas and (2) performed field-based measurements to provide estimations of rock strength and permeability of the variably altered rocks. Correlating our observations allows us to explore the link between alteration and strength, and therewith between hydrothermal activity and flank instability.

Geomagnetic variations associated with the unrest in 2014 and 2018 at the Kusatsu-Shirane Volcano

DOI: 10.57757/IUGG23-2679 - LINK

Geomagnetic field measurements at active volcanoes have been performed to investigate the thermal state within the shallow volcanic edifice. At the Kusatsu-Shirane Volcano, repeated and continuous observations around the Yugama crater lake have been conducted by the Kakioka Magnetic Observatory of the Japan Meteorological Agency since the 1970s. The geomagnetic variations up to 2012 obtained from these observations and their causes were reviewed by Takahashi and Fujii (2014). In this study, we introduce the continuous observations of geomagnetic total intensity conducted since 2010 by the Tokyo Institute of Technology and the observed geomagnetic changes. Since observations began, distinct changes probably attributed to the thermal demagnetization of rocks within the volcanic edifice have been identified twice, associated with the unrest in 2014 and 2018. The features of these variations were summarized, and the locations of the magnetic sources were estimated using simple model calculations. The magnetic dipole source that explains the geomagnetic changes observed during the 2014 unrest was estimated to be deep, which is below the pressure source that explains the tilt change during the same period. However, the dipole source for the geomagnetic changes indicating a demagnetizing trend observed in synchronization with the earthquake swarm activity in April 2018 was found to be located beneath the southeastern rim of the Yugama crater lake, which had never previously been estimated. All these sources are located beneath the highly conductive layer inferred near the surface and are thought to be related to the ascent and accumulation of hydrothermal fluids.

The magnetic dipole source that explains the geomagnetic changes observed during the 2014 unrest was estimated to be deep, which is below the pressure source that explains the tilt change during the same period. However, the dipole source for the geomagnetic changes indicating a demagnetizing trend observed in synchronization with the earthquake swarm activity in April 2018 was found to be located beneath the southeastern rim of the

Yugama crater lake, which had never previously been estimated. All these sources are located beneath the highly conductive layer inferred near the surface and are thought to be related to the ascent and accumulation of hydrothermal fluids.

Kusatsu-Shirane volcano is a famous active volcano in Japan. The volcano has an active crater lake, Yugama, having subaqueous fumaroles. Yugama is a vital observation object in the chemical monitoring of the volcano. The Yugama water contains polythionate occasionally, and the variation in their concentrations probably connects to the volcano's activity.

During the past half-century, the volcano went through three phreatic eruption activities in 1976, 1982/1983, and 2018. In this study, we constructed precise time-series data for the contents of dissolved components in Yugama since the 1960s. We then discussed the variation in the contents of sulfur species in Yugama and its relation to those of the other dissolved components and the volcanic activity of the volcano.

Even during the unrest period that did not lead to eruptions, changes in the dissolved composition of Yugama were observed. When volcanic activity increases, the dissolved contents of fluoride, chloride, and sulfur oxyanions (sulfate and polythionate) increase. Although the content ratio of chloride to sulfate did not change significantly, those of polythionate to chloride and polythionate to total sulfur species increased significantly. However, the details of the variability vary from active period to active period.

The polythionate content in Yugama water varied synchronized with the ORP value, probably reflecting the SO_2/H_2S ratio in volcanic gasses supplied from subaqueous fumaroles into the lake water. The higher SO_2/H_2S ratio in the gasses might induce the production of polythionate in the shallow hydrothermal system and stabilize them in the lake water.

Miyakejima volcano experienced its latest eruption in 2000 with the summit subsidence, and the next event is expected in the near future. An aeromagnetic survey in Miyakejima was conducted in March 2021 in order to investigate the current state of its magnetization structure to identify the potential for another eruption and, thus, mitigate volcanic disaster. The survey flight was conducted using an uncrewed aerial vehicle (UAV), a multirotor drone, to deploy a scalar magnetometer. After processing geomagnetic field data from this survey, in combination with data from previous surveys conducted by using another UAV, an uncrewed helicopter, the average magnetization intensity was determined to be 12.4 A/m. Further, the surrounding area of the crater was relatively highly magnetized; however, the crater rim had a low magnetization intensity. Temporal variation was detected between 2014 and 2021 and dominated the central part of the observation area. Decreased magnetization intensity was identified beneath the caldera, which may become recently demagnetized due to heat supply traveling through fractures in the impermeable layer from the deep heat reservoir.

Telica volcano is a persistently restless volcano with activity expressed as long-lived high-temperature fumaroles and magmatic degassing, high rates of background seismicity and frequent phreatic to phreatomagmatic eruptions. Two decades of geophysical, geochemical, and geologic observations indicate: 1) long-lived fumaroles cause hydrothermal alteration and collapse of crater walls, and deposition of debris in the crater; 2) decreases in gas flux, fumarole temperatures, remotely sensed thermal anomalies, and low-frequency seismicity prior to explosions and eruption of hydrothermal minerals and alteration products indicate sealing of the shallow hydrothermal system and conduit; and 3) eruption of a lava dome and ballistic blocks indicate viscous basaltic andesite magma in the conduit. Deposition of crater wall debris may seal the system at a shallow level but does not affect the deeper magmatic – hydrothermal system. Whereas the partial to complete sealing of the volcanic conduit occurs through the deposition of hydrothermal minerals, and the slow migration of viscous magma. These processes move the volcano from an open to a closed system, resulting in phreatic to phreatomagmatic explosions. We developed a numerical model to investigate near-field surface deformation measured by cGPS. Our model incorporates changes in permeability of the conduit due to mineralization, the accumulation of gas beneath the seal, and subsequent increase in pressure of the system driving surface deformation. Increase in pressure leads to failure of the seal and explosions. Improving our knowledge of this transition from an open to closed system is important for forecasting explosive activity at Telica and similar volcanic systems.

Institute of Hydrogeology- Engineering Geology and Applied Geophysics- Faculty of Science, prague, Czech Republic

Fagradalsfjall is located in the central part of the Reykjanes Peninsula in Iceland. The last eruptions occurred about 7000 years ago, but the Reykjanes Peninsula is seismically active and is episodically hit by large earthquake swarms every 20 to 40 years. This paper, examines the 2021 Fagradalsfjall swarm, which began with a 5.3 magnitude ML earthquake on 24 February and continued for about a month before ending with an eruption on March 19. This swarm was a continuation of the July 2017 (ML < 3.7), December 2019 (ML < 3,7) and July 2020 (ML < 5) in this region, all recorded by 15 stations of the local Reykjanet seismic network. Analyzing the spatiotemporal evolution of the 2021 Fagradalsfjall swarm, we can see that the seismicity originated from the northern part, then moved southward, and finally rebounded to the central part where the eruption occurred. We use the robust double-difference Wadati method to measure in-situ Vp/Vs as a tool to track the presence of magma in different temporal and spatial intervals. The entire dataset consists of 38500 events, which reduces to about 9000 after being relocated by HypoDD and GrowClust and applying some preprocessing constraints to remove outliers such as cross-correlation above 0.85 and phase arrivals at least 8 stations. Furthermore, we limit the Vp/Vs ratio in each event pair between 0.5 and 3 for a better result. Our results are compared with those obtained by application of this method on different earthquake swarms.

Numerical simulation is a useful technique for studying the complex behavior of volcanic hydrothermal systems. Most previous simulations have used highly simplified structures, and few studies have considered the natural heterogeneity of the permeability distribution which significantly affects fluid flow within volcanoes. This is mainly because it is difficult to estimate the subsurface permeability structure. In this study, as a first step towards establishing a comprehensive scheme for constructing a realistic permeability structure, we attempted to numerically reproduce the steady-state hydrothermal system of a volcano using a rough permeability structure based on the three-dimensional resistivity structure. The volcano studied was the Kusatsu-Shirane Volcano (KSV) in central Japan. Several scenarios with different permeability structures were prepared to determine what structures significantly affect hydrothermal flow. In each scenario, saline fluids were injected from the bottom of the domain to simulate hydrothermal circulation within the volcanic edifice. In all scenarios, the fluid that ascended to around the summit area flowed down toward the eastern and western foot of the volcano and discharged mainly along the valleys, reproducing the actual distribution of hot springs around KSV. However, the observed discharge rates were reproduced only when a seal zone surrounding the conduit and low-permeability basement rocks were assumed. Although the constructed permeability structure was relatively simple, the simulation results that considered interpretations of the resistivity model closely reproduced several observed data. This suggests that incorporating information on the resistivity structure can significantly reduce the uncertainty of the hydrothermal fluid flow simulations.

In December 2018, the Anak Krakatau volcano was destroyed in a cascade of eruptions following a flank destabilization. A tsunami triggered by these events devastated coastal areas and caused loss of lives, highlighting the importance of better understanding destabilization processes and possible structural weaknesses. Satellite remote sensing data provided by Planet Labs, Pleiades, and TerraSAR-X allow us to monitor volcanic evolution stages at high temporal resolution and to catalog events for the period 2018-2023. We aim to identify possible zones of structural weakness in the newly forming volcanic building, that may pose risks in future development, by focusing on activity patterns like surface degassing and sealing processes. Posteruptive degassing, observed in the crater lake and on the western shore of the island highlights an off-centered activity. Several periods of coverage and reoccurrence of the surficial degassing pattern by tephra and ashes are observed until June 2020, when a lava flow largely covered and effectively sealed the open degassing surface. A second lava flow covers all of the original open degassing surfaces and degassing now exclusively occurs on the eastern margin of the new lava flow. The alternate layering of tephra and lava flows, acting as inclined sealing planes, indicates the possibility of a critical evolution where pressurization and hydrothermal alteration effects of the lateral gas flow might create future zones of structural weakness. We suggest a close monitoring and cataloging of Krakatau's structural evolution, and investigation of the gas-rock interactions to assess their potential to create future sliding planes.

The volcanic alteration zone at a depth of several hundred meters below the surface is a key feature to assess the degree of the imminence of phreatic eruption; Recent magnetotelluric images indicate that the conductive alteration zone prevents hypocenters of volcanic earthquakes from reaching the surface（Tsukamoto et al., 2018; Tseng et al., 2020; Gresse et al., 2021). A phreatic eruption could occur, when the hypocenters pass through the conducting layer. To approach the surface alteration zone and demagnetized area in the active volcanic edifice, a total intensity aeromagnetic survey using an unmanned aerial vehicle was carried out in 1×2.5 km over Oana Crater, with now on active fumaroles inside, of Mt. Azuma, NE Japan.

