The mission of the International Seismological Centre (ISC) is to produce the most long-term and complete Bulletin of instrumentally recorded seismicity on a global scale. We describe recent achievements in rebuilding the entire ISC Bulletin using the new ISC locator, ak135 velocity model and more robust magnitudes. We explain the plans of extending the Bulletin with earthquake solutions and station readings in the early instrumental period (1904-1963). We note the recent ISC efforts in constraining the depths of moderate to large seismic events by taking the depth phase arrival time measurements from the waveforms freely available on-line and building Probabilistic Point Source Model solutions (ISC-PPSM). We also explain the future of the International Seismograph Station Registry (IR) and its place within the FDSN registry of seismic networks.

In addition, we produce several specially designed data products that stemmed from the ISC Bulletin and allowed ISC to assist several different areas of seismological research. These datasets include ISC-EHB dataset (1964-2020), ISC-GEM catalogue (1904-2019), IASPEI Reference Event List (GT, 1959-2020), ISC Event Bibliography (1904-2023). We also describe the supplementary datasets: the Electronic Archive of Printed Station/Network bulletins, the Seismological Dataset Repository, and the International Seismological Contacts.

Carbon capture and storage technologies are an essential part of EU's decarbonisation efforts. Combined with sustainable energy resources, they are necessary to move Europe towards a net zero carbon emissions economy. Containment risk evaluation includes analysing natural seismicity patterns in the North Sea, where several Mt-scale CO_2 storage projects are being developed. Within the framework of the ACT project SHARP Storage, an extensive unique earthquake bulletin was compiled using seismicity data from all relevant data centres. The bulletin is stored using the IASPEI Seismic Format (ISF). Preliminary processing included duplicate removal and explosion identification. In total, 15,230 events were recorded between years 1382 and 2022, of which 5,408 were identified as likely or potential explosions. For the remaining events, waveforms are currently being collected as a basis for further analysis, including event relocation and magnitude homogenisation.

The magnitude of completeness of this data set varies both spatially and temporally. The most seismically active regions in the study area are the Viking and Central grabens. Coastal areas are populated with more events than the central part of the North Sea due to the denser distribution of seismic stations onshore allowing for the detection of smaller ($M<3$) magnitude events.

Moment tensor inversion, shear-wave splitting measurements, and stress drop analysis will be compared to and complement a review of borehole stress measurements to better gauge the present-day stress field. This is crucial for the understanding of the reservoir and caprock response to large-scale CO_2 injection over time.

The characteristics of seismogenic zone in eastern Taiwan: Implications from seismic b-value

DOI: 10.57757/IUGG23-0534 - LINK

Yu-Lien Yeh[1], *Bor-Yu Huang*[1], *Strong Wen*[1]
[1]*National Chung Cheng University, Department of Earth and Environmental Sciences, Chiayi, Taiwan Province of China*

Taiwan is located on a convergent boundary of the Eurasian Plate and the Philippine Sea Plate. It is one of the countries that have experienced the most earthquakes worldwide. The eastern region of Taiwan is directly above the collision zone and is the most frequent and active with domestic earthquake activity. The areas also have dense dynamic fault systems which located in the Yilan, Hualien, and Taitung areas. Those areas record huge amount of earthquakes yearly. Since seismic b-value has been investigated in different periods throughout Taiwan in the past, they have not yet to study the b-value of the eastern region of Taiwan in detail. Therefore, this study uses the earthquake catalog integrated by the Central Weather Bureau to analyze the spatial-temporal variations of b-values in east Taiwan. The seismic events recorded from January 1996 to June 2019 are adopted. Areas with a low seismic b-value often represent potential areas where major earthquakes are likely to occur. Our results indicate that in eastern Taiwan, the overall b-value has generally demonstrated a decreasing trend in recent years. The rapid re-accumulation of internal stress possibly caused by the compression of the two plates and the ongoing seismogenic behavior. The potential for a catastrophic earthquake is exceptionally high. Therefore, we should act appropriately at any time.

Coexistence of thin-skinned and thick-skinned tectonics near the deformation front in southwestern Taiwan: Implication from a dense seismic array

DOI: 10.57757/IUGG23-0458 - LINK

Wei-Hau Wang[1], *Yi-Shen Lin*[1], *Wei-Chen Huang*[1], *Strong Wen*[1], *Yu-Lien Yeh*[1], *Huey-Chu Huang*[1], *Ying-Nien Chen*[1], *Ruey-Chyuan Shih*[1], *Yu-Chih Huang*[2]

[2]*National Center for Research on Earthquake Engineering, Earth Sciences and Geotechnical Engineering Division, Chiayi, Taiwan Province of China*

While many studies suggested that thick-skinned deformation may occur in the interior of a mountain belt and a thin-skinned contraction wedge is predominant near the foothills, we report the coexistence of both thin- and thick-skinned deformation beneath the foreland basin in southwestern Taiwan based on the high-resolution microearthquake distribution observed by a dense seismic array. We revealed three major tectonic elements in our study area, which are

1. A basal decollement of the thin-skinned wedge at a depth of about 5 km beneath the foothills and coastal plain.
2. A westward-dipping backthrust extending from the foothills to a depth of about 15 km beneath the Coastal Plain.
3. Foreland-vergence blind thrusts rooting on top of the backthrust at depths below ca. 8-15 km.

The foreland-dipping back thrust may result from reactivating an ancient normal fault for being associated with an inverted half-graben. Our numerical modeling further demonstrated that this pre-existing normal fault becomes a passive roof thrust during later orogenic contraction. The rotation and westward movement of this backthrust would compress the rocks in front of it and create blind thrusts beneath the Coastal Plain. This thick-skinned deformation may also have affected the overlying tectonic wedge by building a ramp on the shallow decollement. As a result, the proto-Dajienshan fault might form at the ramp where stress concentrates.

Focal parameters analysis of earthquakes in the S-SE of the Iberian Peninsula (1900-1962)

DOI: 10.57757/IUGG23-0871 - [LINK]

Javier Fernandez Fraile[1], *Maurizio Mattesisni*[2], *Elisa Buforn Peiro*[2]
[1]*National Geographic Institute of Spain, National Seismic Network, Madrid, Spain*
[2]*Complutense University of Madrid, Department of Earth's Physics and Astrophysics, Madrid, Spain*

The objective of this study is to review the Seismic Catalogue of the National Geographic Institute of Spain (IGN, Instituto Geográfico Nacional) for the largest earthquakes occurred in the S-SE zone of the Iberian Peninsula during the period 1900-1962 using all the available information, some of them not used previously. These observations are very heterogeneous, so we have also established a methodology, that allow to evaluate it and thus be able to carry out a joint analysis of the data.

We have selected 16 earthquakes with maximum intensity larger than V and re-evaluated the intensity and the epicenter. Our results shown that at the IGN intensity was overestimated for 9 events with greater variations than one intensity degree in 4 earthquakes (for example from VII to V-VI on November 25th, 1913, earthquake, in Granada). The main factor for these changes in the intensity is the use of the EMS-98 scale that take in the vulnerability of buildings. Only for the April 25th, 1912, earthquake, intensity was underestimated, IV versus the new IV-V intensity.

We have also re-evaluated the epicenters reviewing both macroseismic and instrumental information. We have updated the epicenter of 13 earthquakes with greater variations than 10 km in 4 cases. The largest epicenter modification corresponds to August 11th, 1913 (I_{max}= VII), earthquake. There is a confusion with the name of the population that suffered the greatest effects, and for this shock its macroseismic epicenter has been moved 41 km to the NW from the IGN epicentre using contemporary sources.

The West-Bohemian/Vogtland region (Germany/Czech Republic) is well known for its frequent intraplate swarm activity related to fluid flow within the crust. Previous studies found that non-double-couple components (non-DC: isotropic, CLVD) contribute significantly to the seismic moment tensors of these events. They were interpreted as tensile faulting associated with the migration of deep magmatic fluids through the crust. However, so far the results are restricted to a few larger events. The accurate and precise determination of non-DC components during waveform inversion for moment tensors is difficult, especially for smaller magnitude events (M<3.5).

In earlier synthetic studies the joint inversion of translational and rotational waveforms improved the resolution of the moment tensor. In this project "NonDC-BoVo" – funded within the frame of the ICDP EGER project – two rotational sensors were deployed collocated with translational seismometers. The acquired data present one of the first examples using field data to invert waveforms for the moment tensor. The sensors show a good sensitivity even for low magnitude events. In seven months, the "Seismologie-Verbund zur Erdbebenbeobachtung in Mitteldeutschland" reports 521 events occurring within a distance of up to 30 km.

Here, we present data examples together with an estimation of the magnitude of completeness from rotational recordings. Based on the signal-noise-ratio, we estimate a magnitude of completeness of around 0.3 for the rotational data compared to -0.7 from the catalogue. We found that the transversal translation corresponds well to the vertical rotation for a phase velocity of 2000 m/s at frequencies of 10-20 Hz.

From the laboratory to the field: A traceable on-site calibration approach for seismometers

DOI: 10.57757/IUGG23-3271 - [LINK]

Michaela Schwardt[1], Christoph Pilger[1], Leonard Klaus[2], Thomas Bruns[2], Lars Ceranna[1]
[1]Federal Institute for Geosciences and Natural Resources,
B4.3 Federal Seismological Service- Nuclear-Test Ban, Hannover, Germany
[2]Physikalisch-Technische Bundesanstalt, Department 1.7 - Acoustics and Dynamics,
Braunschaweig, Germany

As part of the EU-funded joint research project "Metrology for low-frequency sound and vibration - 19ENV03 Infra-AUV" laboratory calibration methods for seismometers in the low frequency range down to 0.01 Hz have been developed. These procedures provide the possibility of traceable on-site calibration during operation for field sensors without disturbing the regular measurements and allow an accurate determination of amplitude and phase along with measurement uncertainties. This is of special interest for stations of the Comprehensive Nuclear-Test-Ban Treaty Organization's (CTBTO) International Monitoring System (IMS), which are required to be operational 100% of the time.

The on-site calibration procedure requires a reference sensor co-located to the operational station sensor and the record of sufficient coherent excitation signals within the relevant frequency range. The gain ratio between the station sensor under test and the reference sensor is calculated and subsequently multiplied with the precise frequency response of the reference provided by the newly developed laboratory calibration methods, yielding the frequency response function for both amplitude and phase of the station sensors including site-specific factors.

We present results of on-site calibration tests performed at the seismic IMS station PS19 in Germany using reference seismometers calibrated by laser interferometry in the laboratory. The results deviate less than 5% from the nominal response function for frequencies between 0.01 Hz and 20 Hz for all components. The traceable determination of the response for the individual components in detail improves the sensor and data quality; subsequently waveform amplitudes can be estimated correctly.

Exploration and Application of Gravitational Curvatures Changes in Earthquake Deformation

DOI: 10.57757/IUGG23-1694 - LINK

Yuting Ji[1,2], *Robert Tenzer*[2], *He Tang*[1], *Wenke Sun*[1]
[1]*University of Chinese Academy of Sciences, College of Earth and Planetary Sciences, Beijing, China*
[2]*Hong Kong Polytechnic University, Department of Land Surveying and Geo-Informatics, Hong Kong, China*

The objective of this study is to enhance the observation and understanding of earthquake deformation by developing a method for describing coseismic changes in gravitational curvatures (GC). GC are third-order derivatives of the Earth's gravitational potential, represented as a 3-D tensor matrix with twenty-seven components, ten of which are independent. To achieve this, we first investigate the dislocation Love numbers of the Earth's gravitational potential and derive the Green's functions of GC caused by four independent point sources in a spherical inhomogeneous Earth model. The forms of changes in a half-space Earth model are then presented. Furthermore, a sensitivity study is conducted on three physical quantities involving gravitation, gravitational gradients, and GC to determine their usefulness in seismic source depth detection. Our numerical results show that changes in the GC are more sensitive to the medium information of the field source compared to gravitation and gravitational gradients. This finding indicates that measurements of GC could provide more detailed information on slip fault parameters when considering heterogeneous slip. The method was successfully applied to the 2011 Tohoku-Oki earthquake. In conclusion, measurements of the third-order derivatives of the gravitational potential have great potential in solid Earth studies, especially in light of the launch of the *Gravity* Field and Steady-State Ocean Circulation Explorer (*GOCE*) satellite mission. However, further work is needed in terms of instrument design and development.

How seismometers tilt in response to atmospheric pressure variations: the case of the Hunga Tonga Lamb wave.

DOI: 10.57757/IUGG23-2918 - LINK

Rudolf Widmer-Schnidrig[1], *Walter Zürn*[2]
[1]*Black Forest Observatory, Institute of Geodesy at University of Stuttgart, Wolfach, Germany*
[2]*Black Forest Observatory, Geophysical Institute at KIT, Wolfach, Germany*

The Hunga-Tonga eruption excited atmospheric Lamb waves that circled the globe multiple times and were recorded by barometers and broad-band seismometers of the Global Seismic Network (GSN). Their dominant period was 45 minutes with typical amplitudes of 2-3 hPa.

Based on our previous work we expect that the response of horizontal seismometers at these periods is dominated by tilts due to two distinct physical mechanisms, LDT and TWT: local tilt due to warping of the seismic vault floor (LDT) in response to atmospheric pressure variations and a regional tilt (TWT) due to a lateral pressure gradient along the surface.

We have inspected all the GSN recordings of the Hunga Tonga Lamb wave and only retained 21 stations with clean baro- and seismograms. We find that for any three component sensor the tilt due to vault deformation points in a fixed, sensor specific direction independent of the propagation direction of the Lamb wave. Furthermore we find that LDT is larger than TWT at 80% of retained GSN stations. While accelerations can be well modelled in most cases, pressure gradient induced ground tilts point towards Hunga Tonga for only 7 stations.

Curently we lack any model which would allow us to explain the observed TWT tilt directions for the remaining 14 stations as we do not think that deformations of the Lamb wave front due to wind or atmospheric temperature variations can account for the observed tilt misalignments.

Simulation of atmospheric waves induced by the 2022 Hunga-Tonga volcanic eruption——New insight into the Lamb waves

DOI: 10.57757/IUGG23-1368 - LINK

Shenjian Zhang[1], *Rongjiang Wang*[2], *Xiaofei Chen*[1]
[1]*Southern University of Science and Technology, Department of Earth and Space Sciences, Shenzhen, China*
[2]*Helmholtz Centre Potsdam, GFZ German Research Centre for Geosciences, Potsdam, Germany*

The 15 January 2022 eruption of the Hunga-Tonga volcano generated huge explosions in the atmosphere, which excited various kinds of atmospheric disturbances detected globally by ground-based or spaceborne instruments. Here we show our simulations of these atmospheric waves along with a summary of observation findings. The modelling is achieved by a complete synthetic seismogram calculator (QSSP) considering a hybrid approach of the normal mode theory and matrix method in a layered spherical Earth model including the atmosphere. The synthetic waveform profile, the spectra for nearby stations, as well as the dispersion curves extracted in an array all show good agreement with the observations. Based on these results, especially the dispersion curves for phase speed, we propose a new interpretation for the horizontally propagating Lamb wave. In this model, the Lamb wave can be regarded as the fundamental gravity modes in low frequency band and the fundamental acoustic modes in high frequency band, respectively. The findings may provide new perspectives on the analysis of general atmospheric waves and show the potential of seismic techniques on atmospheric problems.

The 22 December 2018 Anak-Krakatau volcanic flank collapse triggered a devastating tsunami along the Sunda Strait coast, highlighting the need for tsunami early warning systems to detect both volcanic collapse and landslide tsunami triggering from real-time seismic data. Seismically, landslides are deficient in high-frequency radiation compared to tectonic earthquakes. In this study, carried out in the framework of the TSUNAMI_RISK project, we implemented spectral analysis and back-projection to locate low-frequency events (40-70 s) along the Indonesian coast, specifically volcano-induced landslides. Using the Indonesian seismic network, we successfully detected and located the Anak-Krakatau volcanic flank collapse. The back-projection method allowed us to estimate the location about 100 seconds after the event initiation, with detection achieved with stations up to 1° from the source. To assess potential biases in our approach, we evaluated two weeks of continuous long-period seismic data (11-25 November 2019) from high-risk volcano tsunami areas in eastern Indonesia, such as Batu Tara, Iliwerung, Gamalama, and Sangeang Api. We conclude by discussing the expected false alarm rates for various warning thresholds based on the current network configuration in Indonesia and explore the routes to implementing this approach for operational tsunami early warning.

UPFLOW OBS body wave tomography of the whole mantle column beneath the Azores/Madeira region

DOI: 10.57757/IUGG23-3396 - LINK

Maria Tsekhmistrenko[1], *Ana Ferreira*[1]
[1]*UCL, Earth Sciences, London, United Kingdom*

We present preliminary tomographic results obtained within the ERC-funded UPFLOW (Upward mantle flow from novel seismic observations; https://upflow-eu.github.io/) project, which led a passive seismology large-scale experiment in the Azores-Madeira-Canaries region starting in July 2021 and ending in September 2022.
We recovered 49 (out of 50) ocean bottom seismometers (OBSs) deployed in a ~1,000×2,000 km2 area and with an average station spacing of ~150-200 km. We present an initial set of ~6000 multi-frequency (T ~2.7-30 s) body-wave travel time cross-correlation measurements generated with the UPFLOW OBS data from more than 150 teleseismic events. We show a glimpse of the preliminary P-wave tomographic model built with this new dataset. We then combine UPFLOW's OBS data with global seismic data from temporary and permanent stations to obtain an expanded set of ~600,000 measurements. This dataset is used to construct a global P-wave model with enhanced resolution in the entire mantle column beneath the Azores/Madeira/Canaries region. We compare our new, high-resolution model with existing global tomography models and discuss its geodynamical implications.

Madeira is discussed to be a hotspot volcanic complex in the Northeast Atlantic placed on 140 Ma old oceanic lithosphere. Catalog seismicity beneath and around Madeira is sparse and hypocenters are often not well constrained due to lack of station coverage. In 2020 and 2022 two events with Mw 5.3 and Mw 4.9 were widely felt on the island. We used data of a local seismic network consisting of 24 temporary stations in the years 2011-2012 and up to 4 permanent stations to reveal the local seismicity in the Madeira archipelago. We used an adapted velocity model and the LASSIE detection software and found more than 220 additional events, which we located using HYPOSAT. Most of the events concentrate about 30-40 km south of the main island with hypocenter depths in the range of 20 up to 40 km. The seismicity stops at the south coast of Madeira and starts again north of the main island. Other zones of activity are found in the East of Madeira and in the vicinity of Desertas Grande island southeast of Madeira. Hypocenter depths beneath Madeira cluster between 10 and 20 km depth at Moho or sub-Moho level. Our data support the hypothesis that the center of volcanic activity in the archipelago might nowadays be associated with the southern end of the Funchal Ridge.

Shredded subducted Nazca plate leaves slab-fingers behind, in the mantle Beneath southern Costa Rica

DOI: 10.57757/IUGG23-1242 - LINK

Marino Protti[1], Vega Floribeth[1]
[1]Universidad Nacional, Observatorio Vulcanológico y Sismológico de Costa Rica, Heredia, Costa Rica

Subduction of parallel transform faults, at an oblique angle, generates jumps in age of the subducted oceanic lithosphere and produces pronounced bending of the subducting oceanic slab-fingers. Cocos plate subducts/collides under the Panama block in southern Costa Rica. A sequence of north-south parallel transform faults, the Panama Fracture Zone (PFZ), shreds and obliquely subducts fingers of Nazca Plate under southern Costa Rica and southwestern Panama, along an east-west margin. The oblique convergence of these slab-fingers causes the subducted fingers, once quasi anchored in the mantle, to stay behind as the PFZ moves westward with respect to the mantle, producing bending of the slab-fingers as the Cocos plate subducts above them.

For decades, the lack of a dense seismic network in southern Costa Rica has inhibited the acquisition of a detailed geometry of the subducting plates in this region. For that reason, intermediate depth earthquakes (Z 50-80 km) recorded under southern Costa Rica and straight projected to the trench, were interpreted as steep subduction of the young and buoyant Cocos plate. Alternatively, they were interpreted as intra-plate events along the deepest portion of an almost flat subducting Cocos plate.

Based on precise earthquake locations recorded with a dense broadband seismic network in southern Costa Rica, constructed and installed to capture seismic activity associated with the next Osa large (Mw 7.2-7.4) earthquake, we propose here a new model, according to which, seismic events deeper than 50 km occur on subducted fingers of Nazca plate stuck in the mantle, under southern Costa Rica.