The original magnetic anomaly distribution was obtained using Nakatsuka and Okuma (2006) with correcting the main field (IGRF-13) and the diurnal variations. The average magnetization intensity (AMI) was 2.06 A/m estimated by a statistical correlation method (Grauch 1987). After subtracting the contribution of the average magnetization from the original magnetic anomaly, the resultant magnetic anomaly data were inverted into a three-dimensional subsurface magnetization perturbation from AMI using the effective source volume minimization method (Nakatsuka and Okuma, 2014). The result shows a weakly magnetized region below the Tsubakurozawa Crater, where the past eruption occurred in 1893, 1896, juxtaposed with Oana Crater. The weakly magnetized location coincides with the demagnetization source location modeled by using the repeating total magnetic intensity observations (Japan Meteorological Agency, 2020).

At the end of the summer 2021, an increase in CO2 emissions at Vulcano brought to an increase in the alert level and, as a consequence, to the upgrade of the monitoring activities by increasing the number of instruments deployed and the rate of the surveys. One of the new devices installed was a geodetic GNSS mobile network for a Real-Time and High-Frequency monitoring of ground deformation, to increase the detail with respect to the existing permanent network. The mobile stations were initially installed at the northern base of the La Fossa crater, where the highest values of soil degassing were recorded. Two stations were co-located with gravimeters, in order to compare and integrate the data. Afterwards, the mobile GNSS array has been re-configured, to investigate the mud pool area. Thus, four stations were installed around the degassing area, one of them being in the same site of the gravimeter. Data has been acquired at 1 Hz rate and are used for the weekly reporting to Civil Protection. It was the first experience of a RT and HF GNSS mobile network in this area and it was the occasion for testing its performance, as well as different approaches for the RTK positioning in order to find the most suitable for the ongoing phenomena. Furthermore, direct data communication and archiving in the institutional database have been implemented for immediate querying from the control room tools. We report the experiences collected during the installation phase, site selection, RTK approaches and ground motion.

During any emergency response, the real-time GNSS data analysis strategies based on differential approach (i.e. Real Time Kinematic) needs some crucial a-priori information on the reference stations.
In addition to their location in an undeformed area, this choice can be also influenced by other parameters (RMS of the time series, battery voltages, transmission on/off, number of visible satellites, etc.). For this reason, we developed an intelligent homemade algorithm BC-RTK (Base Choice - RTK) able to choose the more reliable baselines to potentially provide the best RTK results, it defines stations' priority to the real-time GNSS analysis whose results are stored in a time-series database.
This algorithm is a part of a software, called GNSS-RTT(Global Navigation Satellite System - Real Time Tracker), developed in 2022/2023. It is an open source software that can be either connected to different GNSS receivers through a different type of connection (Tcp/ip, Ntrip, etc.) or linked to a Ntrip Caster. For the solutions, it is able to get the data in different formats (NMEA, LLH,XYZ, etc.) and at different sampling frequencies up to 200 Hz. The data is stored in an optimized database called InfluxDB(https://www.influxdata.com) for real-time and IoT applications. It was developed to manage the data efficiently, allowing both real-time and post-processed visualization. The visualization is performed by means of web applications, such as Grafana (https://grafana.com) or Chronograf (https://www.influxdata.com/time-series-platform/chronograf).

We will describe the technical aspects relating to the presented software and some preliminary results in test cases.

The seismicity of the South Western part of Romania is linked to tectonic deformation being the result of the dextral movements at the contact between the Carpathians Orogen and Moesian Platform. The most notable active faults in this region are the Oravita-Moldova Noua Fault and Cerna-Jiu Fault. The crustal structure of this region was investigated through classical and modern techniques such as refraction and reflection profiling, seismic tomography, joint inversion of dispersion curves, and receiver functions. Targu-Jiu region was characterized before 2023 by sporadic small to moderate earthquakes. A well-investigated seismic sequence was produced in 2011-2012. The recent double-shock occurred in the area in February 2023 (5.2 and 5.7 ML) and was followed by more than 700 aftershocks. In order to estimate an improved 1-D velocity model for this active region, we extracted from the Romanian earthquake bulletins 170 events, recorded by Romanian Seismic Network. The events were selected based on the following criteria: a minimum of 20 recorded phases for each individual earthquake, the RMS location of less than 1 second, and a maximum azimuthal gap of 180 degrees. The region's velocity model and station corrections were accurately determined by minimizing the misfit between the model predictions and arrival times. The VELEST algorithm was run on the selected data, using P and S-wave travel times and the initial velocity models for generating new improved velocity models. We noticed a reduction of up to 40% in RMS location errors for all resulting velocity models.

Density modeling and elastic parameters calculation in Iran with focus on the Lut Block zone (Eastern Iran)

DOI: 10.57757/IUGG23-1974 - LINK

Gerardo Maurizio[1], *Carla Braitenberg*[1], *Daniele Sampietro*[2], *Martina Capponi*[2]

We propose a new density model in Iran, with a particular focus on the Lut Block zone, in eastern Iran, through inversion of the gravity field starting from a high-resolution seismic tomography model (Kaviani et al, 2020). The density and seismic velocity model allow us to obtain rheological parameters, as shear modulus, and the physical state, like pressure and pressure gradient. We realize a first density model, using known velocity-density relations for crust and mantle (Brocher et al., 2005; Connolly, 2005) optimized with the gravity data. Then we calculate the final 3D density model from constrained inversion of the gravity field with a Bayesian approach. The density model, together with velocities from tomography, allows to calculate principal elastic parameters, using empirical relations (Telford et al., 1976). The area analyzed is tectonically active and presents numerous right-lateral strike-slip faults, that cause the slipping of the East-Iran and the Lut blocks. We observe a high-density crustal anomaly, beginning in an upper crust zone and increasing in density as it descends to the mantle. This is located in an area in the center of the Lut Block, around which we know a part of the East-Iran Block, the Birjand block, is rotating. We analyze the zone in terms of physical parameters, searching for a relation between the density anomaly and the rotation of the Birjand block around it.

Jif3D – an open-source joint inversion platform

DOI: 10.57757/IUGG23-1775 - LINK

Max Moorkamp[1]
[1]*Ludwig-Maximilians-University, Department of Earth and Environmental Sciences, Munich, Germany*

Joint inversion of different geophysical data has been receiving significant attention in recent years due to its potential to improve the quality of subsurface models and provide additional dimensions of analysis over single-data approaches. For example, the relationship between different physical parameters can be used to provide classifications of lithology. However, the technical barrier of entry for new joint inversion methods is very high, as they require efficient forward engines for multiple methods, data and grid management algorithms and useful coupling methods between the different parameters. Jif3D is an open-source C++ joint inversion framework that provides all necessary ingredients for effective inversions in three dimensions. It comprises parallel solvers for gravity, magnetics, DC resistivity, seismic traveltimes, surface waves and magnetotellurics. In addition, a variety of coupling approaches such as Cross-Gradients and Variation of Information are implemented. It can be used as a ready-to-use inversion program or as an experimental platform to develop new approaches thanks to its modular design. Jif3D has been used in a variety of contexts from mineral exploration to large-scale tectonic imaging with different combinations of data. I will show selected case studies using jif3D and discuss possible applications of joint inversion. In particular I will demonstrate the value of joint inversion using seismic, magnetotelluric, gravity and magnetic data from the western United States where currently active tectonics interact with inherited structures to form a complex subsurface.

The efforts of today's society to switch to greener technology and fossil-free energy requires mineral resources. The economical depth of new deposits grows hence deep exploration methods are needed. Magnetotellurics is non-invasive passive electromagnetic method allowing to survey from the surface down to a several tens of km and therefore is a choice when deposit scale information is required. In 2018 a magnetotelluric 3-D array dataset was collected around known magnetite-pegmatite-deposits in Kiruna, Sweden. The survey area is affected by industrial electromagnetic noise from the mine and Kiruna town, which is often a challenge for the magnetotelluric method. Nevertheless, we utilized robust multi-remote reference processing techniques to derive magnetotellurics transfer functions which are in general of a good quality, except a few sites. Many sites exhibit an unusual behavior with phase of main components of the impedance tensor going out of quadrant. This behavior can be indication of noisy data or possibly strong 3D effects. Therefore, we rely on data re-weighting scheme to conclude about the data quality. The final 3-D model was obtained after a few re-weighted least square iterations using diffusion smoothness constrains as model covariance matrix (Second order Tikhonov regularization). Finally, we have obtained a model with stable anomalies at all depths which matches known geology but brings new details and insights into the general understanding of the area.

Generation of planetary core zonal flows by orbital forcings or fingering convection

DOI: 10.57757/IUGG23-0854 - LINK

David Cebron[1], *Remy Monville*[1], *Jérémie Vidal*[1], *Nathanael Schaeffer*[1]
[1]*CNRS - ISTerre, Geodynamo, Grenoble, France*

Zonal flows generation is a long-standing issue in rotating fluids, which can be key in the dynamics of planetary fluid layers (e.g. planetary cores). They are indeed believed to play a significant role in angular momentum exchanges between liquid layers and surrounding solid domains (e.g. Roberts & Aurnou, 2012). Moreover, mean flows could be unstable (e.g. Sauret et al., 2014; Favier et al., 2014), which could sustain space-filling turbulence and mixing. Therefore, understanding the formation of mean flows is essential to model the fluid dynamics of many rapidly rotating systems.

Zonal flows of planetary liquid cores are usually studied as originating from convection in rotating spheres. In the frame of the ERC THEIA (grant agreement no. 847433), we consider here two alternative origins. First, zonal flows can be generated by orbital forcings (e.g. tides, precession) via nonlinear effects within the Ekman layer (Cébron et al., 2021). These flows survive in the relevant regime of vanishing forcings and viscosity. Their competition with bulk driven zonal flows are then considered for various planets and moons. Second, zonal flows can emerge from double-diffusive convection (DDC) in stratified cores (Monville et al., 2019). Applying our results to the early Earth, we obtain that double diffusion can reduce the critical Rayleigh number by four decades, suggesting that its core was prone to turbulent DDC, with large-scale zonal flows.

Effect of heat flux heterogeneities at the core-mantle boundary on geodynamo simulations

DOI: 10.57757/IUGG23-1565 - [LINK]

Thomas Frasson[1], Nathanaël Schaeffer[1], Henri-Claude Nataf[1], Stéphane Labrosse[2]
[1]*Université Grenoble Alpes - CNRS, ISTerre, Grenoble, France*
[2]*ENS de Lyon, Laboratoire de Géologie de Lyon, Lyon, France*

The heat flux at the core-mantle boundary (CMB) is a key parameter for core convection and the geodynamo. Both the mean value and the lateral variations of the CMB heat flux affect the behavior of the geodynamo, and notably the stability and strength of the magnetic dipole in numerical simulations. Inside the Earth, the CMB heat flux is controlled by mantle convection, with possibly large lateral variations. Thus, this could be a significant parameter influencing the dynamo.

This work aims at acquiring a more complete understanding of how lateral heterogeneities of CMB heat flux affect the geodynamo while other relevant parameters are pushed to more realistic values. For this purpose we ran geodynamo simulations with degree 1 and 2 spherical harmonic patterns of heat flux at the CMB. We especially focus on the heat flux distribution between the poles and the equator.

Most of the explored patterns tend to decrease or have little effect on both the magnetic energy and the dipolar fraction of the magnetic field. However, we find that adjusting the distribution between polar and equatorial cooling of the core noticeably affects the dynamo. An equatorial cooling weakens the magnetic dipole, while a moderate polar cooling strengthens the magnetic dipole. These effects are especially strong for moderate heterogeneity amplitudes. Cooling the equator or the poles tend to promote convection outside and inside the tangent cylinder, respectively. The effect on reversal rate is also explored, and exhibits a complex behaviour.

Enclosed fluid layers in planets and moons are ubiquitous and play an important role in the heat and angular momentum balance as well as mixing and energy dissipation. For those rapidly rotating fluid layers, most steering mechanisms such as convection , tides, precession/nutations, librations have been studied mostly in smooth spheres, spheroids and in some cases ellipsoids, neglecting a possible roughness or small scale topography at the boundaries. Meanwhile such anomalies have been considered in stratified oceans and atmospheres showing they contribute significantly to the heat transport, angular momentum exchange and energy dissipation. In the present study we employ experimental and numerical techniques to investigate these questions in the case of neutrally buoyant rapidly rotating fluids. Considering a rotating cylindrical fluid volume with an immersed disc with a single wave length topography pattern oscillating along the rotation axis, we measure the torque necessary to drive the oscillation and characterise the flow structure to identify the fundamental mechanisms at play. In this presentation we report the preliminary results at a fixed Ekman number (E~1e-5) and topography pattern as a function of the oscillation frequency and amplitude.

Plesio-geostrophy for Earth's outer core: Recent advances

DOI: 10.57757/IUGG23-1122 - LINK

Stefano Maffei[1], Andrew Jackson[1], Daria Holdenried-Chernoff[2]
[1]ETH Zurich, Earth Sciences, Zurich, Switzerland
[2]University of California- Berkeley, Earth and Planetary Science, Berkeley, USA

The main tools by which we can study the dynamics of Earth’s fluid core are direct numerical simulations (DNS). In spite of their success, their high computational cost prevents DNS from reaching Earth-like parameters regimes.

Previous studies support the idea that the vast majority of the kinetic energy in the core is contained in columnar, vertically invariant structures. Columnar flow models capitalise on this observation and transform the original, 3D governing equations in a simplified, 2D set. These models have proven their potential in simulating the dynamics of Earth’s fluid core in extreme parameter regimes. However, current approaches are not capable of treating the magnetic field within the same 2D framework.

Plesio-geostrophy (PG) was developed to overcome this limitation. Our PG model describes fluid flows, magnetic field and temperature via 2D variables. We tested our novel PG methodology on a set of linear problems of relevance to the dynamics of Earth’s fluid core: inertial and magneto-hydrodynamics waves propagation, and onset of thermal convection. All diffusivities are taken into account. The effect of viscous boundary layers is parameterised via a novel, fully spectral numerical methodology that does not require special treatments of the critical latitudes. We successfully benchmarked the PG model results against both 3D and other columnar flow models and calculated solutions at geophysically relevant parameter regimes.

Free Core Nutation, Tilt-Over mode, and other inertial modes of the Earth: Clarification

DOI: 10.57757/IUGG23-0956 - LINK

Jeremy Rekier[1]
[1]*Royal Observatory of Belgium, Reference System and Planetology, Brussels, Belgium*

The Earth's rotation varies in time under the gravitational influence of nearby objects, mainly the Sun and the Moon. The response of the Earth to these gravitational disturbances depends on its internal structure. In particular, the existence of the free oscillatory motion of the liquid core called the Free Core Nutation (FCN) amplifies the planet's nutation in the diurnal retrograde frequency bands (as measured in the terrestrial frame of reference). This mode is related to another mode known to fluid dynamicists as the Spin-Over mode (SOM), the latter being one an infinite set of inertial modes restored by the Coriolis force in rotating fluid bodies. In this work, we review the relation between the FCN and SOM and show how the frequency of the latter can influence the FCN frequency in a non-trivial way when the two are close to each other. We also clarify the relation between these modes and another one known as the Tilt-Over Mode (TOM) sometimes conflated with the SOM in the literature. We also explore how other inertial modes may affect the Earth's rotation and magnetic field.

Turbulence in the boundary layer of precession-driven flow

DOI: 10.57757/IUGG23-4286 - LINK

Sheng-An Shih[1], *Santiago Andrés Triana*[1], *Jérémy Rekier*[1], *Véronique Dehant*[1]
[1]*Royal Observatory of Belgium, Reference Systems and Planetology, Brussels, Belgium*

The boundary layer (in the outer core) between the core and the mantle is known to be thin, with the nominal value about 0.11 meters. The presence of turbulence in the boundary layer has been proposed as a mechanism to explain the observed damping of the Free Core Nutation (FCN). However, the small amplitude of FCN makes the turbulence scenario unlikely. A recent study shows that the precession-driven flow is at the margin of turbulence. Here, we use a local Cartesian box model to study numerically the boundary layer. Our numerical results show that the boundary layer at certain latitudes is not turbulent. By considering the total dissipation in the boundary layer, we find an increase by a factor of 1.86 compared to the laminar solution, implying that the effective viscosity is increased by a factor of 3.5. This may have implications for the chemical interaction occurring at the core-mantle boundary.

The influence of a heterogeneously conducting mantle on the secular variation of the magnetic field

DOI: 10.57757/IUGG23-4454 - LINK

Huifeng Zhang[1], *Mathieu Dumberry*[1]
[1]*University of Alberta, Department of Physics, Edmonton, Canada*

Convection in the liquid outer core generates the Earth's magnetic field. Observations suggest that the secular variation of the magnetic field is weaker under the Pacific region. In turn, this indicates that flow in this region at the surface of the core is weaker. One hypothesis to explain this is that the conductance of lower mantle is higher in this region or, alternatively, that it features stratified core fluid trapped under topographic undulations. This leads to a larger electromagnetic coupling, attenuating the flow. In this work, we will test this hypothesis using numerical simulations of the geodynamo, in which we impose heterogeneous mantle conductance.

JS08 - Posters - Advances in Heat Flow Studies: From Fundamental Geodynamic Understanding to Geothermal Energy Applications (IASPEI, IAVCEI (IHFC))

The thickness of the thermal lithosphere in China and its geodynamic significance

DOI: 10.57757/IUGG23-1314 - LINK

Chaoqiang Chen[1], *Lijuan He*[1]
[1]*Institute of Geology and Geophysics- Chinese Academy of Sciences, State Key laboratory of Lithospheric Evolution, Beijing, China*

Based on the latest heat flow data of mainland China and the fine crustal structure data, we calculate the thickness of thermal lithosphere for each heat flow measurement point by solving one - dimensional steady heat conduction equation. The results show that the thickness of thermal lithosphere varies greatly in different areas. By comparing the thickness between thermal lithosphere and seismic lithosphere of the three cratons in China, we concluded that: 1) The western part of the Tarim craton, the middle - upper Yangtze craton, the western part of the NCC and the southern part of the NCC still remain stable, while the eastern part of NCC, the lower Yangtze craton and the southeastern part of the Tarim craton were thinned significantly; 2) In the western NCC, the thickness of thermal lithosphere, seismic lithosphere, and rheological boundary layer(RBL) all thin from west to Yinchuan - Hetao depression in northeast and Fenwei depression in southeast; 3) In the east NCC, the thermal lithospheric thickness of Bohai Bay Basin and the southern part of NCC differs significantly. The thickness of thermal lithosphere in the southern part of NCC is about 60 km thicker than that in Fenwei depression, even though Fenwei depression is to the west of it and theoretically less influenced by subduction of the Pacific plate. 4) The thickness of thermal lithosphere, seismic lithosphere, and RBL of the Yangtze craton gradually decrease from west to east, which may be controlled by the subduction of the Pacific plate.

The results show that the thickness of thermal lithosphere varies greatly in different areas. By comparing the thickness between thermal lithosphere and seismic lithosphere of the three cratons in China, we concluded that: 1) The western part of the Tarim craton, the middle - upper Yangtze craton, the western part of the NCC and the southern part of the NCC still remain stable, while the eastern part of NCC, the lower Yangtze craton and the southeastern part of the Tarim craton were thinned significantly; 2) In the western NCC, the thickness of thermal lithosphere, seismic lithosphere, and rheological boundary layer(RBL) all thin from west to Yinchuan - Hetao depression in northeast and Fenwei depression in southeast; 3) In the east NCC, the thermal lithospheric thickness of Bohai Bay Basin and the southern part of NCC differs significantly. The thickness of thermal lithosphere in the southern part of NCC is about 60 km thicker than that in Fenwei depression, even though Fenwei depression is to the west of it and theoretically less influenced by subduction of the Pacific plate. 4) The thickness of thermal lithosphere, seismic lithosphere, and RBL of the Yangtze craton gradually decrease from west to east, which may be controlled by the subduction of the Pacific plate.

Knowledge of the downward variation of thermal conductivity within Earth's interior is an essential parameter for accurately estimating the sub-surface temperature distribution. The variation is dominantly controlled by temperature and, to a very less extent, by pressure. The temperature dependence is distinct for various rocks and higher for upper crustal rocks than the lower crustal rocks, implying the utmost necessity of detailed study for upper crustal rocks. In thermal modeling, two temperature coefficients are commonly considered for the upper and lower crust. But the upper crust generally consists of a wide variety of rocks.
In the present study, thermal conductivity variation with temperature has been studied in the laboratory by a steady-state method in the temperature range of 25-300 °C on different types of upper crustal rocks, e.g., granitoids and rhyolites. Results show that the temperature dependence of thermal conductivity for different varieties of granitoids, i.e., alkali feldspar granite to monzogranite and granodiorite to tonalite to quartz diorite, indicate two distinct ranges and rhyolites lie between these two varieties. The study also depicts that a single temperature coefficient for the upper crustal rocks needs to be modified, and appropriate values should be considered, depending upon the variations in rock formation of the upper crust. The observed wide variations in the temperature dependence of thermal conductivity for different varieties of upper crustal rocks will be useful for precise sub-surface thermal modeling. The study also investigated how the difference in temperature coefficient for the upper crust can produce a difference in thermal structure.