Seismotectonics of Hornsund, Spitsbergen, European Arctic, based on moderate magnitude seismicity

DOI: 10.57757/IUGG23-2782 - LINK

Myrto Pirli[1], Johannes Schweitzer[2], Berit Paulsen[2]
[1]Independent Researcher, -, Skjetten, Norway
[2]NORSAR, Seismology, Kjeller, Norway

Accurate seismotectonic studies on and around Spitsbergen, European Arctic, are impeded by a number of difficulties. The largely glaciated environment and the geographic distribution of land and sea restrict geotectonic mapping, as well as the deployment of dense, local seismic networks. The nature of tectonic seismicity in the region, which is episodic and dominated by moderate to low event magnitudes, imposes additionally its own challenges. So far, the best studied activity has been the Storfjorden 2008-2016 earthquake series (Mw 6.1, 21 February 2008; Mw 5.1, 29 March 2016) and background seismicity in the offshore area east of southern Spitsbergen, and to a lesser extent, seismicity in Heerland, on central Spitsbergen (mb 5.5, 18 January 1976). Despite the aforementioned challenges, the improvement of the regional seismic network from 2010 onward, has been offering enhanced insight into Svalbard seismotectonics, in particular in areas best covered by seismic station distribution. One such case, is the Hornsund area, where the calculation of moment tensor solutions was possible for two moderate magnitude, onshore events (Mw 4.3, 4 July 2015; Mw 4.6, 31 May 2017). The nearby broadband station facilitates event focal depth determination, insights into the local tectonic structure enabled by geological mapping. We will present the focal characteristics of the activity associated with these earthquakes and discuss their placement within the local and regional geotectonic setting.

Microseismicity associated with the Hebron Fault in SW Namibia – a case study of earthquake clusters in stable continental regions

DOI: 10.57757/IUGG23-0857 - LINK

Benjamin Whitehead[1], *Alastair Sloan*[1], *Diego Quiros*[1], *Guy Salomon*[2], *Beth Kahle*[1], *Richard Kahle*[1], *Robert Muir*[3]

[3]*Department of Geology, University of the Free State, Bloemfontein, South Africa*

The Hebron Fault lies within southwestern Namibia, a stable continental region. It features a prominent northwest-trending scarp which displaces Quaternary alluvial fans and channels. The scarp has a length of 45 km, a maximum height of 10.1 m and an average height of 5.9 m. Fault scaling relationships suggest the scarp formed in 2–5 events of Mw ~7. Interestingly, geomorphological analyses only found evidence for a single event. In common with other major paleoseismic fault scarps in southern Africa, no earthquake cluster is recorded near the Hebron Fault in regional catalogues.
In order to investigate the possibility of missed low-magnitude seismicity, below the detection threshold of the regional networks, a network of 23 4.5 Hz three component geophones was installed around the Hebron fault scarp. Earthquakes were identified using a STA/LTA coincidence trigger and P and S wave arrivals were manually picked. More than 200 earthquakes were located near the Hebron Fault with Ml ≤ 3.6 to a maximum depth of 20 km. A regression through the hypocentres results in a plane corresponding to the expected fault plane. Observed earthquakes at the Hebron Fault may either represent a long-lived aftershock sequence or a form of background seismicity associated with the fault.
The fact that the earthquake cluster associated with the Hebron Fault was missed by regional networks suggests that seismic hazard can be overlooked, particularly in stable continental regions where seismic networks are often not well developed and the repeat-times of large earthquakes are longer than the instrumental record.

Lithospheric structure beneath the ultra-slow spreading Knipovich ridge using noise reduced OBS P-wave Receiver functions

DOI: 10.57757/IUGG23-1638 - [LINK]

Theresa Rein[1]*, Zali Zahra*[1]*, Krüger Frank*[1]*, Schlindwein Vera*[2]
[1]*University of Potsdam, Institute of Geosciences, Potsdam, Germany*
[2]*Alfred-Wegener Institute AWI, Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany*

Ultra-slow spreading ridges are characterized by huge volcanic complexes which are separated by up to 150 km long amagmatic segments. The mechanisms controlling these types of mid-oceanic ridges (MOR) are not yet fully understood. We aim to constrain the crustal and mantle structure beneath a segment of the Knipovich ridge (Greenland Sea) by using Receiver functions calculated from teleseismic events.

Seismic data, recorded on the ocean bottom, are highly contaminated by different noise sources. Results of our noise reduction algorithm based on harmonic-percussive separation (HPS) techniques of selected KNIPAS station data show a significantly reduced noise level on all three seismometer components (below 1 Hz).

Improving the SNR on OBS records reveals the superposition of water and sediment reverberations on the crustal structure information, the latter is strongly hindering the structure interpretation. Here, we compare the real data with a set of synthetic Receiver functions for better analysis of the lithospheric structure. The results of the real data stacks reveal two discontinuities beneath the ridge shoulders: (i) at depths of around 8 km, which can be most likely associated with a Moho, (ii) at depths of around 30 km, which can be linked with the lithosphere- asthenosphere boundary. The center of the MOR and the Logachev seamount are characterized by a strong low-velocity zone at depths of up to 20 km. Comparing the depths of the mantle transition zone discontinuities from KNIPAS data and land station data indicates a low velocity layer east of the Knipovich ridge in the uppermost mantle.

Unraveling the western portion of Parecis Basin by Receiver Function

DOI: 10.57757/IUGG23-3578 - LINK

George Franca[1], *João Pedro R do Nascimento*[1], *André Vinícius de Sousa Nascimento*[1]
[1]*Universidade de Brasília, Observatório Sismológico, Brasilia-DF, Brazil*

The Parecis basin is located in the Midwest region of the Brazilian territory, with approximately 6000 meters of accumulated sediments. We used receiver function data from 5 temporary broadband stations belonging to the Parecis Basin Tectonic Studies network supported by CNPq and a permanent station from the Brazilian seismographic network, all located in the Parecis Basin. Then the HK stacking method and Common stacking point (CCP) of the Receiver Function data were applied, The application of the HK method allowed us to determine a Vp/Vs that varies from 1.74 to 1.89 along the profile and a crustal thickness that varies from 25 to 43 km. In the CCP profile, it was possible to observe the Moho and determine the probable basement of the basin. In addition, an intermediate region between the Moho and the basement was noticed, which was interpreted as the Conrad discontinuity. Therefore, in general, the applied methods showed results consistent with previous studies carried out in the Basin and it was noted that the CCP stacking promoted an evolution in the interpretative aspect of the structures.

Reykjanes Peninsula (SW Iceland) is extraodrinary place from the geophysical perspective. Lying on the on-shore part of the Mid-Atlantic Ridge, interlaced by volcanic systems and hosting sevral high temperature geothermal areas the seismic activity on Reykjanes Peninsula is generally persistent often on a microseismic level but occasionally reaching up to ML~5-6. Throughout the years many temporary seismic stations or small to medium size local seismic networks have beed deployed there for various purposes from geothermal prospection monitoring to short time passive seismic experiments. We analyzed 10 years period of recording of the natural seismicity recorded at the stations of the semi-permanent local seismic network REYKJANET (in operation since 2013) together with several permanent stations of SIL network present in the area of interest. This timespan contained times of relative rest, several small earthquake swamrs associated with purely tectonic origin as well as very turbulent and active periods with magnitudes up to ML=5.4 related to volcanic eruptions. We study the distribution of foci of the background seismicity as well as for the several seismically active periods with consistent set of stations.

We compare different automatically derived earthquake catalogs and their common features like the aseismic zones or upper and lower limit of the foci occurence, seismogenic faults and void areas. The dataset contains also Fagradalsfjall volcanic system dyke intrusions related events in 2021-2022.

We deal with several tens of thousands of foci with high quality stable location imaging the subsurface beneath Reykjanes Peninsula.

For more than four years the Marsquake Service (MQS) detected and catalogued marsquakes from near realtime data recorded by SEIS, InSight's seismometer deployed on the surface of Mars. Now that the data collection phase of the mission is over, we review the procedures and methods developed by MQS and describe the contents of the catalogue. With only a single station, there are obvious challenges in providing a catalogue for the entire planet. Due to the low SNR of marsquakes and the extreme variability of background noise, impulsive seismic signals are rarely evident and standard automated algorithms cannot be used to identify marsquakes, and manual review was needed.

The MQS tools are based on best practice and standards used in seismic networks on Earth, for example we use a single station interactive analysis GUI based on SeisComP. Consistent procedures were developed to distinguish marsquakes from atmospheric noise or other data anomalies, classify events, pick phases, determine distance using a suite of Martian velocity models which has been updated during the mission, determine back azimuth, and locate events. Mars magnitudes are assigned using calibrated magnitude relations.. The final catalogue includes over 1300 marsquakes. Six events are known meteoroid impacts confirmed from visual imaging, their proximity to MQS locations confirms our location methodology. The catalogue contains quakes from within 1 degree of the lander out to 146 degrees distance and magnitudes span from 1 to 4.6. Body waves, crustal phases, surface waves, atmospheric shock waves and even core phases have been observed.

A new seafloor cable-type observation network in the western half of the anticipated Nankai Trough earthquake source area: N-net

DOI: 10.57757/IUGG23-1127 - LINK

Shin Aoi[1]*, Tetsuya Takeda*[1]*, Takashi Kunugi*[1]*, Masanao Shinohara*[1,2]*, Takayuki Miyoshi*[1]*, Kenji Uehira*[1]*, Masashi Mochizuki*[1]*, Narumi Takahashi*[1]
[1]*National Research Institute for Earth Science and Disaster Resilience, Network Center for Earthquake- Tsunami and Volcano, Tsukuba, Japan*
[2]*Earthquake Research Institute the University of Tokyo, Center for Geophysical Observation and Instrumentation, Tokyo, Japan*

The area off the Pacific Ocean in eastern Japan has already been densely monitored by S-net, and in western Japan by DONET and the JMA's Tokai and Tonankai cables. However, the area from off Kochi to the Hyuga-nada, which is the western half of the anticipated Nankai Trough earthquake source area, is a blank area of observation. To eliminate the blank, NIED is now constructing Nankai Trough Seafloor Observation Network for Earthquakes and Tsunamis (N-net). N-net consists of two subsystems, one inshore and one offshore, connecting two landing stations. Each subsystem has 18 observatories connected by a fiber-optic cable approximately 700 to 800 km long, for a total of 36 observatories. N-net is designed as a hybrid system based on the inline system, but with the plug-in node system that allows for future addition of observation equipment. Each observatory is equipped with two pressure gauges for tsunami observation and two accelerometers and short-period velocity meters for earthquake observation to ensure redundancy. For installation on the N-net, NIED has developed a pressure gauge that is less susceptible to pressure measurement due to seismic shaking and attitude fluctuation, a pressure-resistant enclosure that transmits pressure accurately, and an implementation of IP packets on SDH payloads. The observed data will be transmitted to JMA in real time and used for early warning of earthquakes and tsunamis. Offshore system will be laid till 2024, and the construction will be expected to be finished till the spring of 2025.

The area off the Pacific Ocean in eastern Japan has already been densely monitored by S-net, and in western Japan by DONET and the JMA's Tokai and Tonankai cables. However, the area from off Kochi to the Hyuga-nada, which is the western half of the anticipated Nankai Trough earthquake source area, is a blank area of observation. To eliminate the blank, NIED is now constructing Nankai Trough Seafloor Observation Network for Earthquakes and Tsunamis (N-net). N-net consists of two subsystems, one inshore and one offshore, connecting two landing stations. Each subsystem has 18 observatories connected by a fiber-optic cable approximately 700 to 800 km long, for a total of 36 observatories. N-net is designed as a hybrid system based on the inline system, but with the plug-in node system that allows for future addition of observation equipment. Each observatory is equipped with two pressure gauges for tsunami observation and two accelerometers and short-period velocity meters for earthquake observation to ensure redundancy. For installation on the N-net, NIED has developed a pressure gauge that is less susceptible to pressure measurement due to seismic shaking and attitude fluctuation, a pressure-resistant enclosure that transmits pressure accurately, and an implementation of IP packets on SDH payloads. The observed data will be transmitted to JMA

in real time and used for early warning of earthquakes and tsunamis. Offshore system will be laid till 2024, and the construction will be expected to be finished till the spring of 2025.

Smart Sensor Deployments in the Tokyo Area: New Means of Communicating Earthquake Risk and Chances for Seismology

DOI: 10.57757/IUGG23-3372 - LINK

Naoshi Hirata[1], Danijel Schorlemmer[2], Hiroshi Tsuruoka[1], Takashi Furuya[3], Hiromichi Nagao[1]

Affordable devices based on MEMS acceleration sensors have seen a rise in recent years. We have explored the utility of the smartphone-type sensors built into small devices directly plugged to power outlets in the wall for the use by volunteers and companies. We deployed 10 devices to private people in the Zama region, southwest of Tokyo, in 2021 and 50 devices in the larger Tokyo region in 2022 for about a half year each. Additionally, we have equipped the 48-story Tokyo Metropolitan government building in Shinjuku, Tokyo, with many devices on floors ranging from 1st to 44th, and one 6-story building of the Tokyo Narita International Airport with many devices on four floors. All devices have provided us with both three-component acceleration records and seismic intensities in the Japan Meteorological Agency (JMA) scale, which is familiar to non-professional Japanese people. The measured seismic intensities on different floors and within the same floor show a variety of values different to the reported JMA intensity for the wider area. Also, we have obtained human assessments of experienced seismic intensity. Basically, the felt and measured intensities are consistent with some significant outliers. Our original hypothesis is that people with sensors at home are more sensitive and better prepared and behave more reasonably when experiencing large-intensity shaking. We were not able to clearly prove it yet due to a lack of a strong-shaking event during the experiment. We are planning to expand the experiment to more than 1000 households in the Tokyo area.

Truaa Earthquake Early Warning System for Israel –Operational Stage and the Public's Perspective

DOI: 10.57757/IUGG23-1433 - [LINK]

Truaa - Israel's Earthquake Early Warning System (EEWS), is in operational mode since January 27th, 2022. Israel is amongst the few countries in the world to run a national, government- operated EEWS. Building and operating such a system involves not only many technical challenges, but also considering the social aspects of alert strategy and public's perceptions.

In the determination of an alert magnitude threshold, there is an inherent tradeoff between urgency and necessity. In this presentation we combine three independent data sets to inspect Israel's alerting strategy: (1) We analyze the performance of the EEWS in the past two years to derive uncertainties of earthquake early warning alerts in Israel; (2) We re-project these uncertainties to the historic earthquake catalog of 2010-2020 and (3) We analyze a dataset of unnecessary injuries following missile alerts, to estimate the potential toll of unnecessary earthquake alerts.

We then present the social point of view of alerts in Israel, as obtained by a first-of-its-kind questionnaire in Israel, focusing on people's perceptions and perspective on earthquake alerts.

Taken together, we find that the expected injury toll from unnecessary alerts is an order of magnitude lower than the potential damage of shorter reaction time (the time period between the alert and s-wave arrival) and that the public's preferences may allow the alerting strategy to be less conservative, and to accommodate the EEWS uncertainties and limitation by allowing potentially faster alerts.

The roughly 3000 km long East Africa Rift system (EARS) is one of the striking features of the African continent that captures all stages of rift development from the most juvenile to nascent seafloor spreading in Okavango delta and Afar depression, respectively. It provides a natural laboratory for studying a fundamental, and yet enigmatic, component of plate tectonics. A mechanism for rupturing thick, cold, continental lithosphere is not readily apparent in conventional models of mechanical stretching. However, magma production weakens the plate and serve to localize strain, thus better facilitating rifting. Studies of seismicity and volcanism provide insights into this problem and a variety of geophysical, geochemical and geological studies can be used to better understand the role of the crust and mantle in continental breakup.

Permanent seismic station distribution is sparse in the continent but some focused and detailed studies have been conducted using temporary broad seismic networks in collaboration with overseas researchers. Earthquakes of magnitude $M > 7.0$ are observed in EARS from instrumentally recorded seismicity (the 1910 Rukwa earthquake in Tanzania, the 1990 earthquake in South Sudan and the 2006 Machase earthquake in Mozambique) which is a wakeup call for the fast growing construction industry in the region. It is also inferred that the EARS is more active than we think, from recently recorded seismicity, which requires collaborative efforts to enhance studies in the region both for basic science research and disaster risk management purposes.

The African Seismological Commission (AfSC) is a scientific organization established in 2014 by the International Association of Seismology and Physics of the Earth's Interior (IASPEI). It is one of the four regional Commissions of IASPEI. The official launching of the African Seismological Commission was in January, 2014 at the University of Witwatersrand, Johannesburg, South Africa. The mission of the Commission is to promote the science of Seismology within the scientific community of Africa, by promoting research studies, enhance scientific cooperation and train young scientists. In October, 2022 for the first time, a joint General Assembly was held for the African and Asian Seismological Commissions. The joint General Assembly was hosted by the National Research Institute of Astronomy and Geophysics, and was held close to the natural boundary between Asia and Africa in the Hurghada, Red Sea, Egypt. The event was conducted in hybrid (both in-person and online) mode, with more than 180 participants, 140 participated physically and 40 online, from 38 Countries. Since the AfSC launch meeting in Johannesburg in 2014 and subsequent 3 General Assemblies (2016 Aswan, 2018 Al Hoceima, and 2022 Hurghada), diverse resolutions have been undertaken such as increasing the number of AfSC country members, promoting the organization of a Seismological Centre for Africa as well as having an earthquake emergency response team in place in Africa. In addition, the General Assemblies hosts training session for students and young researchers in all topics in seismology, seismotectonics, earth structures, and seismic hazards and risks.

Outcomes Following a 2022 International Workshop on Global Earthquake Monitoring

DOI: 10.57757/IUGG23-4342 - LINK

William Yeck[1], Paul Earle[1], Harley Benz[1], Michelle Guy[1], John Patton[1]
[1]National Earthquake Information Center, US Geological Survey, Denver, USA

In 2018, the U.S. Geological Survey (USGS) hosted an international workshop titled "Future Opportunities in Regional and Global Seismic Network Monitoring and Science", in which members identified and prioritized areas of research to improve global seismic monitoring. This meeting directly informed the USGS National Earthquake Information Center's (NEIC) 5-year strategic plan. The international, real-time, sharing of parametric earthquake data was identified as a critical area of development that could improve monitoring. The need for rapid parametric data sharing became even more apparent following the COVID-19 pandemic, as many monitoring operations were strained. As all monitoring agencies have similar missions, to rapidly report on earthquakes and their effects in efforts to mitigate impacts, the community can greatly benefit by mutually supporting each other through automatic information sharing.

In 2022, the NEIC hosted a follow-up workshop supported by the USGS Powell Center. The workshop prioritized updates following the COVID-19 pandemic and addressed the specific task of international parametric data sharing. We discussed how to rapidly communicate operational information between our agencies (e.g., system outages), the types of automatic derived earthquake data we should be sharing, and infrastructure requirements. The working group decided to explore automatically sharing picks and moment tensors, leveraging easily deployable messaging software such as Apache Kafka. We identified other areas where further discussion could benefit our agencies, such as our standard operating procedures (SOPs) for source characterization. Here we will share the outcome of these meetings and discuss how they fit into NEIC's strategic plan priorities.

EIDA Italian node: seismic data curation preservation e dissemination

DOI: 10.57757/IUGG23-3367 - LINK

Alfonso Mandiello[1]*, Massimo Fares*[1]*, Danecek Peter*[1]*, Stefano Pintore*[1]*, Della Bina Emiliano*[1]*, Diego Franceschi*[1]*, Carluccio Ivano*[1]*, Maniscalco Michele*[1]
[1]*Istituto Nazionale di Geofisica e Vulcanologia, Geofisica, Roma, Italy*

The seismology data archive at Istituto Nazionale di Geofisica e Vulcanologia (INGV), a node of the EIDA federation, currently holds more than 100 TB of seismological waveform data. To guarantee a robust qualitatively superior service needs full care of every step about curation preservation and dissemination of data.

It starts from seismic network inventory management and requires keeping track of all station and network related information and metadata.

Our system has a modular design, whenever possible, by leveraging existing open-source solutions as a customized Tuleap implementation to realize the ticketing system, for injecting and tracking the changes and managing the station's faults. The station metadata and channel responses are managed using the XML database eXist-db to store StationXML documents natively and a new implementation of the fdsnws-station based on it. Then GUI leverages Grafana creating a dashboard to present an overview of the system status of all components.

Then we have deployed an semiautomatic sanity check of data to apply our policies and quality assessment before archive data using a rule manager

Our policy for preservation is to make a replication (synchronized copy) at a new storage archive in Naples and a backup in the tape library.

After all these steps we are ready to disseminate data through webservices and websites (https://eida.ingv.it/).

To complete the service for users we are adding significant computational resources and an adequate processing and analysis framework combining Apache Spark, and ObsPy, creating a "computational archive" where storage resources and computational resources converge.

The EarthScope Geophysical Cloud Data Platform

DOI: 10.57757/IUGG23-3114 - LINK

Chad Trabant[1], Henry Berglund[1], David Mencin[1], Jerry Carter[1], Rob Casey[1], Charlie Sievers[1], Gillian Sharer[1]
[1]EarthScope Consortium, Data Services, Washington, USA

EarthScope Data Services, a merger of UNAVCO and IRIS data activities, has been supporting the international seismological and geodetic research communities for many decades. Historically, the seismological and geodetic facilities independently managed data repositories on self-managed systems. As a component of merger activities, we have established a project to design, develop and implement a common, cloud-based platform. Goals of this Common Cloud Platform (CCP) project include operational improvements such as cost-effectiveness, robustness, on-demand scalability, significant growth potential and increased adaptability for new data types.

The migration and combination of the data facilities to a cloud computing environment represents a major evolution that will benefit researchers, data contributors, and EarthScope data managers. Researchers and other data users will benefit from the increased capacity, flexibility, new services, and adjacency to nearly unlimited compute. We will be developing training materials and conducting workshops to help data users to take full advantage of the platform, in particular the option of processing data in the cloud which avoids slow transfer across the internet. The new platform will also support hazard assessment and mitigation through continued open data access policies, and in particular by operating the geodetic data collection and initial product generation for the US ShakeAlert system.

The project is currently in a development stage, and we anticipate having a demonstration platform partially operational in mid-2023 and fully operational by the end of the year. We will report on the status of the project, as well as anticipated directions and challenges identified so far.

Sharing data - arrival time readings, earthquake parameters, waveforms and further derived products - has for many decades been key to the scientific advancement of seismology and our understanding of the Earth. The establishment of data centers, from institutional to global, that receive, archive, curate and make accessible large volumes of seismological data, following community standards and best practices, was a logical consequence. IASPEI, with its commissions, evolved as a de-facto standards body for seismological data, governed by the community of data providers and users alike.

However, conditions of use for these shared data did not receive much attention by data providers, distributors, and groups working on the definition of standards of data and services. If mentioned at all, generic statements on allowed use were provided somewhere on websites that offered access, often declaring ‘only for scientific/academic purposes’ or ‘not for commercial purposes’. Driven by the desire or requirement to improve FAIRness of our data, better understand data usage and adapt to technological changes, and support open science, putting proper licenses on data and metadata has now become a significant topic.

In this presentation we look at current practices and evolving ideas regarding application of licenses to the holdings of seismological data centers, covering waveforms, earthquake parameters, and further derived products, also including views from other geoscience domains. The relation to (legal) copyright and intellectual property issues, local/national licensing regulations that may hinder a globally uniform approach, and downstream implications for citation, attribution and general re-use of data will also be addressed.

GEOSCOPE: 40 years of global broadband seismic data

DOI: 10.57757/IUGG23-4675 - LINK

Martin Vallée[1], Dimitri Zigone[2], Nicolas Leroy[3], Jean-Yves Thoré[4], Céleste Broucke[3], Armelle Bernard[4], Constanza Pardo[5], Eléonore Stutzmann[1], Frédérick Pesqueira[6], Maxime Bes de Berc[2], Alessia Maggi[2], Luis Rivera[2], Michel Le Cocq[1], Olivier Sirol[3]

[5]Université Paris Cité- Institut de Physique du Globe de Paris, Data Center, Paris, France
[6]Université Paris Cité- Institut de Physique du Globe de Paris, Ovpf, Paris, France

The GEOSCOPE observatory provides more than four decades of high-quality continuous broadband data to the scientific community. Started in 1982 with a few stations, the network has grown over the years thanks to numerous international partnerships. The 33 operational GEOSCOPE stations are installed in 18 countries, filling gaps in the global Earth coverage (in Africa, Antarctica, Indian Ocean, Pacific Ocean islands and more).

Over the years GEOSCOPE contributed to define today's global seismology standards through the FDSN (data format, data quality level, instrumentation requirements), being the French contribution to the international effort (with GSN, GEOFON and others) towards global seismic observations. The stations are equipped with the best quality seismometers (from the very first STS1 in the early 80's to the last STS-6A and Trilium T360 nowadays) and digitizers (Q330HR and Centaur), in order to record with a high fidelity the ground motions generated by all types of seismic sources. Furthermore, most of the stations are also equipped with accelerometers, pressure and temperature sensors allowing for a wider range of observable events such as the recent Hunga-Tonga eruption. All the data are sent in real-time to IPGP, IRIS-DMC, RESIF, and tsunami warning data centers.

In 2022, a workshop has been organized to celebrate the 40th anniversary of GEOSCOPE and illustrate the main scientific achievements made possible by all the global networks. After a look at the history of the network, the recent evolutions of the observatory in terms of instrumentation and data products (near-real time earthquake analyses) will be presented.

The GEOSCOPE observatory provides more than four decades of high-quality continuous broadband data to the scientific community. Started in 1982 with a few stations, the network has grown over the years thanks to numerous international partnerships. The 33 operational GEOSCOPE stations are installed in 18 countries, filling gaps in the global Earth coverage (in Africa, Antarctica, Indian Ocean, Pacific Ocean islands and more).

Over the years GEOSCOPE contributed to define today's global seismology standards through the FDSN (data format, data quality level, instrumentation requirements), being the French contribution to the international effort (with GSN, GEOFON and others) towards global seismic observations. The stations are equipped with the best quality seismometers (from the very first

STS1 in the early 80's to the last STS-6A and Trilium T360 nowadays) and digitizers (Q330HR and Centaur), in order to record with a high fidelity the ground motions generated by all types of seismic sources. Furthermore, most of the stations are also equipped with accelerometers, pressure and temperature sensors allowing for a wider range of observable events such as the recent Hunga-Tonga eruption. All the data are sent in real-time to IPGP, IRIS-DMC, RESIF, and tsunami warning data centers.

In 2022, a workshop has been organized to celebrate the 40th anniversary of GEOSCOPE and illustrate the main scientific achievements made possible by all the global networks. After a look at the history of the network, the recent evolutions of the observatory in terms of instrumentation and data products (near-real time earthquake analyses) will be presented.

2023 marks thirty years since the start of GEOFON operations with the first three stations in Papua New Guinea (Port Moresby, PMG), the Czech Republic (Moravsky Beroun, MORC), in Ireland (Dublin, DSB). The GEOFON program started shortly after creation of the GFZ German Research Centre for the Geosciences in 1992 with the aim to promote global seismic monitoring, standardisation and data exchange. The program has evolved over the three decades in synergy with the seismological community through three important milestones: since late 1990s the development and community adoption of the SeedLink protocol enabling global real-time data exchange; in early 2000s, development of the Arclink protocol as key development to interconnect the EIDA federated data archives, only recently superseded by the use of FDSN web services at global scale; 2008 as the first public release of SeisComP, one of the most widely used seismological packages in seismology, a development triggered after the 2004 Aceh-Andaman earthquake and tsunami within the GITEWS project (German Indian Ocean Tsunami Early Warning System). Although GEOFON's heritage goes back to the 1990s and further down to 1889 building on the initial findings from Ernst von Rebeur-Paschwitz, the program is capable of leveraging third party funded challenging projects to keep modernising with the community. In this presentation we outline the most important developments of GEOFON through a journey in time over three decades, building links between current activities and vision still influenced by the initial aims which have shaped the current GEOFON mission.

Assessment of seismic-network capabilities in the Netherlands

DOI: 10.57757/IUGG23-4564 - LINK

Elmer Ruigrok[1], *Jesper Spetzler*[1], *Pauline Kruiver*[1]
[1]*Royal Netherlands Meteorological Institute, R&D Seismology and Acoustics, De Bilt, Netherlands*

Most of the Netherlands is covered with a thick blanket of unconsolidated sediments. In the more consolidated part of the upper crust, different activities are taking place. Oil and gas fields are produced, salt is extracted through solution mining, there is underground storage of liquids and geothermal heat is exploited. All these activities can alter the stress field around existing faults and therewith potentially induce seismicity.

Over the years, an extensive seismic network has been built to monitor seismic activity. To find out whether this network suffices to monitor current and future subsurface operations, the network capabilities have been assessed. To that end, new tools have been developed to compute magnitude-of-completeness and location uncertainty maps over the Netherlands.

The maps show large spatial variation in network capabilities. The main underlying factor is the large variation of sensor density. Another important factor is sensor placement. On average, noise levels are a factor of 25 lower for 200-deep sensors than for sensors at the Earth's surface, in the frequency band that is used for detection (5 to 40 Hz). Moreover, the local setting is important. A regional network in an urban area performs worse than a similar network in a rural area. The tools also provide a means to study design options for future extensions of the network. A scenario layout can be checked for its capability in terms of the minimum magnitude of locatable earthquakes and their associated uncertainty in location.

Update on the Canadian National Seismograph Network

DOI: 10.57757/IUGG23-5028 - LINK

Nicholas Ackerley[1], *Claire Perry*[1], *David McCormack*[1]
[1]*Canadian Hazards Information Service, Natural Resources Canada, Ottawa, Canada*

Natural Resources Canada (NRCan) completed the refurbishment of the Canadian National Seismograph Network in 2019 and has since started commissioning an Earthquake Early Warning System, due to be completed in 2024. We give an overview of these projects and summarize the status of the networks.

Meanwhile, the software, databases and procedures used for location and alerting of earthquakes in Canada are being modernized. NRCan is deprecating AutoDRM and Antelope in favour of an FDSNWS and SeisComP respectively. Custom legacy database schema, file formats, and automatic location and prompt earthquake notification software are being replaced with QuakeLink, StationXML, QuakeML and a commercial software called GDS. The new system will consist of two fully redundant datacentres, with configurations continuously regression tested to ensure continuous improvement. Earthquake solutions from neighbouring agencies will be available to analysts in real time. Some of the SeisComP plugins developed for NRCAN will be of use to other network operators, including new location and magnitude estimators as well as tools for the efficient generation of waveform data availability statistics. Adoption of QuakeML has forced us to develop a clear event type hierarchy and interpret evaluation status meaningfully. NRCan will mark the transition to SeisComP by adopting a new agency code. We report the progress and discuss lessons learned from this process.

Finally, we report on the development of a new system to monitor volcanoes using InSAR, as well as coda envelope moment magnitudes and a regional seismic travel time model for Canada.

United Arab Emirates national seismic network

DOI: 10.57757/IUGG23-3012 - LINK

Mohamed Alwahedi[1,2], *Ali Megahed*[1,3]
[1]*National Center of Meteorology, Seismology Department, Abu Dhabi, United Arab Emirates*
[2]*University College London, Institute for Risk and Disaster Reduction, London, United Kingdom*
[3]*National Research Institute of Astronomy and Geophysics, Seismology Department, Cairo, Egypt*

The National Center of Meteorology (NCM) established the United Arab Emirates (UAE) National Seismic Network in August 2008. The network has gone through different evolution phases until it reached its current stage of 23 stations. The main aim of these stages is to enhance the coverage of the network to decrease the gap of observation. A site characterization study at each site included geotechnical and geophysical analyses and microtremor testing. Each station equipped with broadband seismometer, and accelerometer. Since 2017, we started to use the modem with 4G as a communication method instead of the VSAT. Data Acquisition, processing, and interactive analysis is running with SeisComP seismological software package.

Also, the NCM exchanges seismic data in real time with regional seismic networks and receive data from GSN network through internet communication, for better monitoring and understanding of the tectonic setting in the region. Since its establishment, the National Seismic Network provided better view for the seismicity in and around the UAE, and updated the database of local earthquakes catalog.

Additionally, the NCM has a major role in studies related to seismicity and tectonics in the region. It participated in academic studies with national and foreign universities, developing the national seismic hazard and risk maps, and re-examining the building codes incorporation with Abu Dhabi city municipality. The NCM is the prime source of information to crisis management authorities in case of any seismic events and works as a national tsunami warning center and it takes part in public awareness for disaster risk reduction.

Near field tsunami hazard and real-time earthquake monitoring: Challenges for Northern Algeria (Western Mediterranean)

DOI: 10.57757/IUGG23-0010 - LINK

Lübna Amir[1]
[1]*USTHB-FSTGAT, Geophysics, Algiers, Algeria*

Historical documents and contemporary recorded events show that tsunami hazard exist for northern Algeria (1365: Algiers; 1790: Oran; 1856, Jijel: 2003, Boumerdes). Marked by a coastline of more than 1200 km in length, the country is exposed to a severe risk for earthquake damage. Not only magnitudes up to 7.5 can be reached even if not that frequent but the fast urban growth raises an issue for crisis management in case of a tsunami could be generated meanwhile the people will have to face the ground shaking with vulnerable infrastructures and dwellings. Operational since 2012, France has created its own tsunami warning system for the Western Mediterranean and the Eastern Atlantic, the CENALT. The source is mostly to come from the Algerian coasts.

Today, open-source softwares like seiscomp (developed and maintained at Gempa, Potsdam, Germany) can provide us with good results for automatic solutions of earthquake analysis (magnitude, location). It is nevertheless challenging to estimate the right depth within 15-20 minutes. Earthquake’s analysis is strongly constrained by the number of available phases recorded in real time. Hence, access to open data is crucial for an accurate earthquake parameters estimation. Tsunami warning systems are established at first with automatic solutions.

In this work, we present several cases studies showing how the seedlink protocol for many public networks listed in the FDSN database helps to provide information for tsunami warning bulletins spread to stakeholders and the public audience. These examples serve to expose the challenge faced by the northern Algerian coasts.

A decade of Indonesia seismicity and its seismotectonic implications: Evaluations from BMKG nationwide earthquake monitoring (2010-2022)

DOI: 10.57757/IUGG23-3804 - LINK

Dimas Salomo Januarianto Sianipar[1], Gatut Daniarsyad[2], Daryono Daryono[2], Yopi Serhalawan[3], Nelly Florida Riama[2], Suko Prayitno Adi[2], Dwikorita Karnawati[2]

[2]Agency for Meteorology- Climatology- and Geophysics of the Republic of Indonesia BMKG, Geophysics, Jakarta, Indonesia
[3]Agency for Meteorology- Climatology- and Geophysics of the Republic of Indonesia BMKG, Geophysics, Sorong, Indonesia

Indonesia is a seismically active region with a complex tectonic setting. To monitor earthquakes in the Indonesia region, the Indonesian Agency BMKG (Badan Meteorologi, Klimatologi, dan Geofisika) has been operating a nationwide monitoring system using the permanent digital seismometer network of Indonesia (network code IA). However, the earthquake catalog/bulletin resulting from this nationwide monitoring has not yet been evaluated and discussed. In this study, we assessed a decade of seismic activity in Indonesia with a focus on earthquakes from 2010 to 2020 (11 years) and 2021-2022 (two years after significant improvement of the network). We analyzed their parameters, mainly the magnitudes, and compared them with their various magnitude types and moment magnitude by the Global Centroid-Moment-Tensor (GCMT) catalog. A unified earthquake catalog with homogeneous (local) magnitudes is obtained. We evaluated 77,987 earthquakes during this period with the data complete at the local magnitude of 3.5 based on the analysis of their frequency-magnitude distribution (FMD). We then computed seismicity rates of M>3.5 for different regions and tectonic regimes in Indonesia. We also discuss the seismicity 2021-2022 after the significant increase of seismic stations in the IA network. Finally, we discussed seismicity evolution and its seismotectonic implications. Our study is necessary for further seismic hazard assessment in Indonesia.

Aotearoa-New Zealand, geonet national seismograph network: Supporting landslide, tsunami, earthquake and Volcano monitoring since 2001

DOI: 10.57757/IUGG23-0317 - LINK

Jerome Salichon[1], Jonathan Hanson[1], Mark Chadwick[1], GeoNet Programme Team[1]
[1]GNS Science, Data Science & Geohazards Monitoring, Lower Hutt, New Zealand

Aotearoa-New Zealand islands sit in the South-West Pacific region where tectonic activity generates one of the world largest seismicity, intense deformation, and volcanic activity. Since 2001, GNS Science Te Pū Ao ensures some of the New-Zealand capability to identify, study, prepare and respond to multiple and frequent geological hazard with the GeoNet programme. GeoNet builds and operates a permanent seismological network routinely maintained and upgraded to provide continuous observations for national and regional events, strong motion and building monitoring. Sensors are distributed over the country with regards to population and hazards exposures. GeoNet strives to optimize its network capability and improve its multi-purposes nature. Around 500 near-real time seismic sensors are acquired, archived, and processed into different products over timelines that match a variety of users and requirements. A range of both rapid and curated products are made available for public awareness, scientists and for earthquakes, landslides, tsunami, and volcanic panels and duty officers. We present the current New-Zealand seismological network, flow process and observation settings as it is, today, a mature observation system. We describe a range of derived seismic products and services designed to enable rapid, dynamic, robust, and resilient scientific seismic information to diverse communities with an open data approach from field instrumentation to data archiving. We discuss expectations and incoming challenges to handle technical and scientific transformations with a care for continuous integration process and maintenance required to evolving monitoring, response, and seismology scopes along with modern 24/7 operations center infrastructure strict design and functions.

Using reported parametric data from the ISC Bulletin to evaluate changes in station performance

DOI: 10.57757/IUGG23-2457 - LINK

Ryan Gallacher[1], James Harris[1], Tom Garth[1], Dmitry Storchark[1]
[1]International Seismological Centre, International Seismological Centre, Thatcham, United Kingdom

Tracking changes in station performance over extended time periods is time-consuming and challenging for many seismic networks. It can also be difficult to compare variations in station performance from different users or station performance between networks. The International Seismological Centre (ISC) receives phase picks for a significant number of networks globally, including from multiple agencies for the same stations. This reported data can be evaluated to provide many metrics for station performance, including average monthly travel time residuals and evaluation of travel time residuals by distance & hypocentre location. We will show how best to access this information which is currently available on the ISC website and outline forthcoming extensions of this functionality. Future features include; a comparison of reported polarities with available earthquake mechanism solutions, providing an indicator for inverted station polarities, response file checks currently being developed by the ISC and station performance metrics for individual agencies. Additionally the station performance metrics are currently undergoing an expansion from only International Registry (IR) stations, managed by the ISC, to including all FDSN stations with picks reported to the ISC. We will summarise the challenges of this expansion and outline how the IR and FDSN station lists will continue to coexist in the future.

The challenge of a rapidly changing regional seismic monitoring network: the Pacific Northwest Seismic Network, USA

DOI: 10.57757/IUGG23-4768 - LINK

Renate Hartog[1], *Mouse Reusch*[1]
[1]*University of Washington, Earth and Space Sciences, Seattle, USA*

The Pacific Northwest Seismic Network monitors seismicity in the U.S. states of Oregon and Washington as part of the U.S. Advanced National Seismic System (ANSS). The network has been in existence for more than fifty years and was initially focused on the Puget Sound region in western Washington and several of the Cascades volcanoes. It now covers all of Washington and most of Oregon. Over the decades, the instrumentation and processing software has changed significantly. For example, we mostly operated analog vertical-component short-period stations in the 1970s, 80s and 90s. We first added digital three-component broadband stations in the mid to late 1990s, and since 2000, continuously streaming three-component strong-motion stations. In the past five years, as a partner in the USGS ShakeAlert Earthquake Early Warning system, we have added hundreds of new strong-motion and/or broadband stations. All our data, waveforms as well as derived products, are publicly available. However, users of both our seismicity catalog and old waveform data need to understand that they come with caveats. Here we present several of these caveats including a study of the spatial and temporal variation of the magnitude of completeness of the PNSN catalog.

The University of Utah Seismograph Stations (UUSS), a member of the U. S. Advanced National Seismic System (ANSS), operates a regional earthquake center responsible for monitoring seismic events (natural and induced) in both the Utah Region and Yellowstone National Park and for seismic monitoring at the Utah Frontier Observatory for Enhanced Geothermal Energy (FORGE). Additionally, we work with partners in adjacent regions and the U. S. Geological Survey to monitor and study earthquakes throughout the U.S. Intermountain West. UUSS operates a regional and urban seismic network consisting of 250 stations and six infrasound arrays. Here, we highlight a recent assessment of the Utah seismic network capabilities and plans for upgrading legacy analog stations, ongoing work to integrate machine learning and measurement of $M_{w,coda}$ for small (M > 2) regional earthquakes into operations, and the development of an infrasound event catalog. We also highlight observations of some recent earthquakes, including the 2020 M_w 5.7 Magna earthquake.

[2]*ETH Zurich, Institute of Geophysics, Zurich, Switzerland*

The Bedretto Underground Laboratory for Geoenergies and Geosciences (BULGG) is a unique research infrastructure located in the middle of a 5.2 kilometers long tunnel that connects Ticino with the Furka railway tunnel, in south-central Switzerland. BULGG is equipped with state of the art instruments that allow to conduct experimental research in various fields. From a seismological point of view, we aim to monitor seismicity that occurs during experiments, as well as monitoring local earthquakes, and possibly induced or run-away seismic events. To accomplish that we set up two real-time monitoring systems based on the SeisComP software, i.e. (i) background seismicity monitoring, and (ii) experimental monitoring. The background monitoring, which is the backbone network, consists of surface and tunnel broadband stations, short period sensors, accelerometers, and geophones sampled at various frequencies (200-2000Hz). Acoustic emission sensors, and an accelerometer sampled at 200kHZ constitute the experimental instance. All sensors stream to a common seedlink server which provides data to multiple clients for processing, real-time visualization, archiving, and risk control via dedicated software. A standard workflow is applied to both background and experimental monitoring that includes, automatic picking, automatic phase association and location, and magnitude estimation. Advanced methods are also applied in real-time, such as, real time double-difference relocation, and real-time earthquake detection based on waveform cross-correlation (template matching). Overall, BULGG is a unique environment to test several types of instruments and implement novel methods on observational and network seismology across scales.