Heat flow variations in five new boreholes in the Vogtland geodynamic region

DOI: 10.57757/IUGG23-1634 - LINK

Petr Dedecek[1], *Jan Šafanda*[1], *Tomáš Uxa*[1], *Vladimír Čermák*[1]
[1]*Institute of Geophysics, Surface processes and paleoclimate, Prague, Czech Republic*

This work details the variations in heat flow density and thermal properties of rocks in five 300–450 m deep fully cored boreholes in the seismically active part of the West Bohemia at the border of Czechia and Germany. All the boreholes were drilled in the crystalline units, with boreholes S1 (Landwüst, 50.26°N, 12.33°E), S2 (Tisová, 50.35 °N, 12.50 °E) and S3 (Studenec, 50.26 °N, 12.52) intersecting metamorphic rocks, borehole S4 (Bažina, 50.15°N, 12.21°E) passing through the sedimentary cover of a newly discovered maar and the underlying granite, and borehole PTP-3 (Potůčky, 50.43 °N, 12.78 °E) completely drilled in granite. Precise repeated temperature logging was performed for all the boreholes, and due to the hilly terrain, topographic corrections were applied using 3-D numerical models to account for the effects of topography on the borehole temperatures. Thermal properties, including their anisotropy, were determined in the laboratory on ten or more rock samples from each borehole. Hence, it was possible to analyze depth variations of the heat flow in the individual boreholes. The largest variations occur in the boreholes located in metamorphic rocks. Due to rock heterogeneity, anisotropy of thermal properties, effect of climate change and water movement, the heat flow density ranges from less than 50 mW m^{-2} to more than 100 mW m^{-2}.

The research is supported by the Czech Science Foundation, project no. 21-23196S.

Marginal seas develop in the western Pacific region, with various evolutionary stages and geological characteristics. Geothermal field could provide some clues for understanding regional tectonics, thus revisiting the geothermal regime of the marginal seas in western Pacific region is in demand and available with the increasing heat flow data. Combing the updated global heat flow dataset of IHFC and other observations, heat flow and thermal structure of the marginal sea basins are analyzed. Our results demonstrate that heat flow varies much among the marginal seas, and the average values for the Okhotsk Sea, Japan Sea, Okinawa Trough and South China Sea are 80 mW/m^2, 93 mW/m^2, 210 mW/m^2 and 75 mW/m^2, respectively, indicating different ages. While the subduction zones exhibit similar geothermal patterns, with relatively low heat flow in the fore-arc regions, extremely high but variable heat flow in the volcanic arcs, and generally high heat flow in the back-arc regions. High heat flow anomalies are observed within the marginal seas, as a result of fluid circulation and recent volcanic activities. High temperature and large heat flow in the back-arc regions can be attributed to the heat contributions from the mantle. The heat flow verse age relation for marginal sea basins can be roughly expressed by $Q(t)=585.8\ t^{-1/2}$. It seems that this *Q-t* relation for marginal seas does not significantly differ from that for oceanic basins. Given the uneven coverage in heat flow data and vagueness in crustal age, this expression needs to be determined with caution in further study.

Department 4: Geosystems- Section 4.8 Geoenergy, Potsdam, Germany

The Global Heat Flow Database of the International Heat Flow Commission (IHFC) is currently under fundamental revision. Here, we present a critical assessment of the terrestrial heat-flow-density data for Germany. The collected legacy data from Germany cover entries from 596 heat-flow locations over a time span of more than 60 years, showing differences in documentation and the availability of metadata. To assess the data, we follow a multi-step procedure: first, we screened the original literature, updated the heat flow data and revised them for completeness and reproducibility. Database entries with missing data essential for heat flow determination (like temperature gradient, thermal conductivity) are flagged as not reliable as they cannot be scientifically reproduced nor quality assessed. This strict procedure is necessary for setting up a dataset following scientific criteria and results in a reduction of the original data set by almost 80% to 138 locations. These were assessed in terms of methodological quality and labeled for different overruling effects, like paleoclimate, heat refraction, or fluid movements. The (area-weighted) average terrestrial heat flow for Germany is 78 ± 7 mWm^{-2} which is by almost 20% higher compared to earlier estimates (ca. 65 mWm^{-2}). The regional average heat flow across Germany varies by the order of 40 %. However, considering a radius of 10 km around each location, the heat flow remains uncertain for ca. 90% of the German onshore area, which raises the demand for new systematic heat-flow measurements in Germany.

[2]*University of Bremen, Geoscience- Geophysics, Bremen, Germany*

Marine heat flow data provide fundamental insights into thermal processes and advective heat transport occurring near and below the seafloor. Processes that influence and are influenced by heat transport within seafloor sediments and basement rocks include:

- the thermal evolution of the oceanic crust and lithosphere;
- the geodynamics of plate boundaries and mantle convection;
- fluid circulation and associated impacts on water-rock interactions, seismicity, tectonics, and magmatism;
- occurrence and stability of gas hydrates;
- maturation of hydrocarbons at passive margins.

Understanding these processes involves the quantification of energy and fluid fluxes, requiring knowledge of the thermal state deduced from observations that include heat flux, sub-bottom temperature, and thermo-physical sediment properties.

Our main objective is the presentation of methods, instrumentation, and recent and on-going projects to demonstrate the wide-range field of application. The Faculty of Geosciences and MARUM (University of Bremen) have a longstanding record of high-quality research in the field of marine heat flow studies. We present exemplary case studies from our field of expertise relating to subduction zones (seismogenic zones), gas hydrates, hydrothermal processes (Layer 2A, fault zones, fracture zones), and ridge related processes. Further on, economical projects like assessment and monitoring of thermal impact of buried off-shore power cables from wind farms on the environment come into focus.

The Amazon deep sea fan is a dynamic setting in which widespread seafloor fluid vents record degassing of a gas hydrate system hosted within an upper slope thrust-fold belt linked to gravitational collapse of the depocentre. This system is to be investigated during the AMARYLLIS-AMAGAS campaign of the R/V Marion Dufresne, to take place in May-June 2023 as a collaboration between research groups in Europe and Brazil. One aim of the campaign is to study the spatial distribution and stability conditions of the shallow gas hydrate reservoir in relation to temperature changes in the past, fluid migration and venting, and to the triggering of the giant slope failures that have recurrently extended across the fan. Three heat flow transects within a 200 km^2 area of the upper fan will target seismically-observed BSR (bottom simulating reflection) patches associated with fluid venting structures at the crests of thrust-fold anticlines. Temperature gradients will be measured using autonomous high-precision temperature probes attached to core barrels, while thermal conductivity will be measured onboard using a needle probe instrument on recovered sediment cores. Together with hydroacoustic and geochemical datasets to be acquired during the campaign, the results are expected to yield insights into the dynamics of the gas hydrate system in relation to subsurface fluid flow and changes in the heat flow in sediments, as well as new information on the poorly-constrained background regional heat flow regime of the Amazon deep-sea fan.

Thermophysical properties for the major rock formations of the Western Himalaya: Implications for 2-D conductive thermal modeling

DOI: 10.57757/IUGG23-1095 - LINK

Eswara Rao Sidagam[1]*, Labani Ray*[1]*, Ayan Dutta*[1]*, Nishu Chopra*[1]*, Nagaraju Podugu*[1]*, Tavheed Khan*[1]
[1]*CSIR National Geophysical Research Institute, Thermal Geophysics, Hyderabad, India*

Thermal modeling of the lithosphere is essential to understand the geodynamics, seismogenesis, and crustal evolution of any region. Surface heat flow, radiogenic heat production, and thermal conductivity variations with temperature are the primary parameters that influence thermal modeling. The Western Himalaya is devoid of all these parameters, which hindered accurate thermal modeling of the region. In the present study, we have measured the above thermophysical properties in the laboratory for the major rock formations of the Western Himalaya along three NW-SE profiles. The major rock formations include sandstone, limestone, dolomitic limestone, slate, phyllite, quartzite, schist, gneiss, and granitoid. Thermal conductivity and heat production of these rocks vary from 2.6 to 5.4 $Wm^{-1}K^{-1}$ and 1.7 to 2.6 μWm^{-3}. The crustal structure along one of the profiles, i.e., Tanakpur-Pangla profile (150 km length), is made using available geological and geophysical (seismological and gravity) information, along with new data on rock thermal conductivity and its variation with temperature and radiogenic heat production to obtain 2D conductive thermal structure beneath the region by finite element method. The 2D temperature-depth distribution along this profile covering Siwalik, Lesser Himalaya, and Higher Himalaya formations reveals that the temperature at Moho varies from 450 °C to 750 °C. At a few locations, subsurface temperatures estimated from the 1D conductivity models are in good agreement with that of the 2D results within the uncertainty limits. The results of 2D thermal modeling provide significant progress in understanding of the first-order characteristics of the conductive thermal field in the Western Himalaya.

A review of heat-flow data from the seas surrounding the Italian peninsula

DOI: 10.57757/IUGG23-0665 - LINK

Massimo Verdoya[1], *Paolo Chiozzi*[1], *Linda Bonorino*[1]
[1]*University of Genoa, Dept. of Earth- Environment and Life Sciences, Genoa, Italy*

Several heat-flow data from the seas of the Italian peninsula, originally scattered in several publications, are gathered in the Global Heat Flow Database (GHFD) Release 2023 (https://doi.org/10.5880/fidgeo.2021.014) and national files. Although data are accessible, it is intrinsically difficult to discern whether they are affected by deviations from purely conductive, steady-state heat transfer unless the original papers are carefully inspected. The superposition of different biases can contaminate the heat-flow values. Uncritically contouring can thus lead to misleading thermal patterns. Moreover, the uneven spatial distribution of heat-flow sites and the differences in measurement techniques may cause additional difficulties in the interpretations. Depending on the possible targets (e.g., calculation of crustal geotherms, modelling or characterisation of advective systems, evaluation of geothermal energy potential), *ad hoc* filtering should be applied to remove the different effects. Within the Global Heat Flow Data Assessment Project (2021-2025) framework, initiated by the International Heat Flow Commission (http://www.ihfc-iugg.org), we reviewed heat-flow data collected during several surveys since the 1960s. We checked the original publications to identify misplaced or forgotten data in the GHFD. The review was based on the newly adopted standard for reporting and storing heat-flow data. Data were critically reviewed, validated and corrected for terrain effects. New heat-flow data from deep wells were also inferred through a minimisation technique accounting for temperatures, radiogenic heat production and the thermal conductivity variation with depth. We obtained significant heat-flow estimates characterising the size and intensity of shallow and deep tectonic events that left a thermal signature in the seas surrounding the peninsula.

A method for determination target areas of hot dry rock resources: A case study in continental China

DOI: 10.57757/IUGG23-1483 - LINK

Yaqi Wang[1], Lijuan He[1]
[1]Institute of Geology and Geophysics- Chinese Academy of Sciences, State Key Laboratory of Lithospheric Evolution, Beijing, China

Geothermal resources have been recognized as an important part of clean renewable energy. The exploration, development, and utilization of geothermal resources, especially the Hot Dry Rock (HDR) resources, are of great significance for achieving carbon peaking and carbon neutrality. However, there is no comprehensive evaluation method to determine the HDR target areas, and the evaluation scale and application disciplines are relatively simple. In this paper, we studied the optimization of the distribution target area of HDR resources through multi-scale and multidisciplinary method, and formed a set of generalized and demonstrative process to guide the exploration of HDR resources. Besides, the Expert scoring method was used to improve the target selection from a qualitative study to a quantitative semi-quantitative study, making the decision more specific and more reliable.

Thermal effect of Emeishan basalt on Paleo-heat flow of the Sichuan Basin: numerical modeling

DOI: 10.57757/IUGG23-1677 - LINK

Jinhui Wu[1,2], Lijuan He[1], Liwen Yan[1,2], Chaoqiang Chen[1,2]
[1]Institute of Geology and Geophysics- Chinese Academy of Sciences, State Key Laboratory of Lithospheric Evolution, Beijing, China
[2]University of Chinese Academy of Sciences, College of Earth and Planetary Sciences, Beijing, China

The Sichuan Basin is an important hydrocarbon-bearing basin in China, and its southwestern part is located in the outer zone of the Emeishan Large Igneous Province. The thermal influence of Emeishan basalt on hydrocarbon development in the Sichuan Basin has been of great interest. Recent paleo-heat flow recovery calculations have yielded the presence of high paleo-heat flows greater than 100 mW/m2 duirng the Permian at some points in the basin, which are thought to be related to Emeishan basalt. In order to understand the causes of these high paleo-heat flows and the thermal effects of basaltic magma overflowing to the surface on the lower strata, the thermal effects of Emeishan basalt were simulated by 2D finite element method. The following conclusions are drawn: (1) The changes in surface heat flow generated by the intrusion of Emeishan basaltic magma into the bottom of the lithosphere and the bottom of the crust are both inconsistent with the high paleo-heat flow of >100 mW/m2 during the Permian of the Sichuan Basin, and magma intruded into the interior of the crust can cause such high paleo-heat flows.(2) The thermal disturbance caused by different thicknesses of magma at the surface to the lower strata at different depths was calculated. The thicker the magma at the surface and the shallower the overlying strata, the greater the thermal disturbance of the magma to the strata, while the adjacent strata are unaffected. The thermal influence on the hydrocarbon source rocks can thus be inferred.

The Sichuan Basin is an important hydrocarbon-bearing basin in China, and its southwestern part is located in the outer zone of the Emeishan Large Igneous Province. The thermal influence of Emeishan basalt on hydrocarbon development in the Sichuan Basin has been of great interest. Recent paleo-heat flow recovery calculations have yielded the presence of high paleo-heat flows greater than 100 mW/m2 duirng the Permian at some points in the basin, which are thought to be related to Emeishan basalt. In order to understand the causes of these high paleo-heat flows and the thermal effects of basaltic magma overflowing to the surface on the lower strata, the thermal effects of Emeishan basalt were simulated by 2D finite element method. The following conclusions are drawn: (1) The changes in surface heat flow generated by the intrusion of Emeishan basaltic magma into the bottom of the lithosphere and the bottom of the crust are both inconsistent with the high paleo-heat flow of >100 mW/m2 during the Permian of the Sichuan Basin, and magma intruded into the interior of the crust can cause such high paleo-heat flows.(2) The thermal disturbance caused by different thicknesses of magma at the surface to the lower strata at different depths was calculated. The thicker the magma at the surface and the shallower the overlying strata, the greater the thermal disturbance of the magma to the strata, while the adjacent strata are unaffected. The thermal influence on the hydrocarbon source rocks can thus be inferred.

Thermal lithospheric thickness and bottom boundary morphology of the North China Craton after thermal subsidence

DOI: 10.57757/IUGG23-1336 - LINK

Liwen Yan[1], Lijuan He[1], Jinhui Wu[1], Chaoqiang Chen[1]
[1]INSTITUTE OF GEOLOGY AND GEOPHYSICS- CHINESE ACADEMY OF SCIENCES, State Key Laboratory of Lithospheric Evolution, BEIJING, China

The present day's thermal lithospheric thickness is usually calculated by one or two-dimensional steady-state heat conduction equation. Using the latest measured heat flow data of the North China Craton(NCC) and the one-dimensional steady-state heat conduction equation, the calculated thermal lithospheric thickness of the NCC is between 34.8-190 km. There are some regions, whose lithosphere is very thin, and the lithosphere adjacent to them is very thick, so the bottom boundary of the lithosphere fluctuates greatly. The last thinning of the NCC stopped at~24 Ma and then entered the thermal subsidence period. To study whether the fluctuates of the bottom boundary of the lithosphere can be maintained during the long-term thermal subsidence process, a thermal subsidence model was established. The modeling results show that after the thermal subsidence of 24 Ma, the fluctuates of the bottom boundary of the lithosphere are difficult to maintain, and the present day's thermal lithospheric thickness of the NCC should not exceed 73 km, and the maximum surface heat flow value of the NCC is 75.6 mW·m^{-2} due to the deep thermal state. The high heat flows anomaly in the NCC is more caused by shallow activities and cannot reflect the deep thermal state. After correction, the current thermal lithospheric thickness of the North China craton is ~73-190 km, and the bottom boundary of the lithosphere changes gently.

Building resilience in coastal communities: A comprehensive approach to making Malta Tsunami-Ready

DOI: 10.57757/IUGG23-1797 - LINK

Blanca Mendiguren[1], Pauline Galea[1], Adam Gauci[1], Denis Chang-Seng[2]

With the highest population density per square kilometre in Europe, and an intensive coastal land use, the Maltese islands recognize the importance of becoming a Tsunami-Ready(TR) country. Through the UNESCO-IOC-led project CoastWAVE, funded by DG ECHO, the UNESCO-IOC Tsunami-Ready Recognized status is first being implemented on a smaller scale in the town of Marsaxlokk, on the southeast coast of Malta. In order to evaluate the population's sea level related coastal hazard understanding and awareness, a risk perception questionnaire about tsunami, sea-level rise and storm surge was carried out, involving different target groups representing the local population. The population showed a general misconception mainly regarding the tsunami and storm surge terms because they are familiar with the impact of the latter in Marsaxlokk. The younger population showed insufficient understanding of the natural signs (e.g., sea drawback) of a tsunami, the risk and potential impact in the locality. Further outreach activities will be carried out in Marsaxlokk, informed by the key survey findings. To fulfil one of the twelve TR Indicators (approved inundation maps), a series of tsunami propagation scenarios were also carried out through the numerical model HySEA to explore propagation times, inundation area and run-up at Marsaxlokk and the Grand Harbour (Valletta). The simulated scenarios included a magnitude 7.1 earthquake-generated tsunami based on the 1908 Messina Strait tsunami, which produced well-documented high sea level records around Malta. The results of the CoastWAVE project will contribute towards the future elaboration of a national tsunami awareness, preparedness and early warning programme.

The aim of research is to develop a seismic monitoring technique in the Uzbekistan to improve the efficiency of landslides, mudflows hazard prediction.

Based on the obtained scientific results: (1) developed seismic monitoring system to improve the reliability and quality of landslides, mudflows forecasts; (2) created catalog of seismograms is designed to identify seismograms of explosions in a quarry, remote and nearby earthquakes, landslides and mudflows movements; (3) based on the analysis of refracted wave data on Angren brown coal open pit, liquefied layers with the danger of sudden landslides movement were identified; (4) a computer program has been developed using mathematical modeling to more accurately identify the initial part of the longitudinal (P) and transverse (S) seismic waves.

Improving REGARD: real-time finite fault estimates with dense GNSS CORS network GEONET in Japan

DOI: 10.57757/IUGG23-2198 - LINK

Naofumi Takamatsu[1], *Keitaro Ohno*[1], *Satoshi Abe*[1], *Takayuki Miyazaki*[1], *Yoshiki Takei*[1], *Shinsuke Murakami*[1], *Satoshi Kawamoto*[1]

GNSS CORS Division- Geodetic Observation Center, Tsukuba, Japan

GNSS continuous observation enables us to rapidly estimate a finite fault model for a large earthquake without saturation of magnitude. Geospatial Information Authority of Japan (GSI) operates a dense and nationwide GNSS continuous observation network named GEONET, which is capable of providing 1Hz displacement data in real-time. After a gigantic 2011 earthquake in Japan, GSI in collaboration with Tohoku university launched a REGARD (REal-time GEONET Analysis system for Rapid Deformation monitoring), which offers a finite fault model based on the real-time displacement data observed in GEONET. The REGARD system has successfully provided the co-seismic displacement and finite fault model information for recent M~7 or larger earthquakes. These results are provided to government agencies in a few minutes from an earthquake occurrence and are taken advantage of their initial response and tsunami prediction.

To achieve the highest reliability in REGARD, we seek the possibility of applying precise point positioning (PPP) instead of the current relative positioning. PPP can improve the robustness of the real-time positioning subsystem in REGARD by its nature of single positioning. The precise satellite orbit and clock information is generated using MADOCA developed by Japan Aerospace Exploration Agency (JAXA). The satellite orbit and clock includes not only GPS and GLONASS but also QZSS, the Japanese satellite positioning system. In our performance assessment, PPP showed a cm-level accuracy, which is close to the performance of RTK.