SeisComP - a perspective on its evolution and applications

DOI: 10.57757/IUGG23-2769 - LINK

Bernd Weber[1], Dirk Rößler[1], Jan Becker[1], Saul Joachim[2], Andres Heinloo[2], Winfried Hanka[2], Angelo Strollo[2]

SeisComP is nowadays the most widely distributed software package for seismological real-time data acquisition, processing and analysis. Initially developed by GFZ German Research Centre for Geosciences, focusing on data acquisition and exchange as well as basic automatic earthquake monitoring, it has since been enhanced with interactive analysis and fast magnitude calculation for tsunamigenic earthquake warning. Over the years, the SeisComP ecosystem has been extended with open and closed source modules that support additional application domains such as local and induced seismic monitoring, moment tensor inversions, earthquake early warning, seismic and infrasound array processing, structural health monitoring, earthquake engineering analysis, earthquake information dissemination as well as tsunami simulation and decision support. The wide use of SeisComP in over 500 earthquake and tsunami warning services, research institutes, universities and industrial enterprises all over the world has simplified and unified the exchange of seismic data, station meta data and earthquake parameters. SeisComP adopted and formed global standards such as SeedLink, MSeed, QuakeML, FDSN stationXML and FDSN web services. The functionality of the SeisComP ecosystem is growing and under active development and maintenance. We give a perspective on the evolution of SeisComP- past, present and future.

Deep-learning-based phase picking in SeisComP using SeisBench

DOI: 10.57757/IUGG23-4534 - LINK

Joachim Saul[1], *Thomas Bornstein*[1], *Frederik Tilmann*[1], *Jannes Münchmeyer*[1,2]
[1]*Deutsches GeoForschungsZentrum GFZ, Geophysics, Potsdam, Germany*
[2]*Univ Grenoble-Alpes, ISTERRe, Grenoble, France*

The open-source, seismological software package SeisComP is widely used for seismic monitoring world-wide. Its automatic phase picking module consists of an STA/LTA-based P-wave detector augmented by an AIC onset picker. With proper configuration, it allows detection and accurate onset picking for a wide range of seismic signals. However, it cannot match the performance of experienced analysts. Especially broadband data are often challenging for phase pickers due to the enormous variety of the signals of interest.

In order to optimize quality and number of automatic picks and reduce time-consuming manual revision, we chose to develop a machine-learning repicker module for SeisComP based on the SeisBench framework. SeisBench supports several deep-learning pickers and comes pre-trained for different benchmark datasets, one of which was contributed by GFZ Potsdam.

The repicking module consists of several submodules that interact with both SeisComP and SeisBench via their Python interfaces. The current workflow is based on existing locations generated with a classical SeisComP setup. Shortly after event detection and preliminary location, our repicker (1) starts to repick previously picked onsets and (2) attempts to generate additional picks.

Preliminary results are encouraging. The deep-learning repicker substantially improves pick quality over a large frequency range. The number of picks available per event has approximately doubled and the publication delay is often reduced, especially for small events. The total number of published events has increased by about 20 per cent.

[2]*University of Bergen, Department of Earth Science, Bergen, Norway*

The SEISAN Earthquake Analysis Software is used widely at regional, national and local seismic networks and by students and researchers in the field of seismology. SEISAN is applied in the monitoring of all kinds of seismic events: Earthquakes, volcanoes, induced and cryo-generated events. SEISAN provides many different programs, from the basic processing and analysis of seismic events at seismological observatories to more advanced research. Based on a flat file database structure it operates on all platforms. SEISAN has undergone steady development since its launch more than 30 years ago. The design and development of SEISAN is and has been conducted in close contact with end users, to ensure fast and efficient workflows. SEISAN includes a comprehensive manual, a tutorial, training exercises and a mailing list where users and experts share information and help each other. SEISAN workshops have been held regularly since the nineties and have in the recent years been supplemented with online web sessions. To the CTBTO national data centres, SEISAN applications are presented at the forum web site. The recent improvements to SEISAN include QuakeML routines for data exchange, near real time event detection and processing and full channel identification and logging of event processing.

The U.S. Geological Survey (USGS) National Earthquake Information Center (NEIC) has coupled improving the speed of its 24/7 response with the need to update its system to adapt to continuously evolving technologies. The NEIC is implementing a new analyst interface and corresponding workflow, called “Quick-Look”, for analysts to do a cursory evaluation of rapid automatic seismic solutions to determine to release automatic data to responders, agencies, scientific communities, and the general public. The Quick-Look capability creates the opportunity to distribute validated automatic seismic solutions considerably faster than solutions currently released via the NEIC human-reviewed workflow and policy. We describe this new interface, which utilizes web services and web displays, quantify data release speed increases, and describe the integration with the legacy monitoring and analysis system.

With a small team the NEIC must balance maintaining the existing operational, global, seismic detection, and monitoring software system, addressing issues across data, infrastructure, security, and workflow, while concurrently designing and building a new system with updated infrastructure, technologies, algorithms, and approaches. We describe how the team manages this leveraging shared technologies and approaches across USGS public and internal applications, which includes containers, continuous integration continuous deployment (CI/CD) pipelines, data messaging and web services, and web-based user interfaces. Using a containerized environment coupled with data messaging and web services, the architecture can exploit standardized approaches across multiple applications to support more rapid, secure, and automated deployments, in hybrid and/or cloud friendly, essentially location agnostic, environments.

Magnitude reassessment for digital records of the Belgian seismic network since 1985

DOI: 10.57757/IUGG23-1837 - LINK

Kris Vanneste[1], *Mahsa Onvani*[1], *Thierry Camelbeeck*[1], *Lecocq Thomas*[1], *Giovanni Rapagnani*[1]
[1]*Royal Observatory of Belgium, Seismology & Gravimetry, Brussel, Belgium*

In the frame of the BELSHAKE project, we collected all digital records by the Belgian seismic network of earthquakes with M_L>2 in a dedicated waveform archive and the associated metadata in a database. We visually inspected all waveforms, calculated missing P- and S-arrival times from the Belgian velocity model, and defined noise, P-, S- and coda-windows. We also developed the tools to recompute local magnitudes and to compute new moment magnitudes. One of the main problems we encountered was missing instrument response information for older records. We tried to reconstruct this information based on information in our station database and/or the original data headers. Analysis of station M_L residuals and PSDs of the noise window allowed to select the correct response or to identify unreliable cases.

The definition of the Belgian M_L scale is based on the Lg wave on the vertical component high-pass filtered at 1 Hz. It has been applied systematically since 1985, but unfortunately not all amplitude measurements are preserved in the database. Furthermore, the scale has not been calibrated for distances < 10 km and does not take into account hypocentral depth. These issues are problematic to determine M_L of recent shallow geothermally induced seismicity. We will use our dataset to derive a better formulation of the Belgian M_L scale. We also compute M_W based on spectral fitting of P- and S-waves with the well-known sourcespec package. This will eliminate the need for empirical magnitude scale conversions to compute magnitude-frequency relations for seismic hazard assessment.

Separating Rayleigh and Love waves based on the SPAC method

DOI: 10.57757/IUGG23-0096 - LINK

Hisashi Nakahara[1], *Matthew Haney*[2]
[1]*Tohoku University, Geophysics, Sendai, Japan*
[2]*U. S. Geological Survey, Alaska Volcano Observatory, Anchorage, USA*

The spatial autocorrelation (SPAC) method was developed by Aki (1957) to estimate subsurface velocity structure from the coherence of ambient seismic noise. The SPAC method has been widely used and extended to various cases. Separation of Rayleigh and Love waves is essential to obtain reliable phase velocity dispersion curves. Three-component displacement data is necessary (e.g., Okada and Matsushima, 1989; Chouet et al., 1998). Cross-correlation between the vertical-radial components helps isolate Rayleigh waves (Haney et al., 2012). Recently, the formulation of the SPAC method was extended to strain, rotation, and tilts by Nakahara et al. (2021) and to the mixed correlations between displacement and strain by Nakahara and Haney (2022). Here, we revisit the separation of Rayleigh and Love waves based on these recent developments of the SPAC theory. Isolation of Rayleigh waves is possible using the following components: vertical displacement, areal strain, and tilts. On the other hand, isolation of Love waves is possible using only the vertical-component rotation. Both Rayleigh and Love waves contribute to most auto- and cross-correlation pairs. Therefore, a reasonable method is to isolate Rayleigh waves first and then estimate the contribution of Love waves. Recently, measurements of strain and rotation are becoming possible thanks to the developments of distributed acoustic sensing (DAS) and rotational seismometers. These technical developments, along with the extended SPAC theory, will clearly distinguish Rayleigh and Love waves from ambient noise, which makes it possible to measure radial anisotropy by virtue of the difference between SV and SH velocities.

Inferring micro-crack damage evolution with increasing stress using direct and coda wave velocity measurements in faulted and intact granite samples

DOI: 10.57757/IUGG23-0529 - [LINK]()

Kiran Pandey[1], Taka'aki Taira[2], Georg Dresen[3], Thomas H. Goebel[1]

A better understanding of damage accumulation before dynamic failure events in geological material is essential to improve seismic hazard assessment. Previous laboratory tests revealed that such failure events are preceded by a phase of extending micro-cracks, leading to detectable changes in bulk seismic properties. We use seismic velocity estimates to measure changes in micro-crack populations and damage in intact actively and faulted Westerly granite samples. We use an array of 16 piezo-ceramic transducers to send and record ultrasonic pulses and to determine temporal seismic velocity changes. The coda-wave interferometry (CWI) and direct phase arrivals determine velocity changes.

The tests show that: 1) Higher confining pressures increase seismic velocities due to reduced pore space and no hysteresis effects during the unloading cycle. 2) During increasing differential stress, the crack growth before the onset of AE activity is aseismic and could be associated with a monitoring or deformation mechanism. However, the velocity measurement records the changes in a medium way before we observe AE or non-linearity in stress and strain data. 3) Direct waves exhibit strong anisotropy, increasing differential stress and accumulating damage before rock fracture. On the other hand, CWI produces velocity variations that are similar to P-wave velocity changes along the vertical axis. 4) Seismic interferometric measurements are thought to be highly sensitive to changes in the medium. However, we found that such measurements also depend on the type of rock damage (i.e., orientation and shape).

Following its deployment at the surface of Mars, the seismometer SEIS of the InSIght – NASA Mission has detected tens of very high-frequency (VF) seismic events (> 1 Hz). In this work, we constrain the regional attenuation properties of the Martian lithosphere using both impacts and VF data to characterize the heterogeneities and volatile content as a function of depth. To carry out this task, we model the high-frequency energy envelopes of the seismic events using a multiple-scattering approach, considering a stratification of velocity and attenuation in the medium. In a first approximation, we consider a simple attenuation structure composed of a heterogenous crust overlying a weakly inhomogeneous mantle. Our inversion results show that a strongly diffusive and globally dry layer of about 20 km thickness in the vicinity of the InSight landing site (northern plains) suffices to retrieve the shape of near impacts, but the thickness has to be increased to at least 60 km to recover the shape of distant VF events. The observed correlation between the depth extent of the diffusive layer and the thickness of the crust indicates that the main cause of scattering is the lithological heterogeneity. Furthermore, our model suggests that the sources of a number of distant VF seismic events are shallow and located in the southern highlands or in close vicinity of the Martian dichotomy.

Integrity of overburden formations to the underlying reservoir rocks plays a vital role in permanent storage of CO_2 within geological traps. Focused fluid escape structures (also known as chimney and pipe structures) are highly permeable (sub-)vertical geological features within the sedimentary rocks that can represent a substantial risk to geological CO_2 storage projects. Despite the importance of such structures to the subsurface hydraulic system, their internal structures and fluid flow properties are poorly constrained to date. In this study, we examined the internal structure of a representative gas chimney underlying the Scanner Pockmark Complex in the North Sea, where methane is currently leaking to the seabed. We recovered an acoustic velocity model of the chimney structure and the host formations, using 3-D full waveform inversion (FWI) technique. The inverted data consists of ~125000 seismic traces from 23 ocean bottom seismometers (OBS) covering an area of 66 km^2. We set the FWI scheme to include only diving waves at offsets of 1300-4600 m, corresponding to incident angles of about 60º to 80º respectively at the maximum well-resolved depth of 700 mbsl. The inverted model, at the maximum frequency of 7 Hz, revealed a complex fluid escape structure with an indirect vertical gas migration pathway that manifested itself as a simple gas pipe structure on a coinciding seismic reflection image. In addition, integration of the recovered velocity structures with a calibrated Gassmann model suggested a patchy gas saturation within the area.

indirect vertical gas migration pathway that manifested itself as a simple gas pipe structure on a coinciding seismic reflection image. In addition, integration of the recovered velocity structures with a calibrated Gassmann model suggested a patchy gas saturation within the area.

Seismic attenuation and lithosphere rheology in the eastern margin of the Tibetan Plateau

DOI: 10.57757/IUGG23-1892 - LINK

Connecting the plateau with cratons in east China, the eastern margin of the Tibetan Plateau is an area with the youngest uplift, strongest deformation, and frequent occurrence of large earthquakes. This region where the topographic characteristics change significantly from south to north becomes an ideal experimental site for investigating the continental geodynamics and seismogenic environment. Most seismological researchers use seismic velocity to constrain the rheological strength and crustal flow distribution in the lithosphere, upon which the deformation can be explored for the crust and upper mantle. However, seismic velocity is related to both rock strength and composition. Therefore, the multiplicity of geodynamic interpretation is unavoidable. However, seismic attenuation is a direct observation of deep temperature and rheological strength. Therefore, we construct a broadband high-resolution layered attenuation model for the lithosphere in the eastern margin of the Tibetan Plateau by using the Pg, Lg, Pn, and Sn waves propagating in the crust and uppermost mantle. The attenuation model provides a fine structure with 3D rheological strength and thermal distribution in the lithosphere. We investigate the dynamic origins of the distribution of soft ductile materials and upon which we exploit the tectonic evolution and seismogenic environment under the lithospheric compression and collision in the eastern margin of the Tibetan Plateau. This research was supported by the National Natural Science Foundation of China (U2139206, 41974061, and 41974054).

At high frequency (f>0.5Hz), spatial variations of seismic attenuation parameters -scattering and absorption- control to a large extent the variability of observed ground motions at the regional scale. Hence, our ability to predict seismic hazard depends critically on mapping frequency-dependent attenuation. To address this issue, we developed a hybrid inversion method to separate attenuation parameters (scattering and intrinsic absorption) in 6 frequency bands covering the 0.75 – 24 Hz range from the modeling of the S-wave energy envelopes. Synthetic envelopes and their partial derivatives with respect to attenuation parameters are calculated using the Monte-Carlo method for elastic waves in a simple but realistic model of the Earth's lithosphere. The hybrid inversion method combines a grid-search with an iterative optimization using the Levenberg-Marquardt algorithm, which respectively test different models of random heterogeneities and constrain the level of scattering and absorption.

The inversion procedure has been applied to more than 10000 waveforms retrieved from the database of the French seismological and geodetic network RESIF. The obtained attenuation maps show the extreme variability of frequency-dependent attenuation parameters (scattering and intrinsic absorption) at the regional scale. In particular, we find zones of strong scattering in the Western Pyrenees at all frequencies and in young sedimentary basins below 3 Hz. Absorption is stronger in the Paris Basin at low frequency and in the French Alps above 3-6 Hz. Western France is characterized by weak scattering and absorption. We also find that scattering generally dominates absorption below 1-2 Hz while the opposite is true at higher frequency.

The Mt.Pollino area is the largest seismic gap in Italy, with faults capable of M6.5-7 but no historical and instrumental M6 events recorded. Between 2010 and 2014 this area has been affected by a seismic sequence of more than 10,000 small magnitude earthquakes and two moderate main events occurred late in the sequence (ML 4.3 and ML 5.0).

The goal of this work is to provide 3D scattering and absorption images of this area using the peak delay time and the coda-Q methods, respectively. Scattering anomalies suggest that the area involved in the sequence is highly fractured, with the strongest scattering contrast interpreted as the Pollino Fault. This large structure acted as a barrier, bounding migration of the seismicity southward, as suggested in recent structural geological works. Declustered high-absorption anomalies mark the area affected by the sequence, suggesting that fluids have played a key role in its development. This result is in good agreement with high VP/VS and high pore pressure anomalies highlighted by recent works on the area.

This work was supported by the PRIN-2017 MATISSE project (no. 20177EPPN2), funded by the Italian Ministry of Education and Research.

Estimation of the depth and frequency-dependent seismic attenuation using acoustic radiative transfer theory

DOI: 10.57757/IUGG23-4428 - LINK

Marcel van Laaten[1], *Ulrich Wegler*[1]
[1]*Friedrich Schiller University Jena, Institute of Geosciences, Jena, Germany*

The acoustic radiative transfer theory is utilized to analyze the propagation of seismic energy in a heterogeneous and random medium, and can be modeled by Monte Carlo simulations. By repeating the simulations and adjusting the non-isotropic scattering and absorption coefficients, the layer-specific intrinsic and scattering attenuation can be determined. The Monte Carlo simulation considers ray tracing in a deterministic and acoustic 1-D model. To validate the code, synthetic tests were conducted and the results indicate that it is possible to resolve both frequency- and depth-dependent attenuation values. The code was then applied to observed seismograms along the Leipzig-Regensburg fault zone. The fault zone was divided into a northern and southern area and the attenuation of the crust was calculated between 3 and 33 Hz. Our results demonstrate that the upper crust exhibits different characteristics compared to the middle and lower crust, as the intrinsic attenuation is dominant in the upper crust and significantly lower in deeper areas where earthquakes occur. In the mantle, the northern and southern regions also differ, with the southern part displaying stronger attenuation due to higher temperature.

Ambient seismic noise acquired in the Cerdanya Basin (Eastern Pyrenees) is used to assess the capability of different methodologies to map the geometry of a small-scale sedimentary basin. We present results based on a 1-year long broad-band deployment covering a large part of the Eastern Pyrenees and a 2-months long high-density deployment covering the basin with interstation distances around 1.5 km. The explored techniques include autocorrelations, ambient noise Rayleigh wave tomography, horizontal to vertical spectra ratio, and band-pass filtered ambient noise amplitude mapping. The basement depth estimations retrieved from each of these approaches, based on independent datasets and different implicit assumptions, are consistent, showing that the deeper part of the basin is located in its central part, reaching depths of 600-700 m close to the Têt Fault trace bounding the Cerdanya Basin to the NE. The results from the different methodologies have an overall consistency, although significant differences appear in some zones. The results show also that when high-density seismic data are available, mapping the ambient noise amplitude in a selected frequency band is a valid tool to quickly map the sedimentary 3D geometry. Besides this methodological aspect, our results help to improve the geological characterization of the Cerdanya Basin and will provide further constraints to refine the seismic risk maps of an area of relevant touristic and economic activity.

We use ambient noise tomography to image the crustal-scale anisotropic structure beneath the Marwar craton of northwestern India to understand the impact of magmatism, crustal growth, and melt distribution. The study region was shaped by several magmatic events that include the Neoproterozoic Erinpura and Malani volcanism, Cretaceous Barmer-Sanchor rifting, and pre-Deccan volcanism. Correlograms of ~300 paths from 29 broadband seismic stations were computed for the vertical and transverse components. Rayleigh and Love wave group velocity dispersion curves of the fundamental mode were computed for the period ranging from 4s to 40s using the frequency-time analysis method. The 3D shear velocity tomography model was constructed by regionalizing the dispersion data to obtain local dispersion curves which were then inverted using a non-linear trans-dimensional Bayesian approach. The geometry of the Barmer-Sanchor rift is clearly delineated by an elliptical zone of low group velocity anomalies. The tomograms reveal low shear velocities (<3km/s) corresponding to thick sediments (~4km) in the rift. The crustal thickness beneath the rift varies from 30km to 34km while the region away from the rift has an average crustal thickness of 39km. The lower crust is characterized by high shear velocities ranging from 3.8km/s - 4.25 km/s that indicate magmatic underplating. Overall, the study region is characterized by positive radial anisotropy (~8%) that decreases away from the rift, crustal thinning beneath the rift, and a high velocity lower crust that reflects magmatic intrusion linked to rifting and magmatic events.

Oceanic Transform Fault (OTF) systems have long been identified to play a crucial role in plate tectonics. However, comprehensive studies of their nature, origin and evolution have been hampered by their remoteness and sparse instrumentation. Morphological studies reveal OTFs as structurally and seismically complex zones characterized by physical segmentation, extensional basins, intra-transform spreading centers (ITSC), parallel to sub-parallel fault strands, etc. How this complexity is reflected in the crust and upper-mantle, and their tectonic implications have been hardly investigated tomographically. In this study, we use first-overtone Rayleigh waves extracted from ~1 year of ambient noise data recorded by 67 ocean-bottom seismometers to image the crust and uppermost mantle down to ~25 km beneath the ~350-km-long Blanco Transform Fault Zone (BTFZ) and adjacent oceanic plates. With the estimated phase velocity dispersion measurements (3.5-8.7 s), we inverted for phase velocity maps and then a 3-D shear wave velocity model. In general and in contrast to the adjacent oceanic plates, we imaged slow velocities along the BTFZ (velocity reduction reaching ~0.4 km/s) from surface to ~25 km depth. An actively deforming crust that opens and sustains pathways for enhanced hydrothermal circulation as indicated by recent local seismic studies that found abundant crustal seismicity along the BTFZ broadly explains this observation. Slower velocities observed in the mantle beneath the Blanco Ridge advocates for extensive serpentinization which might explain the recently documented mantle earthquake swarms linked with aseismic creep in this fault segment.

How the Tibetan Plateau grew farther north from the India-Asia collision boundary has profound implications on the mechanics of continental deformation and accretion. The Hoh-Xil Basin in the northern Tibetan Plateau was once a foreland basin adjacent to the high-elevation proto-plateau until the Early Miocene and was rapidly uplifted since then. Here we collected 363 broadband seismic stations operated from 2007 to 2020, including 226 stations from five linear arrays mainly deployed in two north-south profiles across the core of the Hoh-Xil Basin with an average interstation distance of ~15 km. Based on Rayleigh wave signals extracted from ambient noise cross-correlations, we obtained more than 13000 dispersion curves and constructed a 3-D S-wave velocity (V_S) model using measurements in 6–65 s periods by the direct inversion method. Our model shows significant lateral variations of V_S in the crust and uppermost mantle from the southern to the northern Tibetan Plateau, which should reflect different melt fractions according to the theoretical seismic velocity-melt fraction relationship. We observe widespread partially molten crust in the northern Tibetan Plateau but only isolated pockets in the south manifested as low-V_S anomalies in the middle-lower crust. The spatial correlation of these low-V_S anomalies with strong uppermost mantle low-V_S anomalies and young crust-/mantle-derived magmatism in the Hoh-Xil Basin suggests that the plateau grew through magmatic intrusion and accretion induced by the asthenospheric upwelling due to lithospheric mantle removal. These findings lead to implications for the role of delamination-driven magmatism in the continental crust growth in collision orogens.

Intra-crustal low-velocity zones (LVZs), indicating the mechanically weak crust, are widely observed in Southeast Tibet but remain controversial. New constraints on LVZs in this area are obtained from a joint inversion of receiver functions and Rayleigh wave dispersion using a newly deployed linear seismic array. Our shear-wave velocity model reveals two isolated LVZs (~3.5 km/s) in the middle crust at almost the same depth (~30-40 km) wrapping around the rigid Daliangshan sub-block. Combined with previous observations, the two middle-crust LVZs may attribute to the crust materials transporting from the central Tibetan Plateau to its southeast margin. The mechanically weak LVZs in the middle crust might imply decoupling between the upper and lower crust. We speculate that the middle crustal flow model plays a major role in the southeastern margin of the Tibetan Plateau accommodating the deformation caused by the collision between the Indian and Eurasian plates.

The Burmese arc consists of the Indo-Burman Ranges (IBR), an accretionary wedge in the west and the Central Myanmar Basin (CMB) in the east. It is bounded in the east by the seismically active Sagaing Fault to the Shan Plateau. Intermediate-depth seismicity below Myanmar occurs at depths up to ~150 km, generally understood to be related to the subducting Burma slab. We use ambient noise tomography to construct a regional three-dimension (3-D) shear wave velocity model, aiming at figuring out the transition from oceanic subduction to continental subduction/collision along the Burmese arc and how it affects the upper plate crustal deformation. Our dataset includes 30 seismic stations from a recently deployed temporary seismic array and ~50 permanent stations in and around Myanmar. Ambient noise corss-correlations are calculated at periods of 5-60 s and are inverted for a 3-D velocity model from the crust to the uppermost mantle. Our model shows a low-velocity anomaly extending to >20 km depths beneath the northern part of the CMB that accurately defines the Chindwin Subbasin. The crust beneath the IBM is characterized by low velocity, which probably reflects the fluid-rich accreted sediments that has experienced metamorphism in the mid-lower crust. Underneath the Sagaing Fault an N-S trending high-velocity anomaly is clearly visible at depths of 40-70 km in the uppermost mantle extending from 20°N to 24°N. The anomaly could represent a remnant slab of the Incertus Arc collision/subduction and mark the eastern boundary of the Burma plate.

Common ambient noise tomography studies use straight ray tomography for deriving group or phase velocity maps from long-term cross correlation of station pairs. Being suitable for low frequencies and large inter-station distances, this simplification can be problematic in near-surface studies where higher frequencies are considered and stronger lateral velocity variations are encountered. The eikonal tomographic approach avoids the assumption of straight rays by computing local group or phase velocities from the gradient of the traveltimes measured between the virtual sources and receivers, therefore approximating the true propagation trajectories of surface waves. In this work, we applied the eikonal approach to data from a dense, one-month long seismic deployment consisting in 400 3-component nodes installed over a 10x10 km zone in the heavily industrialized area of the Tricastin Nuclear Site (Rhône valley). This area is located above a sediment-filled, deeply incised canyon dug during the Messinian Salinity Crisis. The extreme subsurface topography of this canyon makes this area an interesting target for an eikonal tomographic study. We implemented an automated method that measures the phase traveltimes of the fundamental mode of Rayleigh and Love waves from the ambient noise cross correlations' phase spectra. We then applied the eikonal approach to the measured traveltimes, resulting in a set of phase velocity maps for Rayleigh waves that are in good agreement with the existing geological knowledge and cover a frequency range from 0.4 to more than 5 Hz.

Common ambient noise tomography studies use straight ray tomography for deriving group or phase velocity maps from long-term cross correlation of station pairs. Being suitable for low frequencies and large inter-station distances, this simplification can be problematic in near-surface studies where higher frequencies are considered and stronger lateral velocity variations are encountered. The eikonal tomographic approach avoids the assumption of straight rays by computing local group or phase velocities from the gradient of the traveltimes measured between the virtual sources and receivers, therefore approximating the true propagation trajectories of surface waves. In this work, we applied the eikonal approach to data from a dense, one-month long seismic deployment consisting in 400 3-component nodes installed over a 10x10 km zone in the heavily industrialized area of the Tricastin Nuclear Site (Rhône valley). The observation of main seismic phases reaching the core shadow beyond 100º is known to traverse through the core of the Earth like PKP or PKiKP waves. Besides these, Pdiff wave that diffracts along the Core-Mantle Boundary (CMB) can also propagate into the core shadow. PKP is not the first wave that arrives in the shadow zone. Scattering of PKP at the CMB or in the whole mantle creates precursors to PKP arriving a few seconds before the actual PKP arrival. However, the scattering of P waves in the whole mantle allows waves to arrive more than 100 s prior to the PKP precursor if they do not enter the core but scatter around it through the fast mantle material. This energy arrives after the theoretical arrival of the Pdiff phase appearing to be the coda of Pdiff. We studied high-frequency (1-2 Hz) seismogram stacks of several large magnitudes (≥ 7.9 Mw) earthquakes. Individually Pdiff coda can be observed at very long distances beyond 150° in these events and deeper events allow for more clean observations. The Monte Carlo method is used to simulate the global earthquake scattering in a 1D spherically symmetric heterogeneous model. Simulation in an independently derived model of heterogeneity matches the observation of the Pdiff coda. An analysis of the origin of Pdiff coda is discussed using simulations with different scattering layers from the lithosphere to CMB. We demonstrate that the single scattering in the whole mantle explains the essential features of the observed Pdiff coda.

Seismic and ultrasound tomography can provide rich information about spatial variations of elastic properties inside a material rendering this method ideal for geophysics and nondestructive testing. These tomographic methods primarily use direct and reflected waves, but are also strongly affected by waves scattering at small scale structures below the resolution limit. As consequence conventional tomography can unveil the deterministic large scale structure only, rendering scattered waves imaging noise. With Adjoint Envelope Tomography (AET) we propose a mathematically rigorous tomographic approach to image the distribution of small scale heterogeneity and absorption. AET is based on a forward simulation of energy propagation using Radiative Transfer Theory to synthesize seismogram envelopes and an adjoint (backward) simulation of the envelope misfit to obtain the gradient for iterative model updates -- in full analogy to full-waveform inversion (FWI). We present the mathematical concept, technical aspects of the simulations and applications of the approach to numerical experiments and an ultrasound experiment in a metric size concrete specimen. The trade-off between the quality factor Q used to quantify intrinsic attenuation and the fluctuation strength ε representing the characteristics of the heterogeneity reflects the similarity of the effects of absorption and scattering have on ballistic waves. We discuss a strategy to reduce the effect of this trade-off in the application of AET by using dedicated time windows for the imaging of both properties.

Seasonal changes in shallow earth structure in the permafrost region of Alaska

DOI: 10.57757/IUGG23-0351 - LINK

Toshiro Tanimoto[1], *Aaron Anderson*[1]
[1]*University of California- Santa Barbara, Department of Earth Science, Santa Barbara, USA*

We analyzed data from the EarthScope Transportable Array in Alaska in order to understand the nature of near-surface melting in the permafrost region. Data consisted of (1) temperature, (2) vertical seismic data, (3) horizontal seismic data, and (4) wind data. Observations at some stations indicate a rapid melting phenomena in the summer that causes a thousandfold increase in horizontal power spectral density. This rapid rise in horizontal seismic noise typically occurs in July, lasting about 30 days. The initiation of this major melting period does not happen immediately after the surface temperature exceeds 0^{o}C; instead, there is a delay of about a month. After the peak horizontal amplitude is reached, it gradually returns to the pre-melting level. Many stations show that this return occurs by December. However, some stations require until March or April in the following year to arrive back to their pre-melting level. For all stations, this return occurs well after the surface temperature becomes negative in September or October. This suggests that the melt layer remains at depth as surface temperatures drop below freezing, perhaps sandwiched between the developing ice from the surface and the underlying permafrost ice. However, we noted some caution is required at a few stations because a transient surge in horizontal amplitudes occurs in February and November that appears to be correlated with winds. We summarize the temporal characteristics of individual stations, their seasonal geographic patterns throughout Alaska and a potential mechanism to explain a sudden increase of horizontal noise.

[2]*NIED, Storm- Flood- and Landslide Research Division, Tsukuba- Ibaraki, Japan*

Vibrations induced by a streamflow are major component of seismic ambient noise. They stand out in seismograms especially in the upstream basins, where the flow speed is high and the amount of cultural noise is low. In hydrological point of view, real-time monitoring of river discharge and water depth in the upstream basin is essentially important for early forecast of flooding. However, in-situ monitoring of streamflow is extremely difficult in the upstream basin due to poor accessibility and complexly distributed tributaries in rough terrains. Therefore, a new tool is demanded for remotely monitoring of flow conditions in the upstream basins. The use of seismic noise will be a good candidate for this purpose (e.g., P.C. and Sawazaki, 2021).

In this study, we compared records of Hi-net seismograph and water-level observation in northeastern Japan. The target period is from October 10 to 17, 2019, when the 2019 Typhoon Hagibis passed through eastern Japan. After clipping transient signals such as earthquakes from the Hi-net seismograms, we computed envelopes of the seismogram in the frequency ranges of 2 Hz to 32 Hz. Then we compared them with the water level records located in the same river basins.

As a result, we found that correlation between the seismogram envelope and the water level tends to be higher in higher elevation areas. By fitting the two observables with a power-law relationship, we found that the water level is roughly proportional to the 0.2 to 0.6 power of the noise energy.

Time-lapse monitoring of seismic velocity at a volcanic area can provide important information about the dynamics of the volcanic system and its temporal variability. One standard technique to monitor small changes in the medium is ambient noise interferometry. This technique is based on quantifying relative velocity variations (dv/v) by measuring changes in the ambient noise cross-correlation signal phase. In this study, we demonstrate that together with velocity variations, the study of changes in seismic attenuation (Qc) extracted from ambient noise cross-correlation could be relevant for volcano monitoring.
The Qc is determined using the lapse-time dependence method (Calvet and Margerin, 2013), in which, Qc is measured as a function of the coda window length for different onsets of the ambient-noise cross-correlation coda. We apply this technique to the 2021 Cumbre Vieja eruption in La Palma (Canary Islands), which started on Sept. 19th and had a significant social and scientific impact. First, we determine a reference Qc model of the Cumbre Vieja volcano using data from Aug. 1st to 31st, 2021. Then, we analyze the spatio-temporal Qc variations during the nineteen days preceding the eruption, and we compare our results with previously obtained dv/v results. We observe an increase of Qc during the pre-eruptive phase, corresponding to a dv/v decrease. We hypothesize that the observed correlated Qc increase and dv/v drop could be explained by the ascent of hydrothermal fluids towards the surface before the eruption.

Capability of highly stable vibration source, which is named ACROSS, that we have used is evaluated for monitoring near surface ground structure. Near-surface change in ground structure due to environmental effect is often observed, because near surface part is sensitive to the environmental change such as strong ground shaking, rain fall, ground water level, and atmospheric temperature. Effect of strong ground shaking was found in the experiment in Awaji (Ikuta et al. 2002) and interpreted as opening of preferred oriented cracks and water penetration with the change in seismic velocity (Ikuta and Yamaoka,2004) and amplitude (Tsuji et al., 2022). These findings are attributed to a simple configuration of source and receivers, in which receivers are deployed about 1000m below the source. Effect of atmospheric temperature is also found in this site and can be attributed to the change in the energy dissipation in the shallow part. Effects of rain and ground water are investigated in Suzuki et al. (2021) using both P and S wave simultaneously. Different response is found between seasonal change and short-term change after raining. Seasonal change can be interpreted as the change in crack density and saturation, but short-term change can be interpreted as micro-scale mixture of water and air in fractures. Oba et al (2022) found a clear response to rain fall in later arrivals of vibration signal observed by a seismic array of about 2km from the source. These finding shows the capability to distinguish variety of penetration of ground water with vibration source.

Quantifying Changes in the seismic velocity (*dv/v*) from repeating sources or ambient noise surveys is an established tool in seismology. *dv/v* has been shown to correlate to a multitude of parameters such as stress variations, pore pressure changes, and modifications in the microscopic and macroscopic integrity of the sampled medium (i.e., “damage”). In turn, these parameters are impacted by an even greater number of mechanisms, for example, precipitation, temperature, surface loading, seismic activity, hydrology, volcanic activity, or tidal forces. However, their relationships to *dv/v* are often non-linear, hard to quantify, and poorly understood. Additionally, for “field data”, it can be challenging to decipher the contribution of each individual parameter to *dv/v* changes. In this work, we analyse continuous seismic data and interdisciplinary datasets from Mt St Helens (USA) and the Kamchatka peninsula (Russia) to illustrate the diversity of mechanisms impacting dv/v and discuss potential strategies to unravel the observations. We show that, for volcanic areas in particular, analysing *dv/v* is a complex task due to the addition of volcanic activity, high-relief topography, and strongly heterogeneous subsurface structures.

Temporal variation of shallow subsurface structure is monitored by the SPAC-based method using a seismic array on a landslide area. We deployed a seismic array that consists of 14 three-component seismometers with a natural frequency of 4.5Hz on flat ground with diameters of 28m x 75m in a landslide area in the western part of Shizuoka prefecture, Japan. We used the data from October 2020 to May 2022.
We applied the SPAC method using ambient noise data. The SPAC is obtained for each day and temporal variations are investigated. We compared the daily SPAC with the reference SPAC, which is obtained by stacking all the daily SPAC. The results show a characteristic change in SPAC that includes weekly changes, rainfall-related changes, and seasonal changes. In the weekly changes, a systematic difference is found between weekends and weekdays. Regarding the rainfall-related change, the large vibration, which has a significant impact on SPAC analysis, by a stream near the array is often observed during/after heavy rain. We statistically estimated and removed the effect of these two changes to monitor the variation due to the subsurface structure. We found the SPAC in the high-frequency region decreases due to rainfall, which is regarded as being due to a rise in the groundwater level caused by rainfall. MMSPAC (multimode spatial autocorrelation) method (Asten.2006, Ikeda.2012) is used to estimate the most strongly affected depth ranges to compare the structure model using reference SPAC. The seasonal change may be associated with the state of the shallow groundwater.

The Maltese islands, approximately 314 km^2 in area with a high population density, face high levels of water stress due to low amounts of rainfall and a dependence on groundwater abstraction. Until now, *in-situ* borehole readings have been the only method utilised to monitor the quantitative status of groundwater in the Maltese islands. This study investigates an innovative, cost-effective approach to groundwater monitoring in a small island environment by computing cross-correlations and autocorrelations of ambient seismic noise recorded on seismic networks of broadband and short-period stations in the Maltese islands. We compare the borehole readings of groundwater levels ranging from 0.28-3.39 m above mean sea level with the variations in seismic velocity ($\delta v/v$). We apply appropriate filters for the broadband and short-period stations of 0.1-1 Hz and 0.3-3 Hz, respectively. The results demonstrate clear seasonal changes in the seismic velocities, which can be correlated with changes in groundwater levels in nearby boreholes. We find that variations of the $\delta v/v$ from autocorrelations are more pronounced than the cross-correlation, with maximum seismic velocity changes of ~2% and ~0.3% respectively. The quality of the $\delta v/v$ deteriorates at longer interstation distances where seasonal variations are less noticeable. Presumably, this is because longer interstation paths tend to traverse more complex geology, different types of aquifers, or even the sea.

Temporary variation of shallow groundwater level derived from cultural noise interferometry in southern Longitudinal Valley, Taiwan

DOI: 10.57757/IUGG23-3898 - LINK

Wen-Tzong Liang[1], *Jian-Cheng Lee*[1]
[1]*Institute of Earth Sciences, Academia Sinica, Nankang- Taipei, Taiwan Province of China*

We have computed the cross-correlation functions (CCF) of the cultural noise to measure the temporal variation in seismic velocity for each station pair among the local Chihshang array in Taiwan, which was deployed in 2013-2020. A significant seasonal variation of asymmetric CCFs in the frequency band of 2-8 Hz, which is supposed to be the cultural noise, has been identified in this study. We further extract the velocity change (δv/v) by using the stretching method with the largest value up to 12% and found that the δv/v highly correlates with the nearby shallow groundwater level (GWL) fluctuation that usually occurs from September to November after rain season every year. On the other hand, the temporal variation of δv/v can only be observed for coda CCF with frequency higher than 3 Hz, which indicates that the source depth is within 30 m in the near surface layer based on its corresponding sensitivity kernel. The station pairs along the eastern side of Longitudinal Valley present smaller amplitude of δv/v, which may reflect a reduced GWL fluctuation in this region. Even though there is a clear 1-month lag between the rainfall and the GWL, there is no phase delay between the time series of the observed δv/v and the GWL. Our results suggest that we are capable of quantitatively monitoring the transient groundwater storage by a analyzing the cultural noise cross correlation functions in the Chihshang area, where is covered with a thick gravel bed in the southern Longitudinal Valley.

We have computed the cross-correlation functions (CCF) of the cultural noise to measure the temporal variation in seismic velocity for each station pair among the local Chihshang array in Taiwan, which was deployed in 2013-2020. A significant seasonal variation of asymmetric CCFs in the frequency band of 2-8 Hz, which is supposed to be the cultural noise, has been identified in this study. We further extract the velocity change (δv/v) by using the stretching method with the largest value up to 12% and found that the δv/v highly correlates with the nearby shallow groundwater level (GWL) fluctuation that usually occurs from September to November after rain season every year. On the other hand, the temporal variation of δv/v can only be observed for coda CCF with frequency higher than 3 Hz, which indicates that the source depth is within 30 m in the near surface layer based on its corresponding sensitivity kernel. The station pairs along the eastern side of Longitudinal Valley present smaller amplitude of δv/v, which may reflect a reduced GWL fluctuation in this region. Even though there is a clear 1-month lag between the rainfall and the GWL, there is no phase delay between the time series of the observed δv/v and the GWL. Our results suggest that we are capable of quantitatively monitoring the transient groundwater storage by a analyzing the cultural noise cross correlation functions in the Chihshang area, where is covered with a thick gravel bed in the southern Longitudinal Valley.