A risk-driven approach in assessing the potential effectiveness of earthquake early warning for schools in the Patras region, Greece

DOI: 10.57757/IUGG23-3441 - LINK

Elisa Zuccolo[1,2], Nikolaos Melis[3]

Earthquake early warning (EEW) constitute a major tool for seismic resilience enhancement in modern societies, helping mitigate some of the devastating effects of earthquakes (e.g., deaths, business interruption) in the face of increasing exposure and vulnerability to seismic events worldwide. However, traditional EEW approaches (such as feasibility studies and decision-making related to triggering alerts by different end users) are essentially based on seismological considerations.
In this study, jointly developed with the University College London in the framework of the EU H2020 TURNkey Project (https://earthquake-turnkey.eu/), we adopt a risk-based approach to EEW. We present the results of a state-of-the-art feasibility study for EEW in schools performed across the Patras region of Greece, which combines traditional seismologically-driven EEW decision criteria (warning time) with proxy risk-oriented measures for earthquake impact (building fragility and the number of exposed students). The results, showing the effectiveness of EEW under certain conditions, are the premises for the demonstration of an innovative end-user-centred approach for improved risk-informed decision-making on triggering EEW alerts, which merges earthquake-engineering-related seismic performance assessment procedures and metrics with multi-criteria decision-making within an end-to-end probabilistic framework. The approach, demonstrated using an archetype school building for the case-study region, emphasizes that the best action (i.e., “trigger” or “don’t trigger” an EEW alert) for a given level of ground shaking depends on the stakeholder preferences towards the predicted damage/loss estimates consequences.

The Hunga Tonga - Hunga Ha'apai (HTHH) eruption of 15 January 2022 was an exceptional event by the period, magnitude, and duration of propagation of the atmospheric waves it generated, circling the globe multiple times. Even though several volcanic eruptions in the past 150 years era of scientific instrumentation generated notable barometric disturbances, the HTHH eruption is comparable only to the Krakatoa eruption of 1883 by the magnitude of the atmospheric pressure waves that it generated. For instance, the very energetic Mt Pinatubo eruption of 1991 did not produce pressure waves of the same period and magnitude as the Krakatoa or HTHH eruptions. An analysis of the timing of the multiple passes at barometric stations is reported in Symons (1888) for the Krakatoa. Since the HTHH event also gave rise to a pressure wave that circled the Earth's atmosphere multiple times in the last 134 years, it is of interest to perform similar timing statistics on the multiple passages at stations that recorded them. A review of the Krakatoa analysis and a comparison with the HTHH are presented, with possible implications for the changes in the global state of the atmosphere during the interval between the two events.

Symons, G.J. (ed) The Eruption of Krakatoa and Subsequent Phenomena (Report of the Krakatoa Committee of the Royal Society). London, 1888. Internet Archive. 1888.

Geomagnetic detection of the atmospheric acoustic resonance at 3.8 mHz during the Hunga Tonga eruption

DOI: 10.57757/IUGG23-3864 - [LINK]

Yozuke Yamazaki[1], Jürgen Matzka[2], Gabriel Soares[3]

Modeling studies have predicted that the acoustic resonance of the atmosphere during geophysical events such as earthquakes and volcanos can lead to an oscillation of the geomagnetic field with a frequency of about 4 mHz. However, observational evidence is still limited due to scarcity of suitable events. On 15 January 2022, the submarine volcano Hunga Tonga-Hunga Ha'apai (20.5°S, 175.4°W, Tonga) erupted in the Pacific Ocean and caused severe atmospheric disturbance, providing an opportunity to investigate geomagnetic effects associated with acoustic resonance. Following the eruption, geomagnetic oscillation is observed at Apia, approximately 835 km from Hunga Tonga, mainly in the Pc 5 band (150–600 s, or 1.7–6.7 mHz) lasting for about 2 hr. The dominant frequency of the oscillation is 3.8 mHz, which is consistent with the frequency of the atmospheric oscillation due to acoustic resonance. The oscillation is most prominent in the eastward (Y) component, with an amplitude of about 3 nT, which is much larger than those previously reported for other events (<1 nT). Comparably large oscillation is not found at other stations located further away (>2700 km). However, geomagnetic oscillation with a much smaller amplitude (∼0.3 nT) is observed at Honolulu, which is located near the magnetic conjugate point of Hunga Tonga, in a similar wave form as at Apia, indicating interhemispheric coupling. This is the first time that geomagnetic oscillations due to the atmospheric acoustic resonance are simultaneously detected at magnetic conjugate points.

On 15 January 2022 at 04:15 UTC, an enormous explosive eruption of the Hunga Tonga-Hunga Ha‘apai submarine volcano (short: Hunga) occurred in the Tonga-Kermadec volcanic area. Strong Lamb and tsunami waves were generated. Besides these phenomena also seismic waves could be observed on seismic stations all over the world.

Consequently, seismic body and surface waves of the Hunga main explosion were recorded at seismic stations in Germany. The onset times of PKPbc phases determined at stations of the German Regional Seismic Network (GRSN) as well as corresponding slowness and azimuth calculated by array methods allowed an unambiguous assignment to the Hunga event and an epicenter localization deviating approximately 1 to 1.5 degrees from the volcano. Furthermore, at least one additional event is detected about 4 minutes after the main event.

To assign a seismic magnitude to the Hunga event, we analyzed the surface wave trains. The Ms magnitudes vary between 5.8 and 6.3 within the individual stations of the GRSN, with a mean value of 6.0.

The Tonga-Kermadec subduction zone is characterized by strong earthquake activity. This allows us to compare seismic recordings of the Hunga event with those of earthquakes from the same area with shallow focal depths and comparable magnitudes. It turns out that PKP phases of the Hunga eruption have significantly smaller amplitudes in the short-period range than for the compared earthquakes but similarly strong in the long-period range. We conclude that a long-period excitation is characteristic for the seismically relevant focal process of the Hunga event.

The 2021 Tajogaite eruption in La Palma, Canary Islands, was accompanied by strong volcanic tremor. In September 2021, during the first two weeks of eruption, we deployed two small-aperture seismic arrays. We chose two locations around Montaña Caldero and Llano del Jable, located about 4 km SE and 2 km NE of the eruption site. The arrays were composed of 1 three-component and 9 vertical-component short-period seismometers, sampled at 100 sps by a 12-channel data acquisition system. In each array, the receivers were spread with an aperture of about 400 m. Although they operated intermittently due to failures in the power supply related to ash fall, they provided long time series of multichannel seismic data that allow for the characterization of the syn-eruptive tremor. The analysis of the recorded wavefields reveals a persistent tremor source linked to the activity of the eruptive vents. The main component of the wavefield in the 1-3 Hz frequency band propagates with apparent slowness around 1 s/km, impinging on the arrays from directions of ~300 and 260ºN, respectively. These directions are slightly deviated from the active vents azimuths, a fact that we attribute to propagation effects produced by the topography and heterogeneous velocity structure. Subtle variations in the apparent slowness and propagation azimuths are investigated using the relative slowness estimate method, that allows for a precise determination of the apparent slowness vectors.

We present a research project intended to investigate the structure of Cumbre Vieja volcano in La Palma, Canary Islands, after the September-December 2021 Tajogaite eruption. Starting in the summer of 2023, we will deploy a dense network of 35 broadband seismometers provided by GFZ and University of Granada, that will add up to the ~20 permanent stations already in operation by the Spanish National Geographic Institute (IGN) and the Volcanological Institute of Canary Islands (INVOLCAN). In this way, we expect to obtain a dense coverage of the whole island with inter-station distances of about 5 km. This broadband network will be in operation for a period of about a year. Additionally, we will perform a series of large-N experiments using 200 geophones (provided by GFZ). First we will deploy these instruments along linear profiles across the island, in N-S and E-W directions. In a second stage, we will move the geophones to a bidimensional grid configuration centered at the eruption site. We estimate that inter-station distances will be of ~0.5 km in both cases, and the recording periods will span around 4-5 months per configuration. The data obtained from these deployments will be used to perform a dense receiver function analysis and ambient noise tomography to improve the knowledge of the shallow velocity structure of the volcanic rift around the eruption area down to a depth of a few km and to image the magma sources in the crust and uppermost mantle.

We present a research project intended to investigate the structure of Cumbre Vieja volcano in La Palma, Canary Islands, after the September-December 2021 Tajogaite eruption. Starting in the summer of 2023, we will deploy a dense network of 35 broadband seismometers provided by GFZ and University of Granada, that will add up to the ~20 permanent stations already in operation by the Spanish National Geographic Institute (IGN) and the Volcanological Institute of Canary Islands (INVOLCAN). In this way, we expect to obtain a dense coverage of the whole island with inter-station distances of about 5 km. This broadband network will be in operation for a period of about a year. Additionally, we will perform a series of large-N experiments using 200 geophones (provided by GFZ). First we will deploy these instruments along linear profiles across the island, in N-S and E-W directions. In a second stage, we will move the geophones to a bidimensional grid configuration centered at the eruption site. We estimate that inter-station distances will be of ~0.5 km in both cases, and the recording periods

will span around 4-5 months per configuration. The data obtained from these deployments will be used to perform a dense receiver function analysis and ambient noise tomography to improve the knowledge of the shallow velocity structure of the volcanic rift around the eruption area down to a depth of a few km and to image the magma sources in the crust and uppermost mantle.

Lineament analysis based on satellite images as a tool for strain localization associated with seismic and volcanic activity

DOI: 10.57757/IUGG23-3764 - LINK

Alonso Arellano-Baeza[1]

The analysis of satellite images showed that the strain energy accumulation deep in the Earth's crust that precedes a strong earthquake can be detected by applying a lineament extraction technique. A lineament is a straight or a somewhat curved feature in a satellite image, which is possible to detect by a special processing of images based on directional filtering and/or Hough transform. We analyzed tens of earthquakes that took place in the Pacific coast of South America with a Richter scale magnitude over 4.5, using ASTER/TERRA and LANDSAT satellite images. All events were located in regions with small seasonal variations and limited vegetation to facilitate the tracking of features associated with the seismic activity only. The images were taken during the time interval of one year before and after an earthquake. It was found that the number and orientation of lineaments changes significantly one month before an earthquake approximately, and a few months later the system returns to its initial state. This effect increases with the earthquake magnitude. The application of the same technique to volcanoes showed that the behavior of lineaments associated to their seismic activity is opposite to that obtained previously for earthquakes. This discrepancy can be explained assuming that the main reason of earthquakes is compression and accumulation of strain in the Earth's crust due to subduction of tectonic plates, whereas in the case of volcanoes we deal with the inflation of a volcano edifice due to elevation of pressure and magma intrusion.

In recent years the use of Distributed Acoustic Sensing (DAS) in seismology is gaining extensive usage in different applications. A High-Fidelity DAS system (HDAS) was deployed during the 2021 Tajogaite eruption on Cumbre Volcano (La Palma, Canary Islands), allowing the recording of most of the syn-eruptive and post-eruptive seismicity. The eruption lasted from Sep. 19^{th} until Dec. 13^{th} of 2021. The HDAS was installed on 19^{th} Oct. 2021 and is still operating.