Inspecting tidal signals observed by passive image interferometry

DOI: 10.57757/IUGG23-3065 - LINK

Jozef Müller[1], *Tom Eulenfeld*[1], *Ulrich Wegler*[1]

Solid Earth is subjected to nanostrain tidal deformations caused by gravitational attraction of the Moon and Sun. This causes periodic deformations of imperceptible fractures in the shallow rock that likely result into subtle variations of seismic velocities. It is possible to theoretically model the gravitational tidal deformations while the seismic velocities can be estimated, e.g., using ambient noise recordings processed with passive image interferometry. Combining these two pieces of information could allow for in-situ assessment of bedrock properties beneath seismic stations. In this study, we tried to accomplish this task using 18 standalone seismic stations (i.e., no array) from a network of the Integrated Plate Boundary Observatory Chile, complemented by several others in Europe and in the Americas. The velocity changes were mostly estimated with seismic recordings filtered in 1-4 and 4-7 Hz bands, using hourly Green's functions acquired after temporal stacking. Analysed coda lapse time windows of the Green's functions were 1-6, 5-10 and 8-13 seconds. Tide-related velocity changes were observed (mostly the M2 component). However, our results show that observability of such tide-related velocity variations seems to be strongly related to the station proximity to oceanic coastlines. This raises reasonable doubt about the required solid Earth tides origin of the observed tidal signals.

SANS: Daily Global Seismic Ambient Noise Source Maps

DOI: 10.57757/IUGG23-1857 - LINK

Jonas Igel[1], Daniel Bowden[1], Andreas Fichtner[1]
[1]ETH Zurich, Department of Earth Science, Zürich, Switzerland

With amplitude and full-waveform based ambient noise tomography and monitoring methods on the horizon, knowledge of the underlying noise source distribution is vital to avoid possible misinterpretations, e.g., in terms of time-varying Earth structure. Particularly the oceanic microseisms have strong spatio-temporal variations on multiple scales which could influence full waveform or travel time measurements if not taken into account properly. In this work, we present daily Seismic Ambient Noise Source (SANS) maps of the secondary microseisms (0.1 to 0.2 Hz) on a global scale which are made available to the public here: sans.ethz.ch (Igel et al., 2022).

The computation of daily global SANS maps is possible due to recent improvements of non-linear finite-frequency noise source inversion methodology including pre-computed wavefields and spatially variable grids (Igel et al., 2021). Furthermore, by introducing an initial model from a different noise source imaging method - Matched Field Processing (MFP) - we accelerate the convergence of the inversion and improve the final maps. In collaboration with the Swiss National Supercomputing Centre (CSCS), we are able to run daily global SANS inversions which can be viewed, downloaded, and implemented into other studies. This paves the way for future full waveform ambient noise source and structure inversion workflows.

Six degree-of-freedom (6-DoF) ground motion measurements are recorded combining a rotational sensor and a seismometer. This allows in principle to determine the back azimuth of a moving source using a single point measurement. We investigated the movement of a vibroseis truck operated from 20 November 2019, 11:00 UTC to 21 November 2019, 14:00 UTC. We used 480 Sweep signals each lasting 15 seconds in a broad frequency range between 7 to 120 Hz from 160 different locations. We derived back azimuths for each sweep from 6 DoF data and calculated root mean square amplitudes of each ground rotation component. We repeat this procedure for 5 other nearby rotational sensors of the same type. Within the first day, the North pointing rotation axis of all sensors recorded larger amplitude signals at the beginning of the experiment proving that SV shear wave energy is dominant. Later, we observed larger amplitudes on the East component following the direction of the moving vibroseis truck. Conventional methods to locate a seismic source rely on the P wave polarization or arrival times measured with a network of stations. In this study we used S waves to track the vibroseis truck movements since rotational sensors are not sensitive to P wave motions.

The increase in urban population has caused many cities to upgrade their infrastructures and embrace the vision of a "smart-city". This endeavour relies on sensor data providing relevant information for local authorities and the general public. Our study is part of a project to evaluate different types of geodata and machine learning (ML) tools for this purpose, focusing on the city of Oslo, Norway. We aim to collect information about any kind of unusual event that produces a seismic signature, e.g., explosions or sudden mass movements, to facilitate fast emergency response. Furthermore, there is ongoing construction of tunnels and under-ground water storage facilities under populated areas in Oslo, activities which are accommodated by blasts felt by citizens. A challenge with seismic records from urban areas is the presence of a multitude of sources and high background noise level, requiring advanced processing methods. We use seismic data recorded on 10-12 Raspberry Shake sensors to quickly detect, classify, and locate urban seismic events, blasts in particular. We present a ML approach to first identify rare events and then build an automatic classifier from those templates. For the first step, we employ an outlier detection method using autoencoders trained on the continuous background noise. Badly reconstructed signals are identified as outliers and located using their surface wave (Rg) signatures on the seismic network. From several blast areas we select a cluster with most activity and train a supervised classifies using a Convolutional Neural Network to detect similar events.

The UPFLOW experiment: new observations from a ~1,500 km aperture array of 49 ocean bottom seismometers in the mid-Atlantic

DOI: 10.57757/IUGG23-3187 - LINK

Ana Ferreira[1], Miranda Miguel[2], Maria Tsekhmistrenko[1], Upflow Team[3]
[1]University College London, Earth Sciences, London, United Kingdom
[2]IPMA, Geophysics, Lisbon, Portugal
[3]UPFLOW, Upflow, Europe, United Kingdom

Constraining upward mantle flow is crucial to understand global mantle flow and directly link the Earth's interior with the surface. However, mantle upwellings that connect the deep mantle to the surface are poorly understood. The goal of the UPFLOW project (https://upflow-eu.github.io) is to develop new high-resolution seismic imaging methods along with new data collection to greatly advance our understanding of upward mantle flow. UPFLOW deployed 50 and recovered 49 ocean bottom seismometers (OBSs) in a ~1,000×2,000 km^2 area in the Azores-Madeira-Canaries region starting in July 2021 for ~13 months, with an average station spacing of ~150-200 km. The experiment included institutions from five different countries: Portugal (IPMA, IDL, Univ. of Lisbon, ISEL), Ireland (DIAS), UK (UCL), Spain (ROA) and Germany (Potsdam University, GFZ, GEOMAR, AWI). Most of the instruments had three-component wideband seismic sensors and hydrophones, but three different designs of OBS frames were used. Our analysis shows high-quality data, notably a substantial noise decrease in vertical component long-period data (T>~30s). We show illustrative recordings of teleseismic, local events and non-seismic signals (whales, ships, Tonga eruption), as well as systematic analyses of the background noise levels, clock skew and horizontal component rotation angles.

We present the detection and localization of local seismic events from a seismic network consisting of more than 350 short-period and broadband stations deployed in the Eifel volcanic region, centered around the Laacher See. The network spans an area of 180 km by 120 km. Using a combination of stacking and migration method and characteristic function generated by a re-trained neural network which are imaging P and S wave phase arrivals, we are able to detect and automatically locate seismicity in the network from continuous waveform data, including those events associated with dormant volcanic processes. The Eifel region has been geologically active for millions of years, with the most recent volcanic explosive eruption 13,000 years ago at the Laacher See. While the area is currently considered volcanic dormant, the ongoing seismic activity provides insight into the magmatic activity at depth. Our results can help to improve our understanding of the transcrustal magmatic system beneath intraplate volcanic fields and potential for future volcanic activity in the Eifel. The method and example presented here can be applied to volcanic provinces elsewhere support volcanic monitoring and fast, automatic processing of seismicity.

On-Fault Micro-Seismic Monitoring with Multiple Acoustic 3D Arrays: Insights from the Bedretto Underground Lab

DOI: 10.57757/IUGG23-2110 - LINK

Lu Tian[1], *Men-Andrin Meier*[1], *Alexis Shakas*[1], *Marian Hertrich*[1], *Domenico Giardini*[1], *the Bedretto Team*[1]
[1]*ETH Zurich, Institute of Geophysics, Zurich, Switzerland*

Accurate hypocentre parameters are crucial but challenging for characterising underground rock deformation. Microseismicity can reflect the small-scale deformation processes that occur before, during and after larger earthquake ruptures. The Fault Activation and Earthquake Rupture (FEAR) project will execute controlled fault stimulation experiments on the 50-100 metre scale at the Bedretto Underground Lab, an in-situ test bed with a granitic overburden of more than 1000 metres. The main objective of the FEAR project is to monitor earthquake rupture processes in the fault zone, and to better understand the microphysical rupture processes.

Until the full monitoring system is completed, most of our seismic sensors are located along the Bedretto tunnel. This non-optimal network geometry leads to large hypocentre location uncertainties. To best monitor seismic activity in the target volume, we develop an alternative monitoring method that uses beamforming from four miniature 3D arrays tetrahedral deployed above the tunnel. Using four acoustic emission sensors with the apertures ranging from 0.7 to 1.5m, each 3D array is capable of detecting weak and very high frequency (up to 100 kHz) signals.

We use synthetic data to show that earthquake hypocentres can be accurately estimated with back-projection, by combining four array beams. We test and calibrate the array method using seismic signals from controlled sources during an active seismic campaign. Tetrahedral arrays will form an important part of the integrated FEAR monitoring system, which includes on-fault to regional measurements, using acoustic emissions and accelerometers, fibre-optic cable network, fluid flow and hydro-bio-chemical monitoring.

Spatial b-value distribution based on Gaussian process inference using a geological prior with focus on California and Turkey

DOI: 10.57757/IUGG23-4748 - LINK

Sebastian von Specht[1], *Matthias Holschneider*[1], *Gert Zöller*[1], *Christian Molkenthin*[1], *Sebastian Hainzl*[2]
[1]*University of Potsdam, Institute of Mathematics, Potsdam, Germany*
[2]*Helmholtz Centre Potsdam German Research Centre for Geosciences GFZ, Department of Geophysics, Potsdam, Germany*

As a population parameter, reliable estimation of the b-value is intrinsically complicated, particularly when spatial variability is considered. We approach this issue by treating the spatial b-value distribution as a non-stationary Gaussian process for the underlying earthquake-realizing Poisson process. For Gaussian process inference the covariance—which describes here the spatial correlation of the b-value—must be specified a priori. We base the covariance on the local fault structure, i.e. the covariance is anisotropic: elongated along the dominant fault strike and shortened when normal to the fault trace. This adaptive feature captures the geological structure better than an isotropic covariance or similarly defined and commonly used running-window estimates of the b-value.

We demonstrate the Bayesian inference of the Gaussian process b-value estimation for two regions: California based on SCEDC earthquake and Turkey based on the AFAD earthquake catalog. The covariances in the inferences are calibrated with the SCEC community fault model the GEM fault model for California and Turkey, respectively.

Our model provides a continuous b-value estimate (including its uncertainties) which reflects the local fault structure to a very high degree. We are able to associate the b-value with the local seismicity distribution and link it to major faults. In light of the recent Turkish earthquake sequence, we also assess the temporal evolution of the b-value of recent seismicity before and after major events.

Constraining earthquake depth at teleseismic distance: Picking depth phases with deep learning

DOI: 10.57757/IUGG23-4563 - LINK

Jannes Münchmeyer[1], Frederik Tilmann[2], Joachim Saul[2]
[1]Univ Grenoble-Alpes, ISTERRe, Grenoble, France
[2]Deutsches GeoForschungsZentrum GFZ, Geophysics, Potsdam, Germany

Automated teleseismic earthquake monitoring is an essential part of global seismicity analysis. However, while constraining earthquake epicenters in an automated fashion is an established technique, constraining event depth is substantially more difficult, especially in the absence of nearby stations. One solution to this challenge are teleseismic depth phases but these can currently not be identified by automatic detection methods. Here we propose two deep learning models, DepthPhaseNet and DepthPhaseTEAM to detect depth phases. The first model closely follows the PhaseNet architectures with minor modifications; the latter allows joint analysis of multiple stations by adding a transformer to this basic architecture. For training the models, we create a dataset based on the ISC EHB bulletin, a high-quality catalog with detailed phase annotations. We show how backprojecting the predicted phase arrival probability curves onto the depth axes yields excellent estimates of earthquake depth. The models achieve mean absolute errors below 10 km. Furthermore, we demonstrate that the multi-station model, DepthPhaseTEAM, leads to better and more consistent predictions than the single-station model DepthPhaseNet. To allow direct application of our models, we integrate them within the SeisBench library for machine learning in seismology.

Detection of deep low-frequency tremors from past paper records at a station in southwest Japan based on convolutional neural network

DOI: 10.57757/IUGG23-1600 - LINK

Ryosuke Kaneko[1], Hiromichi Nagao[2], Shin-ichi Ito[2], Hiroshi Tsuruoka[2], Kazushige Obara[2]
[1]The University of Tokyo, Graduate School of Information Science and Technology, Tokyo, Japan
[2]The University of Tokyo, Earthquake Research Institute, Tokyo, Japan

Since deep low-frequency tremors are considered to be associated with large earthquakes that occur adjacently on the same subducting plate interface, it is important to investigate tremors that occurred before the establishment of modern seismograph networks such as the High Sensitivity Seismograph Network (Hi-net). We propose a deep-learning solution to detect evidence of tremors in the scanned images of paper seismogram records from over 50 years ago. In this study, we fine-tuned a convolutional neural network (CNN) based on the Residual Network (ResNet), pre-trained based on images of synthetic waveforms in our previous study, using a dataset comprised of images generated from real seismic data recorded digitally by Hi-net to facilitate a supervised analysis. The fine-tuned CNN was able to predict the presence or absence of tremors in the Hi-net images with an accuracy of 98.64%. Gradient-weighted Class Activation Mapping (Grad-CAM) heatmaps created to visualize model predictions indicated that the CNN's ability to detect tremors is not degraded by the presence of teleseisms. Once validated using the training images, the CNN was applied to paper seismograms recorded from 1966 to 1977 at the Kumano observatory in southwest Japan, operated by Earthquake Research Institute, The University of Tokyo. The CNN showed potential for detecting tremors in scanned images of paper seismogram records from the past, facilitating downstream tasks such as the creation of new tremor catalogs. However, further training using an augmented dataset to control for variables such as inconsistent plotting pen thickness is required to develop a universally applicable model.

The detection of earthquakes is a fundamental prerequisite for seismology and contributes to various research areas. Recent advances in machine learning technologies have enabled the automatic detection of earthquakes from waveform data. In particular, various state-of-the-art deep-learning methods have been applied to this endeavor. In this study, we proposed and tested a novel phase detection method employing deep learning, which is based on a standard convolutional neural network in a new framework. The novelty of the proposed method is its separate explicit learning strategy for global and local representations of waveforms, which enhances its robustness and flexibility. Prior to modelling the proposed method, we identified local representations of the waveform by the multiple clustering of waveforms, in which the data points were optimally partitioned. Based on this result, we considered a global representation and two local representations of the waveform. Subsequently, different phase detection models were trained for each global and local representation. For a new waveform, the overall phase probability was evaluated as a product of the phase probabilities of each model. This additional information on local representations makes the proposed method robust to noise, which is demonstrated by its application to the test data. Furthermore, an application to seismic swarm data demonstrated the robust performance of the proposed method compared with those of other deep learning methods. Finally, in an application to low-frequency earthquakes, we demonstrated the flexibility of the proposed method, which is readily adaptable for the detection of low-frequency earthquakes by retraining only a local model.

A novel application of deep learning in extracting Earth's free oscillation

DOI: 10.57757/IUGG23-1398 - LINK

Shiyu Zeng[1], Rumeng Guo[1], Binbin Liao[1], Kun Dai[1], Yijun Zhang[1], Xiaoming Cui[1], Jiangcun Zhou[1], Jianqiao Xu[1], Xiaodong Chen[1], Mingqiang Hou[1], Heping Sun[1]

The normal modes (i.e. Earth's free oscillations) are long-period low-frequency seismic signals, which are excited by a variety of factors, such as earthquakes, volcanic eruption, landslide, avalanche and so on, are an essential vehicle for global seismic tomography to elucidate large-scale heterogeneities within the deep Earth. Accurate extraction of signals on normal mode spectrum is a prerequisite for the imaging inversion, providing the differences between the observed and synthetic normal mode spectrum. However, the normal mode spectrum has great complexity due to many structural factors within the Earth, so unacceptable false and dismissed selections of the signals always occur, which hinder the development of exploration of the deep Earth's deep interior based on normal mode data. To address these problems, we build a deep-learning based neural network, named ModeNet, which is capable of precisely and efficient selecting the frequency windows to cover the target normal modal signals on a noisy spectrum, which could outperform the conventional spectrum-FLEXWIN method without relying on comparisons with synthetics. We also define our own method to evaluate the performance of ModeNet on the testing set and obtain a precision as high as ~0.98. Moreover, ModeNet achieves good generalization in processing seismograms of different events with different noise levels, components, and time window data, as well as superconductivity-gravimeter observations. Therefore, ModeNet could be implemented as a valuable tool for the future deep Earth inversion.

Source and spectral characteristics of ordinary and low-frequency earthquakes inferred from the probabilistic analysis of 10-year large data sets

DOI: 10.57757/IUGG23-4419 - LINK

Mariano Supino[1], Lauro Chiaraluce[1], Kazushige Obara[2]
[1]Istituto Nazionale di Geofisica e Vulcanologia, Osservatorio Nazionale Terremoti, Roma, Italy
[2]ERI, Earthquake Research Institute, Tokyo, Japan

We analyze two large data sets of 10 years (2009-2018) of ordinary earthquakes (OEs) detected in Italy by INGV and low-frequency earthquakes (LFEs) detected in Japan by JMA. We estimate the joint probability density function of seismic moment (M0) and corner frequency (fc) from S-wave displacement spectra. We use unfiltered signals and manually revised S-wave arrival times.

We estimate a wide range of moment magnitudes (Mw = 0-6 for OEs, 0.5-2.5 for LFEs) and observe a self-similar scaling between M0 and fc for both OEs and LFEs with a constant stress-drop of ~MPa and ~kPa, respectively. However, OE spectra show a constant corner frequency fc* ~10 Hz for Mw <~ 2.5. We refer fc* to the cut-off frequency of the medium anelastic attenuation, acting as a low-pass filter and producing an apparent corner frequency that does not scale with the earthquake source (M0).

Conversely, for the same Mw <~ 2.5, LFEs exhibit fc between 1 and 8 Hz that scale with M0, showing that their low-frequency content is a real source characteristic and not an apparent consequence of anelastic attenuation.

Finally, both OEs (for Mw <~ 2.5) and LFEs show a systematic underestimation of local magnitude when compared with moment magnitude, that we analytically explain as a consequence of anelastic attenuation (fc*) for OEs and of low stress-drop (~kPa) for LFEs.

Our method allows the use of raw earthquake waveforms to infer robust information both for monitoring purposes and for physical interpretations of the earthquake source in different tectonic settings and at different scales.

We improved near-realtime processing of seismic data by creating an automated workflow for seismic events detection, location and spectral parameter estimation in a form of a Python package. For detection task we take advantage of EQTransformer - deep neural network picker supported by GaMMA phase association. For source location we use both NonLinLoc (picking/travel-time based algorithm) and BackTrackBB software (partial waveform stacking algorithm). The source parameters including seismic moment, source size, static stress drop, apparent stress and radiation efficiency are calculated using spectral fitting method, where the inverse problem is solved using Markov-Chain Monte-Carlo method. Package performance was tested on the data from the LUMINEOS local surface network composed of 24 sensors located in Legnica-Głogów Copper District (LGCD), Poland. The region is one of the most seismically active in Europe, with several thousand seismic events induced every year (M>0.4) by copper ore mining and maximum local magnitudes reaching M4.2.

We used our workflow to analyze the seismicity framing strong mining rockburst in the LGCD on November 29, 2016. This tragic M3.4 event caused 8 fatalities and massive tunnels collapse. We aim to recognize plausible spatio-temporal changes of the source parameters revealing the source contribution to the damaging potential of this induced earthquake sequence. The obtained results can be used not only for scientists but also mining engineers, who are responsible for safety in the mine.

Seismic stations are operated 24 hours, recording groundmotions by various non-earthquake sources continuously.Meteorological phenomena and human activities areexamples of non-earthquakes. The rapid air expansion bylightning produces a shockwave that creates a cracksound, thunder. Thunder-induced seismic waves recorded atdense seismic stations in Seoul, South Korea are analysedfor inversion of thunder source spectra. Thethunder-induced seismic signals were well identified atdistances of < ~20 km. In the course of source-spectralinversion, the propagation and acoustic-to-seismiccoupling effects are counted. Direct acoustic-to-seismiccoupled seismic waves present apparent phase velocitiesof sound speed in atmosphere. Thunder-induced seismicwaves are dominant at high frequencies (>20 Hz). Thethunder-induced acoustic waves in the atmosphere areobtained by removing the acoustic-to-seismic couplingeffect and site-response effect from the observedthunder-induced seismic waves. The quality factors foracoustic wave attenuation in the atmosphere aredetermined. We determine acoustic thunder source spectraare determined by stacking the inverted acoustic spectra.Human activity is another major source of high-frequencyseismic noise. Analysis with seismic noises in threeconsecutive months of each year enables us to estimatethe noise levels without seasonal effects. The daytimeseismic noise-level changes in major cities of 11countries are assessed using the 3 month records fordecades. The annual seismic noise levels present strongcorrelations with gross domestic product (GDP),particularly with manufacturing and industrial GDP. Theseismic noise levels increase quickly with GDP in low GDPregions but slowly in high-GDP regions. The seismic noiselevels increased by 14 % to 111 % for 5-23 yr dependingon the economic conditions. The high-frequency noiselevel may be a proxy to present the economic condition.