The HDAS was installed around 10 km from the eruptive vent and was connected to a submarine fibre optic cable directed toward Tenerife Island. Since then, the HDAS has been recording seismic with a temporal sampling rate of 100 Hz and a spatial sampling rate of 10m for a total length of 30 (first phase) and 50 km using Raman Amplification (last period).

The HDAS recorded thousands of local earthquakes as well as regional and teleseismic events. It was revealed to be an excellent tool for volcanic monitoring, allowing a better location of deeper events which location was made difficult by the small aperture of the seismic network of La Palma.

The HDAS was also able to record the low-frequency (<1 Hz) component of the volcanic tremor up to a distance of tens of kilometres from the volcano. We show how, using array-like techniques, it is possible to identify and separate the volcanic tremor signals from the oceanic ambient noise. In this work, we demonstrate the effectiveness of using DAS as a real-time volcano monitoring tool.

This work is devoted to the analysis of the background seismic signal acquired in volcanic areas, specifically Campi Flegrei caldera (Italy), with the main aim to extract the statistical characteristics of the several transients and persistent signals occurring in that area. Indeed, any continuous seismic acquisition is not a trivial superposition of several seismic contributions coming from different internal or external sources. In particular, looking at the crisis of 2006 at Campi Flegrei, apart from the background hydrothermal noise, the meteo-marine contributions, and the anthropogenic noise, several Volcano-Tectonic and Long-Period events were recorded tracking the unrest phase. The identification of the statistical characteristics, in terms of high-order statistics and spectral contents, of any of these signals is crucial in the modeling and in the recognition. Here adopt the FIF analysis which is able to extract detailed information about the wavefield. We are able to identify the main characteristics of volcanic and non-volcanic signals, whose characteristics are general and not related to the investigated volcano. Moreover, this technique can well track any change in the dynamics of the caldera, revealing multi-scale patterns that are deeply changing when reaching the unrest phase. This provides a strong indication of the dynamic state of a volcano to be used in the monitoring processes.

Using machine learning for the classification of Seismic Signals at Vulcano, Italy

DOI: 10.57757/IUGG23-0436 - LINK

Susanna Falsaperla[1], Ferruccio Ferrari[1], Horst Langer[1], Salvatore Spampinato[1]
[1]Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Catania- Osservatorio Etneo, Catania, Italy

A Vulcanian eruption is described as an eruptive style with strong explosive characteristics. The name derives from the island of Vulcano in Italy, the first place in which it was observed during the last eruptive activity between 1888 and 1890.
In this paper we analyze the seismicity recorded at Vulcano during a seismic unrest starting in September 2021 and still present as of November 2022. The distinctive feature of this seismicity is the presence of a variety of signals, most of which have a very long period (~0.5 s) signature. Low frequency content is interpreted as due to fluid involvement. Therefore, the high occurrence rate of VLP seismicity is a potential indication of pressure buildup within the volcanic system, and may herald phreatomagmatic activity (usually the first stage of a Vulcanian eruption), with serious consequences for inhabitants and tourists.Our analyses exploit machine learning procedures, with particular reference to pattern classification, at the aim of identifying varying classes of seismic events and trace their evolution over time. This classification can be useful for surveillance purposes contributing, along with other early warning methods, to reduce the devastating consequences of eruptions for people and property.

Stress transfer between volcanic dyke and seismic activity accompanying the 2021 Fagradalsfjall eruption, Iceland

DOI: 10.57757/IUGG23-4698 - LINK

Tomas Fischer[1], *Pavla Hrubcova*[2]
[1]*Charles University- Faculty of Science, Applied geophysics, Prague, Czech Republic*
[2]*Institute of Geophysics- Academy of Science, seismic, Prague, Czech Republic*

The 2021 Fagradalsfjall volcanic eruption in the Reykjanes Peninsula, Iceland, was preceded by a M_L 5.3 earthquake of 24 February 2021, which was followed by an intensive earthquake swarm lasting one month. Precise relocations show two hypocenter clusters in the depth range of 1-6 km. The swarm and later eruption occurred in the area which was the place of several swarms in the period of 2017-2020. We analyze the spatiotemporal characteristics of the activity, the Coulomb stress change caused by the ML 5.3 earthquake and by the magmatic dyke and the moment tensors of previous swarms to better understand the stress transfer between seismic and magmatic activity.

Our analysis shows a coincidence of several phenomena which could have contributed to driving the seismic and volcanic activity. The stress change analysis suggests that the forming magmatic dyke has increased the Coulomb stress on the M_L 5.3 earthquake fault. The following earthquake rupture resulted in unclamping of the fissure where the dyke formed and in Coulomb stress increase in the area of aftershocks and the following earthquake swarm. The WSW-ENE trending cluster of the 2021 and previous swarms show a stepover, forming an extension structure at the intersection with the dyke. And the moment tensors of the 2017 swarm events show that volumetric components vary along the cluster. Interestingly, the 2021 eruption occurred in the extension structure, suggesting that magma erupted at the place of crustal weakening.

Strain-rate field of Japan estimated from GNSS data using basis function expansion with ABIC

DOI: 10.57757/IUGG23-2680 - LINK

Yukitoshi Fukahata[1], Tomohisa Okazaki[2], Takuya Nishimura[1]
[1]Kyoto University, Disaster Prevention Research Institute, Uji, Japan
[2]Riken, Center for Advanced Intelligence Project, Seika- Kyoto, Japan

Estimation of a strain-rate field from spatially discrete geodetic data has been a longstanding issue. On this problem, Okazaki et al. (2021) has recently developed a method based on basis function expansion with smoothness prior. In their method, the relative weight between observed data and the prior are objectively determined by Akaike's Bayesian information criterion (ABIC; Akaike, 1980; Yabuki and Matsu'ura, 1992); bi-cubic B-spline functions are used for basis functions, which makes inversion computation much faster (Nozue and Fukahata, 2022). By applying the method to GNSS data in Japan, strain-rate fields are estimated for three periods: 1997-1999, 2006-2009, and 2017-2020; the number of the used GNSS sites for each period is 880, 1337, and 1340. Except for deformation related with volcanic activities and large earthquakes, the obtained strain-rate fields are roughly stationary in time, while they show large variation in space. In order to interpret such spatially heterogeneous deformation, plate tectonics is considered to be inappropriate, because it basically postulates rigid motion for each plate. Instead, we propose a framework of inter-arc and intra-arc deformation, considering that Japanese Islands are composed of five island arcs (Kuril, northeast Japan, west Japan, Izu-Bonin, and Ryukyu). Using the framework, we can easily classify complicated deformation in Japan into the inter-arc deformation, such as the formation of the Hidaka Mountains, and the intra-arc deformation, such as the Niigata-Kobe tectonic zone.

Stress and strain on Mt Etna. A synopsis of 20 years of continuous monitoring of seismic and ground deformation data

DOI: 10.57757/IUGG23-0837 - LINK

Horst Langer[1], Luciano Scarfi[1], Marco Aloisi[1], Graziella Barberi[1]
[1]Istituto Nazionale di Geofisica e Vulcanologia, Osservatorio Etneo, Catania, Italy

Continuous acquisition of high quality geophysical data allows developing a comprehensive geodynamical picture of Mt. Etna and the adjacent areas. We focus on seismic and ground deformation data recorded in the time span 2002 to 2021. Ground deformation measurements on the western flank of the volcano reveal a general trend of inflation, which is an expression of volcano doming and progressive magma accumulation.

The seismicity on Etna shows a rather heterogeneous picture. In general, hypocenter depths increase from SE towards NW. Besides, shallow events are frequent in the central part of the area. Focal mechanisms provide information about the forces acting in the seismic source and rupture orientation. We used unsupervised learning - Self Organizing Maps and K-means clustering - for the classification of 577 seismic moment tensors.

In the shallow levels normal faulting is frequent. The dispersion of strike direction of the axes for these events mirrors the complex stress field caused by magma dynamics in the shallower portion of the plumbing system. P- and T- axes of deeper events – orientated radially and concentric with respect to the summit area - indicate the existence of a pressure source in the central part of the volcano. The volcano related stress field interferes with the regional field, partly overriding it. The prevalence of the former becomes evident by comparing strain release for volumes inside the volcano edifice to those for adjacent volumes. It is five to ten times larger than in adjacent areas even for the deepest layers.

Changes in the seismic complexity prior to and during the 2014 Holuhraun eruption in Iceland

DOI: 10.57757/IUGG23-3850 - LINK

Maria R.P. Sudibyo[1], *Eva P. S. Eibl*[1], *Sebastian Hainzl*[2]
[1]*University of Potsdam, Institute of Geosciences, Potsdam, Germany*

Section 2.1: Physics of Earthquakes and Volcanoes, Potsdam, Germany

Changes in seismic complexity could reveal the dynamic changes inside a volcanic system prior to an eruption, which can be utilized to improve eruption forecasting. Permutation Entropy (PE) is a robust method to quantify the complexity of a time series, by calculating it directly using the amplitude. Examples of successful PE applications are eruptions forecasting at Strokkur Geyser, Iceland, the 1996 eruption of Gjálp, Iceland, and the eruptions of Shinmoedake volcano, Japan, in 2011, 2017, and 2018. While PE could show temporal changes prior to an eruption, these features are not always prominent. To improve this method, we calculated not only PE by using seismic amplitudes, but also Phase Permutation Entropy (PPE) by using seismic instantaneous phases. We calculated both PE and PPE for seismic station FLUR from January 2014 to December 2015, which covers the eruption period of Holuhraun in Iceland. During the unrest period, both PE and PPE show changes in entropy, but their patterns are not always the same. While PE shows a strong increase which marks the onset time of dyke propagation two weeks before the main eruption, it does not show a clear transition toward the main eruption. In contrast, PPE only shows a gradual change when the dyke started migrating. Jowever, it displays strong changes at the possible subglacial eruptions on 23 August, the small eruption on 29 August, and the main eruption on 31 August 2014. This proves the capability of PE and PPE to contribute to the framework of eruption forecasting.

Volcanic tremor is a semi-continuous seismic and/or acoustic signal that occurs at time scales ranging from seconds to years, with highly variable amplitudes and spectral features. Having a fast, robust, automated method to detect and characterize tremor in high temporal resolution would be beneficial to eruption forecasting and monitoring efforts, as well as to retrospectively building tremor catalogs for research purposes. As part of the NSF-funded PREEVENTS eruption forecasting project, we test and develop a pair of machine learning algorithms (one for seismic, one for acoustic) that can detect tremor in near-real time and classify it according to its spectral signature. First, we manually label tremor time windows on single station seismic and low-frequency acoustic (infrasound) spectrograms from the 2021-2022 eruption of Pavlof Volcano, Alaska, and train a convolutional neural network and random forest algorithm for both data types. We then use the trained models to classify seismic and infrasound data leading up to, during, and after the eruption, and compare temporal trends observed in our classifications alongside eruption chronologies compiled by the Alaska Volcano Observatory. We also implement a local network-wide weighting scheme to reduce false detections. Lastly, we assess the transferability of our models by applying them on unseen data recorded from past eruptions at Pavlof and other Alaska volcanoes. We envision that our machine learning models will aid tremor-related monitoring and research, and will advance our understanding of the relationship between tremor and subsurface volcanic processes by making consistent tremor catalogs more accessible.