Towards Routine Automatic Estimation of Standard Body- and Surface-Wave Magnitudes at ISC

DOI: 10.57757/IUGG23-1893 - LINK

Natalia Poiata[1], *Domenico Di Giacomo*[1]
[1]*International Seismological Centre, International Seismological Centre, Thatcham, United Kingdom*

Magnitude is a fundamental source parameter facilitating the characterisation of the size and amount of energy released by earthquakes and other types of seismic events. It provides an important input to a wide variety of seismological studies, from seismic hazard to statistical analysis of seismicity and nuclear explosion discrimination. Seismic network operators and observatories routinely estimate standard types of body- and surface-wave magnitudes using established procedures, however, the reported results are often inconsistent due to the differences in the implemented waveform processing schemes. These inconsistencies become more evident with the increasing volumes of recorded data currently faced by seismic networks. With the scope to address the issue, the International Seismological Centre (ISC; www.isc.ac.uk) aims to provide a routine estimation of the standard body- and surface-wave magnitudes using the global waveform data. We take the advantage of the comprehensive event-related information at ISC and the increasing amount of openly available, from the seismological data management centres, waveform data to provide an automatic and reproducible estimation of standard magnitudes following the guidelines of the International Association of Seismology and Physics of the Earth's Interior (IASPEI) Working Group on Magnitude Measurements.

In this presentation we describe the details of the procedure and examine the results of the magnitude estimations for over 69,000 earthquakes (M > 4.0) reported in the ISC Bulletin for 2016-2020. We will further discuss the performance of the procedure, compare obtained estimated magnitudes with those in the ISC Bulletin and present the advantage of including broadband body- and surface-wave magnitudes.

Automatic earthquake monitoring is widely used by a seismic network and fast reported for significant events. Traditional earthquake location methods require P-wave and S-wave manual phase picking or accurate automatically obtained first arrivals as first step. The event location is determined based on the inversion to best fit of all travel times. In this study, we design a procedure to locate earthquakes based on back-projection stacking of seismic energy. The stacking of seismograms using a varying time delay computation based on a regional crustal model. The grid search is used to fine optimum location in 3-D spatial grids based on the maximal value of all stacked seismograms after tested all grids of the model. Synthetic test indicated the stable results to find collect location and original time. Taiwan is one of the most seismically active regions in the world. The seismic networks of CWBSN, TSMIP and BATS are designed for different purposes to record seismic ground motion in Taiwan. Almost those real-time data streams are continuously transmitted back to Academia Sinica. We have tested event location based the catalog of the CWB fast report using this dataset. The real data testing got high consistent results of event within network and moderate consistency for event located in the border of network. Our determination procedure is under polishing to get stable results and speed the process time. It provides a potential application to join the system of earthquake warning system in Taiwan and other seismic tectonic applications in the near further.

Detection of hidden earthquakes after the 2011 Mw9.0 Tohoku earthquake and their relation to regional crustal deformation

DOI: 10.57757/IUGG23-0631 - LINK

Koji Tamaribuchi[1], *Hisao Kimura*[1]
[1]*Meteorological Research Institute, Department of Seismology and Tsunami Research, Tsukuba, Japan*

Seismic activity increased throughout Japan after the 2011 Mw9.0 Tohoku earthquake. Microearthquakes (M<2 inland and M<3 offshore) were not adequately catalogued, making it difficult to comprehensively quantify changes in seismic activity after the 2011 Tohoku earthquake. Therefore, we developed an automatic source determination method using machine learning and detected "hidden" earthquakes that were more than twice as large as those in the conventional earthquake catalog from March 2011 to February 2012. This method includes phase discrimination using CNN and quality control using ensemble learning. We then merged the automatically determined catalog with the JMA unified earthquake catalog, and extracted inland seismic activity throughout Japan from the newly obtained merged catalog. We quantified the seismic activity based on the ETAS model from the obtained seismic catalog. The relative change in background seismic activity in April 2011 indicates that it is, on average, two to three times higher than before the Tohoku earthquake. We also found a positive correlation between the background seismic activity ratio and the maximum shear strain rate in the vicinity, based on the one-month difference in GNSS data. The obtained hidden earthquakes contribute to better resolution and quantification of seismic activity.

Acknowledgements
We used the waveforms from JMA, NIED, universities, and institutions, and the JMA unified earthquake catalog. We used GEONET (F5) coordinate data from GSI. We used Kasahara et al. (2016) to estimate ETAS parameters, and Shen et al. (1996, 2015) to calculate strain rates.

Using relative event locations of swarms of small earthquakes to look for seismically active structures in Northeastern North America

DOI: 10.57757/IUGG23-0347 - LINK

John Ebel[1]
[1]*Boston College, Weston Observatory, Weston, USA*

Swarms of small earthquakes and microearthquakes have been observed in several different places in the northeastern U.S. and southeastern Canada over the past several decades. The modern seismic network that has operated during this time has allowed earthquakes to magnitudes below M 1.0 in these swarms to be detected and located. A relative earthquake location method using waveform crosscorrelations allows for very precise relative event locations to be computed, which can be used to look for spatial trends in the earthquake swarms. Absolute events locations are best determined using event recordings on portable seismic instruments in the epicentral area. Relative and absolute location analyses of several swarms show a consistent pattern of the swarm seismicity aligning along known or suspected preexisting faults. These swarms, located in New York, Connecticut, Maine and New Brunswick, may be indicating which pre-existing structures in Northeastern North America might be seismically active in the future. Whether or not these structures could host a strong earthquake in the future is not clear from the data. Even so, the analyses suggest that studies of the relative event locations of future swarms of small earthquakes and microearthquakes may help clarify the picture of which pre-existing zones of weakness may pose the greatest seismic hazard in the region.

Study of waveform envelope method in foreshock identification

DOI: 10.57757/IUGG23-3137 - LINK

Yanyan Han[1], Lingyuan Meng[1], Shiguang Deng[1]
[1]China Earthquake Networks Center （CENC）, Department of Earthquake Prediction, Beijing, China

The *M*6.4 Yangbi earthquake, which occurred in Yunnan Province on May 21, 2021, has attracted a lot of attention for its abundant foreshocks and superior monitoring capability around the mainshock. It seems to be a typical foreshock-mainshock-aftershock sequence in China Mainland in recent decades, and the key question is whether it is possible to distinguish foreshocks from normal seismic activities. The *b*-value derived from the Gutenberg-Richter (GR) law, as an important seismicity parameter, has the characteristics of decreasing during foreshock activity and increasing during normal aftershock sequence by previous studies. At present, the sequence's *b*-value is usually calculated by using the earthquake catalog, which makes it difficult to obtain the *b*-value results in a short time after the earthquake. In this study, we select the foreshock event waveform recorded by the station closest to the earthquake epicenter and obtain the envelope function of the waveform. Each peak of the envelope can be regarded as an earthquake event. The peak amplitude and time correspond to the magnitude and time of earthquakes. Similar to the GR relationship, the corresponding relationship between magnitude and peak number is preliminarily established, and the corresponding *b*-value results are obtained. This study aims to explore the effectiveness of the waveform envelope method to identify foreshocks in China mainland, and tries to solve the problem that the *b*-value cannot be accurately calculated due to the lack of catalog after a large earthquake.

[2]Università di Pisa, Dipartimento di Scienze della Terra, Pisa, Italy

DAS technology is particularly suitable for microseismic monitoring application in geothermal environments, especially for the development of Enhanced Geothermal Systems. This acquisition technology still lacks appropriate modeling and analysis tools able to handle such a large amount of data without losing efficiency. Since free DAS datasets are still a rarity, we aim to generate an open-access synthetic (but realistic) DAS dataset that may help the geophysical community to develop “ad hoc” data analysis methods suitable for these datasets. In the presented work we make use of the software 'Salvus' which allows the simulation of DAS data. In particular, it outputs a strain measurement between all points defined as receivers in the simulation. Using the repositories of DAS data collected at the geothermal test site FORGE, in Utah (USA), we tried to simulate realistic DAS acquisition conditions of seismic events related to low-magnitude natural seismic activity from the nearby Mineral Mountains and microseismic events related to hydraulic stimulation operations for the generation of an EGS. In order to obtain realistic synthetic data, we first analyze the spectral properties of real noise waveforms by using the Power Spectral Density Analysis. We model the synthetic noise waveforms using a stochastic approach. Then we add it to the synthetic event traces and compare them with the observed ones. We finally test a new semblance-based event detector on a 1-hour continuous waveforms of synthetic data to evaluate the performance of the detector in different operational conditions (e.g., different noise levels and inter-event times).

DAS technology is particularly suitable for microseismic monitoring application in geothermal environments, especially for the development of Enhanced Geothermal Systems. This acquisition technology still lacks appropriate modeling and analysis tools able to handle such a large amount of data without losing efficiency. Since free DAS datasets are still a rarity, we aim to generate an open-access synthetic (but realistic) DAS dataset that may help the geophysical community to develop “ad hoc” data analysis methods suitable for these datasets. In the presented work we make use of the software 'Salvus' which allows the simulation of DAS data. In particular, it outputs a strain measurement between all points defined as receivers in the simulation. Using the repositories of DAS data collected at the geothermal test site FORGE, in Utah (USA), we tried to simulate realistic DAS acquisition conditions of seismic events related to low-magnitude natural seismic activity from the nearby Mineral Mountains and microseismic events related to hydraulic stimulation operations for the generation of an EGS. Recent work has shown increasing utility of Distributed Acoustic Sensing (DAS) in microseismic monitoring operations, including those related to Enhanced Geothermal Systems. DAS can transform km-long fiber optic cables into a distributed array of seismic sensors capable of imaging the entire wavefield. However, the large quantity of data DAS acquisition produces hurdles to near-real-time seismological data analysis. In this study, we test waveform-coherence-based methods used to detect and locate microseismic events with DAS data that can be applied in near-real time. The merits of the approach rest in its potential to enable continuous seismic monitoring using DAS.

The detection approach uses a semblance-based method that evaluates waveform coherence along hypoerbolic trajectories with different curvatures and vertex positions. It returns a time series of coherence values that enable the declaration a seismic event when coherence values exceed a given threshold. We then test a waveform-stacking method based on the use of trace short-term-average/long-term-average (STA/LTA) values to estimate event hypocenter locations. We stack waveforms based on theoretical travel times for both P- and S-phases and constrain the source location based on peak stacked amplitude values. A grid search of variable source locations and origin times produces the best-fit solution where the stacked amplitudes reach peak values. The method does not require phase identification and picking and can be applied to low signal-to-noise-ratio data. We will present results of the method using synthetic data and validation on real data from the 2022 FORGE (Utah, USA) DAS dataset.

Distributed Acoustic Sensing (DAS) is being explored in a variety of environments as a promising technology for the recording of seismic signals in dense array configurations. There is a particular interest for deploying DAS arrays on the ocean floor, as this environment presents formidable challenges for conventional seismology. Recent DAS studies on submarine cables demonstrate promising data fidelity showing detections of local and teleseismic events, as well as microseisms, infragravity waves and other oceanic signals spanning a broad frequency range. However, most of such experiments are short-term (lasting a few days to a few weeks) and lack systematic assessment of the instrument response, background noise and its seasonal variations, and, more generally, instrument capability. Here, we describe first results from a longer term (1 year starting in July 2022) DAS experiment on the Monterey Bay Accelerated Research System (MARS) cable in Monterey Bay (California), which extends offshore for a length of 52 km, and on which we have been acquiring data since July 2022, for almost a year. Here we describe the experiment and present examples of observations background noise and a variety of detected signals, including microseisms, infragravity waves, regional and teleseismic earthquakes (in particular T-waves) over the first 10 months of the deployment. In addition to these observations, one of our goals is to integrate the continuous DAS data into the real-time seismic monitoring system in northern California including Earthquake Early Warning.

The recent democratization of optical fiber geophysics opens new inroads to explore complex and difficult-to-access wave propagation environments. Here, we present an analysis of one year of continuous Distributed Acoustic Sensing (DAS) data recorded along two optical fiber cables located in the Puget Sound and Puget Lowlands, Washington, USA. The first cable is 12 km long and includes a 4 km long subsea component (average ~100 m water depth) and the second cable is 30 km long in an urban to suburban setting. Both DAS deployments make use of a Sintela Onyx interrogator. During the observation time, interrogators on both fibers observe local, regional, and teleseismic earthquakes. We find that the overall detection threshold for our terrestrial DAS observations is equal to and in some cases slightly better than the urban seismometers of the Pacific Northwest Seismic Network (PNSN). In addition to DAS, we present concurrent Ultrastable Laser Interferometry (ULI) observations on fiber in the same cable as one used for DAS. Distant teleseismic earthquakes provide a means to compare DAS and ULI strain measurements and yield strain correlation coefficients greater than .95. Regional earthquakes generate subsea Scholte waves and thereby enable a lower detection threshold than PNSN stations. A fiber running through the city of Seattle is used to map the spatial variability of engineering site parameters such as VS30. These results point the way to several areas of progress in understanding earthquake hazard including using optical fiber geophysics.

In last few years, a number of technologies to use fibre optic cables as sensing devices have been established, among them Distributed Acoustic Sensing (DAS) and State-of-Polarisation (SoP). The potential of these technologies for monitoring a range of Earth System parameters in submarine cables has been demonstrated through several pilot experiments. Yet, continuous access to sub-marine optical fibre scientific data has currently not been achieved anywhere, neither has full integration of the various techniques.

The SUBMERSE project links Research and Education Networks (NRENs), universities, research institutes and industry to establish multi-method monitoring along submarine optical telecommunication cables at several key cable routes branching off from Portugal, Madeira, Svalbard and in the Aegean. Those pilot sites should serve as a blueprint for establishing continuous monitoring services along many more cables.

The project comprises technical developments for integrating DAS and SoP measurements, for establishing differential SoP measurements between repeaters and for operating DAS in 'lit' fibres, i.e., fibres carrying telecommunications traffic. Furthermore, a range of geoscientific and marine biology use cases are included, which seek to establish code/services for monitoring earthquakes, tracking whales, measuring the sea state and other Earth System variables. Effective data management, dissemination and training through community specific services will be addressed in several tasks as they are crucial for the success of this project due to the large size of data, sensitivity of a subset of the recordings and current lack of established community standards. SUBMERSE clearly commits to open and FAIR data exchange.

Distributed acoustic sensing (DAS) can be deployed on existing submarine fibre optic cables to add sensor capability to the cable infrastructure. This does not require offshore installations and the DAS interrogation can also coexist with data traffic on telecom fibres. In this way, DAS provides a cost-efficient means to monitor marine cables with application to environment studies and seismology, seabed activity from e.g. fishing, and changes to the cable condition. For monitoring of seismic signals, DAS provides several advantages over traditional seismic sensors including a dense spatial sampling of the wavefield (on the order of metres) over long ranges (>100 km). It also poses some challenges. For example, the single-component measurement (along the cable) can lead to ambiguity in event location due to the unresolved directionality of incoming waves.

Here we will present observations from a long-term study on a Tampnet North Sea submarine telecom cable. We have characterized local earthquakes and underwater explosions in addition to anthropogenic activity. After post-processing to suppress marine noise, a detailed image of the earthquake wavefield with clear P- and S-arrivals can be observed. Recordings of underwater explosions are characterized by low-frequency first arrivals refracted through the subsurface followed by slower propagating high frequency and high amplitude direct arrivals through the water column, which can clearly be observed over the full length of the cable. Furthermore, tracking the travel-time moveout along the non-straight cable route allows for positioning of the source, which we demonstrate by back-propagating the recorded wavefield.

S05a - Advances in Earthquake and Explosion Monitoring Using Distributed Acoustic Sensing

Overview of the global DAS monitoring month 2023

DOI: 10.57757/IUGG23-2322 - LINK

Andreas Wuestefeld[1]
[1]*NORSAR, Solutions, Kjeller, Germany*

The IRIS DAS RCN has coordinated a global measurement campaign of fibre optic sensing systems. The campaign took place between 1 Feb – 28 Feb 2023 and comprises triggered DAS data from teleseismic events (>M5, USGS catalogue) with contributions from academia and industry (downhole, pipeline, railroads, etc.). The dataset comprises more than 20 DAS systems recording at the same time in different regions of the globe with cable length between 1 and 100km. The nominal recording parameters are 100Hz and 10m channel spacing, but varies between systems. The recorded data will help in establishing the next-generation global monitoring system based on DAS. About 150 interesting global earthquakes are covered during that period, and each participant upload triggered data window of 3600 to a central storage location. This thus also helped to identify bottle-necks in data format, storage, and legal issues. in addition to the triggered event data, continuous data for 24 hours of 14-02-2023 are available for many systems. We anticpate lively and interesting research to be possible with such a rich and unique dataset.

Optical interferometry can be used to measure the propagation time of the light along fibre optic cables, enabling the detection of environmental perturbations such as earthquake waves as they interact with the fibre [Marra et al., 2018]. However, at any point in time, the measured signal is an integration of the optical path length changes along the entire fibre. This can result in a high measurement noise floor since the ambient noise along the entire length of the seafloor cable is integrated. Over the lengths of thousands of kilometres of transoceanic seafloor cables, this can prevent the detection of smaller magnitude events.

We present a novel technique that allows many discrete spans along a single fibre optic cable to be used as individual ocean bottom seismometers. These spans are tens of kilometres long and this reduction in length of each line-receiver allows us to monitor specific locations along the cable path. From an observation window of four months, we show that earthquakes, tides, wave heights and ocean microseisms can all be recorded on individual spans between repeaters on a 5,860 km-long transatlantic cable, in addition to monitoring along the whole cable length.

On the continental shelf we observe strong correlations between periodic signals at different frequencies with tides, wave heights and microseisms. In the comparatively quieter deep ocean we have detected two teleseismic earthquakes greater than M_w7. Other enigmatic signals related to ocean tides and the solid Earth's microseisms are also evident.

For the efficient use of geothermal energy, especially for heat provision, energy must be provided close to a consumer structure, thus in urban areas. Exploration for potential reservoir or storage horizons and their microseismic monitoring during operation are, therefore, mandatory.

For this purpose, the joint project SENSE tests seismic exploration and monitoring approaches based on fibre-optic sensing in urban areas using both active and passive seismic sources. To carry out the seismic measurements, a field-ready demonstrator is being built to carry out spatially distributed dynamic fibre-optic strain measurements. In addition to available instrumentation, strain changes with respect to a known reference are recorded, thereby also enabling the detection of long-term/quasi-static strain changes. This brings decisive advantages with regard to the detection of deep or long-wave signals as well as for the exclusion of very slow deformation movements in connection with the use of the geological subsurface.

We exemplify the monitoring of borehole operations and the horizontal recording of the seismic wave field using cables in Berlin and Potsdam with the new developments tested. Processing workflows encompass shot gather extraction, and picking of dispersion curves that yield after inversion shear wave velocity models exposing several velocity interfaces. To this end, we expect that SENSE will deliver new options for urban monitoring also beyond geothermal.

Characterizing and monitoring the highly variable near-surface underneath urban areas is crucial for understanding phenomena such as resource distribution and storage potential, changes in hydrological systems, and seismic hazard at the sub-kilometer scale. Our current understanding of the urban subsurface is limited by our ability to image its structure and temporal variations at high resolution using classical geophysical approaches. Distributed Acoustic Sensing (DAS) deployed on unused telecommunication fiber-optic cables (dark fibers) is an attractive alternative to classic seismological studies in urban areas, as it enables continuous recording of the seismic wavefield across long distances (10's of km) at high spatial (~1 m) and temporal (down to seconds) resolution across a broad frequency range (mHz to kHz).

Here, we explore the potential and challenges of using DAS deployed on dark fiber networks for characterizing and monitoring the near-surface beneath urban areas. We will discuss dark fiber experiments conducted in a variety of settings, including several km-long profiles crossing agricultural areas and densely populated centers in California, and experiments conducted within the city of Potsdam (Germany). We evaluate the usability of anthropogenic signals as passive sources for near-surface imaging and monitoring, as well as the potential for active source seismic imaging in complex noise environments. Challenges associated with poorly documented deployment and coupling conditions of dark fiber networks and the large data volumes generated in these studies will also be discussed. Ultimately, we aim at providing insights into the challenges and opportunities of using dark fiber DAS for understanding the urban subsurface.