Volcanic tremor related to the activity of Volcán de Colima during December 2014 to August 2015

DOI: 10.57757/IUGG23-4788 - LINK

Dulce Vargas-Bracamontes[1], Jesús Quiroz-Rodríguez[2], Rebeca Martínez Alvarez[2], Norma Elizabeth Quiroz-Pérez[2], Raúl Arámbula-Mendoza[3]
[1]CONACYT-Universidad de Colima, Centro Universitario de Estudios Vulcanológicos, Colima, Mexico
[2]Universidad de Guadalajara, Centro Universitario del Sur, Cd. Guzmán, Mexico
[3]Universidad de Colima, Centro Universitario de Estudios Vulcanológicos, Colima, Mexico

During July 10th and 11th, 2015, Volcán de Colima experienced the most intense volcanic eruption since its Sub-Plinian explosion that occurred in 1913. During this phase, pyroclastic density currents were generated, reaching up to 10.3 km south of the volcano. Starting in January 2015, there was a significant increase in the occurrence of tremor signals including harmonic, monochromatic, broad-spectrum, spasmodic and banded tremor, as well as tremor composed of LPs and tremor accompanying Vulcanian explosions. In this study, we quantified the different types of tremor observed and correlated their occurrence throughout the various eruptive phases presented within the period December 2014 to August 2015. We also characterized the evolution of these tremors, determining their fundamental frequencies, overtones, spectral range, amplitudes, and patterns in the frequency gliding. This allows for a better understanding of the changes presented in the precursory, eruptive and post-eruptive seismicity related to the constant activity of the volcano during the period under study. Finally, we evaluated possible models that could explain the generation of the tremor signals recorded during the analyzed period.

During July 10th and 11th, 2015, Volcán de Colima experienced the most intense volcanic eruption since its Sub-Plinian explosion that occurred in 1913. During this phase, pyroclastic density currents were generated, reaching up to 10.3 km south of the volcano. Starting in January 2015, there was a significant increase in the occurrence of tremor signals including harmonic, monochromatic, broad-spectrum, spasmodic and banded tremor, as well as tremor composed of LPs and tremor accompanying Vulcanian explosions. In this study, we quantified the different types of tremor observed and correlated their occurrence throughout the various eruptive phases presented within the period December 2014 to August 2015. We also characterized the evolution of these tremors, determining their fundamental frequencies, overtones, spectral range, amplitudes, and patterns in the frequency gliding. This allows for a better understanding of the changes presented in the precursory, eruptive and post-eruptive seismicity related to the constant activity of the volcano during the period under study. Finally, we evaluated possible models that could explain the generation of the tremor signals recorded during the analyzed period.

The recent advances in the hardware development of instruments that record gradients of the seismic wavefield made several novel measurement strategies at active volcanoes possible. Especially the recording of rotational motions is a prominent candidate to solve some of the problems that are eminent in volcano monitoring. Near field recordings of volcano-induced events often suffer from unaccounted effects of local tilt and unknown shallow velocity structure. In addition, if the station number is limited moment tensor inversions (MTI) are very often unconstrained. However, possible advantages of gradient measurements in these fields come also with a price: the wavefield gradient is very sensitive to local site conditions/heterogeneities.
To investigate the advantages and drawbacks of the combined recording of translational and rotational motion measurements (6C), we designed an experiment using six blueSeis-3A rotational motion sensors together with six TrilliumCompact seismometers at Stromboli volcano, Italy. In order to estimate the responses of different sites as well as to evaluate the performance of 6C recordings for location and moment tensor inversion, the stations were distributed along two rings at different height levels. Standard estimates of backazimuth and 1D-velocity profiles using 6C are performed. The results are compared to synthetic data which involve growing complexity of the modelled structure. The results of this tests confirm that local heterogeneities play a key role in the complexity of the recorded gradient wavefield. This complexity needs to be accounted for in order to be able to perform a MTI which should reduce the ambiguity using sparse seismic networks.

In this work we present one of the most spectacular fireball events detected by the MOROI (Meteorite Orbits Reconstruction by Optical Imaging) (Nedelcu et al. 2018) part of the FRIPON (Fireball Recovery and Inter Planetary Observation Network) (Colas et al. 2020) all-sky camera network. The meteor was recorded on 3rd of November 2022 at 01:30:03 UT by cameras Bacau (ROBC01), Paulesti (ROPH01) and Obarsia Noua (ROOT01). The ablation phenomenon started at an altitude of 95 km above the sea level and the meteoroid fainted/ left the Earth's atmosphere at 90.6 km. The fireball event had a duration of 12.22 seconds. We determine the physical parameters of the meteoroid resulting from the luminous trajectory (Gritsevich 2008, 2009, Sansom et al. 2019, Boaca et al. 2022). We compute its mass, its velocity and determine the orbital elements using Meteor Toolkit (Dmitriev et al. 2015).

Development of 2.05 um Fiber Lasers for CO2 DIAL lidar Measuring Martian CO2 and Pressure

A new concept of Martian differential absorption lidar (DIAL) operating in the 2050 nm CO2 absorption band for atmospheric CO2 and pressure observations has been proposed recently. Based on the concept, we are awarded to develop 2.05 um fiber lasers by the NASA Planetary Instrument Concepts for the Advancement of Solar System Observations (PICASSO) Program. The laser is designed to be an all-fiber master oscillator and power amplifier (MOPA) system with laser output of ~3 mJ at a repetition frequency of 2 kHz. The primary master oscillator (PMO) is locked to the center of the selected CO2 absorption line (2050.428 nm). The frequency of a second MO (SMO) is locked to that of PMO. This SMO frequency is adjustable and switched between the online (2050.44156 nm) and offline (2050.50812 nm) wavelengths for demonstration. The online wavelength is optimally selected so that the CO2 absorption optical depth (AOD) is ~1.1 at 3 km and the measurement in the low Martian atmosphere has largest signal-to-noise ratio. The online wavelength can also be adjusted to a line slope location where AOD is larger to observe atmospheric pressure at higher altitudes. We will present more detail about this project and instrument development at the conference.

Towards constraining Venus structure by means of atmospheric loading displacement response

DOI: 10.57757/IUGG23-2575 - LINK

Surface mass loads produce a wide spectrum of deformation responses in planetary bodies that can be exploited to probe material properties in planetary interiors. In particular, the redistribution of fluid mass associated with Venus's atmospheric dynamics leads to periodic changes in the Venusian surface displacements and thus gravitational field. These periodic variations could potentially be detected by upcoming Venus missions, e.g., VERITAS (Venus Emissivity, Radio Science, InSAR, Topography, and Spectroscopy) and EnVision, which are expected to greatly improve our knowledge of Venus's gravity field.

By combining a state-of-the-art general circulation model of Venus's atmosphere with a novel approach to the solution of the quasi-static momentum equations in the coupled gravito-elastic problem, we explore the sensitivity of the atmospheric loading response to mantle structure. In addition, we investigate the effect of 3-D crustal and lithospheric variations on Venus's gravity field and the tidal and load Love numbers. Preliminary results suggest that an accurate estimation of the time-varying gravity field and surface displacements can provide important constraints on the interior structure of Venus through the measurement of the load Love numbers.

Analysis of SL-Index and Hot Spot for extraction and quantification of knickzones over the Upper Alaknanda for prolonged river profile

DOI: 10.57757/IUGG23-3331 - LINK

Priyanka Negi[1], Ajanta Goswami[1], Girish Chandra Joshi[2]

This work presents the SL-Index, one of the geomorphic indices which is extremely sensitive to variations in river gradient and serves as a useful tool for highlighting the disturbances along a river. In this study, we perform the different segmentation method with 3 fixed values of horizontal spacing (dL) = 1000 m, 1500 m, and 2000 m of the Middle Alaknanda Catchment. The SL-Index value was employed for the successive SL-Hot spot approach and further the SL-HCA map shows the spatial distribution of hot and cold spot using interpolation technique, that helps to select the zone of large landslides and principal knickzones. We generally concentrated on the positive or high anomaly since high values predicted over-steepened segments along the river channel. Then, to investigate the possibility of identifying the knickzones on a longitudinal stream profile, the analyses for this work were carried out using a 10 m resolution grid. The height and the elevation of knickpoints were analysed and it was observed that the largest portion of the knickpoints is situated in the upper part of the catchment or near river head. Further, to validate the SL-HCA approach, various knickpoints along the drainage network were assessed through the aerial imagery, validated with the detailed field survey. The findings of our result shows that the SL-index correlated well with knickpoints that controls the intensity of SL values is related to rock differential erosion, landslides, lithological variations, base-level changes, and the meandering course of the river.

Keywords: SL-Index, longitudinal river profile, knickzones, Alaknanda

Imaging of NE Japan volcanic arc by wide-band magnetotellurics

DOI: 10.57757/IUGG23-0555 - LINK

Shogo Masuda[1], *Yasuo Ogawa*[2], *Ichiki Masahiro*[3]

Resistivity is a physical parameter sensitive to the existence and connectivity of the crustal fluids and melts. In this paper, we present a 3-D resistivity model covering an area of 50km x 50km in the central part of the NE Japan volcanic arc. We have compiled wide-band magnetotelluric data, which were collected over 30 years. We used full impedances and tippers of the 410 stations between 0.4 and 1,300s periods.

The final model shows the existence of a continuous low resistivity belt in the SSW-NNE direction along the volcanic arc in the deep crust (20 km to 30 km depth). On the forearc side, we also see a distribution of low resistivity anomalies, which imply fluid upwelling. These low resistivity anomalies in the deep crust correspond to strain-concentration areas along the volcanic arc and the forearc. The low resistivity zone along the volcanic arc locally shallows to a depth of 10 km, branching toward active quaternary volcanoes, such as Naruko volcano, Mt. Kurikoma, Onikobe caldera, and Takamatsu-dake. These swallow anomalies below the volcanoes imply magmatic melt and correlate well with the co-seismic subsidence zones due to "2011 off the Pacific coast of Tohoku earthquake" detected by InSAR.