Passive Imaging of Shallow Subsurface in Urban Melbourne Using Distributed Acoustic Sensing

DOI: 10.57757/IUGG23-3152 - LINK

Voon Hui Lai[1], *Meghan S Miller*[1], *Chengxin Jiang*[1]
[1]*Australian National University, Research School of Earth Sciences, Acton, Australia*

Distributed Acoustic Sensing (DAS) provides a new, non-invasive means for high resolution subsurface imaging in urban environments by repurposing existing telecommunication cables. However, urban fibre optic networks, which are designed around telecommunication needs, introduce unique challenges to passive seismic imaging including complicated array geometry and non-uniform seismic noise. A 25-km long DAS array was deployed along a telecommunication fibre that spans across metropolitan Melbourne, Australia for a duration of 3 months (December 2021 to March 2022). This dataset provides an ideal test case to address the challenges of using urban dark fibre and establish an effective workflow for ambient noise correlation with DAS recordings in urban settings. Traffic noise from vehicles and trains are the dominant signal at a frequency range of 1-30 Hz. Ambient noise correlation is performed using NoisePy, a high-performance python tool specifically designed to deal with large data volume. Cross-correlation functions show clear surface wave dispersion up to 15 Hz. Acausal move-out times are also observed, indicating strong scatterers off the fibre array and varying ground-coupling conditions. The subsurface velocity model obtained from ambient noise correlation reveals strong structural variations at 10-m scale up to 1 km depth across Melbourne and shows good correspondence with the mapped geological boundaries including an 800 kyr basalt flow and Miocene marine and terrestrial sediments. The exciting results from the Melbourne experiment demonstrate that DAS can be used to build high-resolution subsurface models for metropolitan areas with high seismic hazard risk that may be poorly instrumented with inertial seismometers.

Distributed Acoustic Sensing (DAS) provides a new, non-invasive means for high resolution subsurface imaging in urban environments by repurposing existing telecommunication cables. However, urban fibre optic networks, which are designed around telecommunication needs, introduce unique challenges to passive seismic imaging including complicated array geometry and non-uniform seismic noise. A 25-km long DAS array was deployed along a telecommunication fibre that spans across metropolitan Melbourne, Australia for a duration of 3 months (December 2021 to March 2022). This dataset provides an ideal test case to address the challenges of using urban dark fibre and establish an effective workflow for ambient noise correlation with DAS recordings in urban settings. Traffic noise from vehicles and trains are the dominant signal at a frequency range of 1-30 Hz. Ambient noise correlation is performed using NoisePy, a high-performance python tool specifically designed to deal with large data volume. Cross-correlation functions show clear surface wave dispersion up to 15 Hz. Acausal move-out times are also observed, indicating strong scatterers off the fibre array and varying ground-coupling conditions. The subsurface velocity model obtained from ambient noise correlation reveals strong structural variations at 10-m scale up to 1 km depth across Melbourne and shows good correspondence with the mapped geological boundaries including an 800 kyr basalt flow and Miocene marine and terrestrial sediments. The exciting results from the

Melbourne experiment demonstrate that DAS can be used to build high-resolution subsurface models for metropolitan areas with high seismic hazard risk that may be poorly instrumented with inertial seismometers.

Three days after the 2022/12/20 M6.4 earthquake near the Mendocino triple junction, we deployed a distributed acoustic sensing (DAS) system on ~15 km of dark telecommunications fiber within 50 km of the mainshock epicenter, sampling at 250 Hz every 2 m, and applied a a real-time automated earthquake detection system.

The detection algorithm estimates coherent array energy and adapts to environmental noise levels; spatial filtering suppresses environmental noise and emphasizes local earthquake signatures. With this system we identified ~5 times the number of earthquakes as in a comprehensive regional catalog (with M_c ~1.9), up to M5.4 (the largest aftershock), and detections are consistent with an independent deep-learning-enhanced catalog based on seismometer data alone. On-site computing provides rapid processing and real-time notification: average latencies for processing 1-second-long time windows with 50% overlap were <0.6 seconds.

Additionally, we deployed nodal seismometers every ~350 m along the DAS array to constrain local ground motions and site conditions. Amplitudes vary strongly along the cable due to a combination of wavefield and site effects, but vary systematically for both P and S waves, and waveform clipping is not observed. Thus, we developed linear site corrections and calculate local earthquake magnitudes DAS strains. In general, the magnitude accuracies are comparable to regional network estimates, and we are evaluating the ability of these DAS data to accurately recover apparent source time functions from empirical Green’s function deconvolutions.

An Ms6.9 earthquake occurred in Menyuan, Qinghai, China on Jan 7th, 2022. This earthquake destructed the high-speed railway passing through the epicentral area and rise concerns on the seismic hazard of the Tianzhu Seismic gap, which is about 150 km long. Two DAS arrays were deployed with about 40km long dark fiber optic cable for aftershock monitoring and subsurface imaging. Three automatic methods were utilized to scan earthquake signals on the continuous data including: a neural network, template-matching method, and a hybrid method integrating array-detection and template-matching. All of three methods reported more than 80% aftershocks in the routine catalog and up to 50% newly detected events. For the template-matching method, using aftershocks occurred in the first two-day as templates provides about 91% catalog events and 50% additional events. The other two methods do not depend on the prior information, which means quicker response. The fault-related signal is also observed on the seismic wavefields of earthquakes, which helps to identify blind faults in the Menyuan basin. Ambient noise tomography method was used to construct 2D Vs profile along one cable. Strong lateral variation emerges and faults can be identified on the NCF COG gather. Such high-resolution shallow structure model and earthquake catalog provides additional information of seismic hazard in the Menyuan region.

Mount Etna (Sicilia, Italy) is one of the most active volcanoes worldwide, located at the boundary between the African and the Eurasian plates. It is characterized by the occurrence of many phenomena such as lava flows, ash eruptions, earthquakes. Its eastern flank is also characterized by a complex system of active faults, associated with an eastward flank movement, up until the submarine environment. As Etna flanks are densely inhabited areas, we aim at better understanding the link between these phenomena to better assess associated hazards and risks.

Since 2018, we have been measuring several locations with Distributed Fiber Optic Sensing yearly, enabling us to observe strain at meter-scale spatial interval and on a broad frequency range. We show records and present results from selected cables. Close to the summit active craters, we interrogate dedicated cables, and could analyze the ground response in association with explosions and volcanic tremor. In urban areas, we interrogate telecommunication cables and record local earthquakes. In the submarine area, we interrogate a cable which crosses the North Alfeo fault with several different optical techniques. In the southern flank of the volcano, we show volcanic signals from a cable deployed in a borehole. We also demonstrate how simultaneous multi-fiber measurements can help constrain earthquake hypocenter location.

We discuss opportunities and challenges of using fiber optic cable in various environments such as the Etna volcano and beyond, for an integrated vision from deep processes, their interaction with the sub-surface dynamics and the volcano-tectonic structures.

Distributed Acoustic Sensing (DAS) has become a popular method of observing seismic wavefields: backscattered pulses of light reveal deformation with meter-scale resolution along a fiber-optic cable. In contrast, a few newer systems transmit light through a cable and collect integrated phase delays over the entire cable, such as the Microwave Frequency Fiber Interferometer (MFFI). The outstanding advantage of these integrated systems is that they can be interrogated over significantly longer distances of hundreds or thousands of kilometers, may be used at the same time as live telecommunication, and can be significantly cheaper. However, they provide only a single time series representing strain over the entire length of fiber.

In the first part of this contribution, we present a theory for integrated fiber optic sensing. This enables a quantitative comparison of these new systems with established DAS measurements. Furthermore, we note that sensitivity to deformation depends critically on local fiber curvature, which offers opportunities to mimic distributed measurements with integrated systems. In the second part, we present the first results of a quantitative, head-to-head comparison of a DAS and the integrated MFFI system using pre-existing telecommunication fibers in Athens, Greece.

Microseismic event detection in continuous DAS data using a convolutional neural network (CNN)

DOI: 10.57757/IUGG23-1820 - LINK

Nepomuk Boitz[1], *Serge Shapiro*[1]
[1]*Freie Universität Berlin, Geowissenschaften - Geophysik, Berlin, Germany*

Detection and localization of microseismicity is an inevitable task to monitor fluid injections into subsurface rocks during hydraulic stimulations. Traditionally, such observations are done with downhole geophones, but in the last years, the usage of distributed acoustic sensing (DAS) using fiber-optic cables placed into boreholes has become a standard technique. However, DAS registrations still have lower signal-to-noise ratios than geophones, i.e., they are not able to detect small-magnitude events. In this work, we develop a convolutional neural network (CNN) that is capable to detect and distinguish P- and S-arrivals in continuous DAS recordings. This network is trained on several hours of DAS data recorded at the Utah FORGE EGS project in 2019. By also incorporating arrival-time information from geophones placed in the same borehole during the training, we are able to shift the detection threshold towards smaller magnitude events significantly. Although the number of microseismic events (≈150) used for training is small, the tested network performance is high and provides a complete event catalog down to magnitude Mw=-1.6. This means, that after a short training phase, the network can be used for long-term real-time observation. Although the network currently only detects seismicity, event localization is feasible with small network adaptations. Furthermore, the methodology and network architecture can be easily adjusted for similar case studies, where long-term seismic monitoring is required (e.g. EGS or CO_2 sequestration).

Distributed Acoustic Sensing (DAS) interrogators have become commercially available, enabling long term measurements in diverse environments. Collection of permanent data is facilitating new applications such as earthquake detection.

Pre-installed standard communication fibres can be used for the detection of seismic activities. However, the signal to noise ratio (SNR) is rather low at earthquake frequencies and therefore it is difficult to detect seismic waves at high ambient noise. Although standardized laboratory tests reveal a higher noise floor at low frequencies for DAS interrogators, the detection of earthquakes is still possible through filtering and signal enhancement methods. Furthermore, efficient real-time data evaluation is necessary for early-warning mechanisms.

This article compares data of 3 different fibre lines with different characteristics and ambient noise for earthquake detection. Tests are performed with an inner-city line, which is exposed to high noise by day due to traffic loads and low noise at night. Additionally, a fibre line in a rural area with lower noise behaviour is investigated. Furthermore, DAS measurements at a fibre line at the national underground seismic observatory were performed and compared with the close by seismometers.

In this paper we focus on methods for detection and evaluation of seismic waves and discuss the technical challenges of detecting small signals in big data. The paper also addresses matters of performance related to real-time data evaluation.

In the past decade, the use of fiber optic cables to sense ground motion (Distributed Acoustic Sensing-DAS) has become a topic of great interest in seismology because of its wide sensitivity range, dense spatial sampling and new deployment possibilities.

How exactly DAS cables respond to ground motion is however largely unknown, limiting the application of a number of staple seismological techniques (e.g. earthquake magnitude estimation, waveform tomography) that can require accurate knowledge of a signal's amplitude and frequency content.

Here we present a method for accurately simulating a DAS cable and its response. The scheme is based on particle-based numerical modelling, allowing the investigation of the effect of varying DAS-ground coupling scenarios. After computing the strain field directly, we define a virtual DAS cable, formed by a single string of interconnected particles. This allows us to control all aspects of the cable-ground coupling and their properties at an effective granular level through changing the bond strengths and bond types for both the cable and the surrounding medium. Arbitrary cable geometries and heterogeneous materials can be accommodated at the desired scale of investigation.

We observe that at the meter scale, realistic DAS materials, cable-ground coupling and the presence of unconsolidated trench materials around it dramatically affect wave propagation, with differences exceeding at times the magnitude of the recorded signal. These differences show that cable coupling and local site effects have to be considered when designing a DAS deployment and analysing its data when either true or along-cable relative amplitudes are considered.

Distributed acoustic sensing (DAS) sees increased utilization in the seismological community in recent years and various applications are investigated for the usage of DAS in different branches of seismology.

Strong-motion seismology uses records of earthquakes of engineering concern (MW>4.5) with hypocentral distances within few hundreds of kilometers. This demands dense networks over a wide area and installation of typical strong-motion instruments (accelerometers) can be achieved quickly and at a reasonable budget, compared to other network types. For DAS, installation and operation are more involved, and deployment is very still limited. Consequently, DAS recordings of nearby large events are still very unlikely and rare compared to accelerometers.

On September 18, 2022, a shallow earthquake sequence with a M_W 6.9 mainshock struck near Chishang (Taiwan) and was recorded by DAS in Hualien city, appr. 100 km north. Shaking of the mainshock and several aftershocks were noticeable in Hualien, though not damaging with PGA recorded at 0.28 m/s^2 nearby the DAS site. The DAS campaign was originally conceptualized as a test suite with different fiber installations: including buried, within a gutter (as in commercial fiber installation) and loose within a basement. The test site is in an urban area affected by surface rupturing during the 2018 Hualien earthquake.

The presented recordings provide not only an unprecedented insight how strong-motion appears on DAS but also how effective different installation techniques are for this kind of event. The waveforms are also compared to records of a collocated broadband seismometer and an accelerometer 1 km away.

Distributed Dynamic Strain Sensing (DDSS), a.k.a. Distributed Acoustic Sensing (DAS), is becoming a popular tool for volcano monitoring. The sensing method relies on measuring the phase-shift of Rayleigh back-scattered light throughout the fibre due to strain variations in the fibre glass. This provides distributed strain-rate measurements at fine temporal and spatial sampling intervals. During 3 months in 2019, we recorded signals from thousands of mild volcanic explosions from Mt. Etna using a multi-instrument network deployed in an area at ca. 2.5 km distance from the active craters. Infrasound sensors were laying at the surface with a dense array of broadband seismometers (BB). Two types of fibres were also buried ca. 30 cm depth in the non-consolidated scoria from the area. First fibre was a 1.5 km long standard fibre, interrogated with an iDAS unit. The second fibre was a 0.5 km long engineered fibre, interrogated with a Carina unit. Relation between infrasound and DDSS data suggests a ground response of the loose scoria due to the acoustic pressure waves from explosions. Further analysis suggests a non-linear relationship between acoustic pressure and strain-rate data. However, signal saturation is encounter in some of the strain-rate data, which affects the interpretation of the non-linear relation. Therefore, we present an algorithm to correct the signal artefacts, allowing us to restore the true strain-rate signal and exceed the dynamic range limited by the initial DDSS recording parameters. The outcome includes strategies in the selection of acquisition parameters prior to DDSS campaigns to avoid signal saturation.

The 18th-century European press network functioned in a non-linear way: newspapers tended to publish news from far-off countries rather than those of merely local interest. Thus, some Italian news may be only reported in non-Italian gazettes, or Italian gazettes omit to report some interesting details that reach instead – via the underground network of handwritten reports and diplomatic correspondence – some foreign gazettes. On the other hand, however, exaggerations or outright hoaxes are frequent both in Italian and non-Italian gazettes.

In order to understand how journalistic communication functioned and how the traces of some earthquakes were collected and preserved by seismological compilations, we examined the output of several Italian and European gazettes in the months after the great Lisbon earthquake of 1 November 1755.

During this period the European press network overflows with reports of the effects of the “big one” in Portugal and abroad, and also publish a spate of news of other earthquakes in Europe and the Mediterranean area. Some - the 9 December 1755 Valais earthquake, the 13 February 1756 Rhodos, and the 18 February Düren earthquakes - were real enough and quite strong too. Others were minor or - in some cases - even wholly fictitious events. Our survey discovers the traces of a few earthquakes still unknown to the current parametric catalogues and allows us to reevaluate an earthquake that turns out to represent the historical maximum for the city of Treviso (Veneto, Italy).

The 18th-century European press network functioned in a non-linear way: newspapers tended to publish news from far-off countries rather than those of merely local interest. Thus, some Italian news may be only reported in non-Italian gazettes, or Italian gazettes omit to report some interesting details that reach instead – via the underground network of handwritten reports and diplomatic correspondence – some foreign gazettes. On the other hand, however, exaggerations or outright hoaxes are frequent both in Italian and non-Italian gazettes.

In order to understand how journalistic communication functioned and how the traces of some earthquakes were collected and preserved by seismological compilations, we examined the output of several Italian and European gazettes in the months after the great Lisbon earthquake of 1 November 1755.

During this period the European press network overflows with reports of the effects of the “big one” in Portugal and abroad, and also publish a spate of news of other earthquakes in Europe and the Mediterranean area. Some - the 9 December 1755 Valais earthquake, the 13 February 1756 Rhodos, and the 18 February Düren earthquakes - were real enough and quite strong too. Others were minor or - in some cases - even wholly fictitious events. Our survey discovers the traces of a few earthquakes still unknown to the current parametric catalogues and allows us to

reevaluate an earthquake that turns out to represent the historical maximum for the city of Treviso (Veneto, Italy).

The information background of pre-instrumental seismicity in Europe and possible improvements

The European PreInstrumental Earthquake CAtalogue (EPICA) the 1000-1899 was recently compiled as an input dataset of the European Seismic Hazard Model 2020. EPICA updates, maintaining the same principles and compilation strategy, the SHARE European Earthquake Catalogue (SHEEC) 1000-1899, which was the first continent-wide catalogue resulting from standardised procedures applied to a harmonised set of historical macroseismic data. EPICA exploits the updated knowledge of the European pre-instrumental seismicity gathered in the European Archive of Historical Earthquake Data (AHEAD). These data are macroseismic intensity distributions supplied by descriptive historical seismological studies and online macroseismic databases, and parameters contained in regional catalogues. Among these datasets, the most representative of the knowledge of each earthquake was chosen independently from national constraints and parameterized with standard procedures. As a result, the harmonisation of earthquake data and parameters across country borders is maximised.

However, the availability and reliability of data across Europe is incomplete and uneven, and the level of update of both macroseismic studies and parametric catalogues differs considerably from one area to the other. Such heterogeneity reflects on the uniformity of the catalogue, so that the room for improving the knowledge of the European seismic history is still large. In addition, the methods for the definition of macroseismic parameters and their associated uncertainties remained unchanged in the last decade and need to be improved.

This works aims at highlighting both advantages and unsolved questions related to the knowledge of past European seismicity, focusing on possible improvements.

Integrating macroseismic intensity data recorded through time with those calculated from epicentral parameters with intensity prediction equations (IPEs) is an effective way of investigating the knowledge of the seismic history (i.e., the list of documented effects) of a given site and to estimate its representativeness. For this purpose, we calculated the effects that were not documented at a set of sites in Italy by considering an IPE constrained with intensity values documented at close sites for the same events.

We first selected 228 localities according to their geographical distribution and to the number of related documented intensity data contained in the last version of the Italian Macroseismic Database DBMI15 and we then estimated the number of earthquake effects that could be potentially lost. The latter were calculated with a probabilistic approach in order to take into account both the uncertainties related to the assessment of the intensity value at the site and the nature of macroseismic data (ordinal, discrete, and range limited).

We finally provided a quantitative estimate of the effects of known past earthquakes that can be considered potentially lost at the 228 sites analyzing the results at both the local (site-by-site) and regional scale. The results showed that at least one effect with intensity greater than or equal to 6 MCS could be potentially lost with a high probability at almost the totality of the investigated sites. Moreover, some geographical dependences and correlations with the intensity levels were identified.

Wartime earthquakes in borderlands

DOI: 10.57757/IUGG23-1703 - LINK

Sofia Baranello[1,2], Romano Camassi[1], Viviana Castelli[1]
[1]Istituto di Geofisica e Vulcanologia, Bologna, Bologna, Italy
[2]Università degli Studi di Bologna, Dipartimento di Fisica e Astronomia, Bologna, Italy

The amount of traces that an earthquake may leave in historical records depends on many variables: its size, the relevance (political, economic, and cultural) of the area affected by it, the historical period in which it occurred, the space/time concomitance of other major geopolitical events that may overshadow the earthquake and hinder the production and circulation of information on its effects. If an earthquake is less than destructive and affects a marginal or border area, the likeliness that its memory will be quickly effaced is particularly high in wartime.

Such an earthquake occurred during the French phase of the Thirty Years' War (first half of the 17th century) in the Duchy of Savoy, an Alpine region and the main Italian theatre of war. It left only vague traces in a few seismological and historical compilations (Italian and European), none of the European parametric catalogues picked it up. The chance discovery of a short description of its effects in a diplomatic dispatch recently led us to undertake its study.

It was no easy feat, given the complexity of the socio-political context of the time, characterized by war events affecting all the territories where this earthquake could have been felt, but the effort was worthwhile because this earthquake currently turns out to be the most significant one in the seismic history of a major industrial city of northern Italy.

We present the Paliki, Kefalonia, Greece earthquakes of 1867 and 2014 in an effort to compare the effects and assign macroseismic intensities of earthquakes originating from the same seismogenic source. For the first event our sources are the three detailed field reports by Schmidt, Typaldos and Vergotis and four local newspapers. For the 2014 events (26 January and 3 February) the second-degree building inspections and the vulnerability categorization following the 2011 census, as well as ample photographic material and witness reports were used for intensity assignment. In both cases, 90% of the localities on the island were almost similarly affected by both earthquakes. Particularly, the studied earthquakes ruined or severely damaged the villages and towns in Paliki peninsula. We investigate the evolution, in terms of population and building activity, of these localities within the time span of 147 years between the two earthquakes, taking also into account the several significant earthquakes that occurred within this span. A total number of 65 (1867 event) and 97 (2014 events) intensity datapoints are collected from the island of Kefalonia. The macroseismic parameters of the historical event, when compared to the instrumental ones, show significant similarities.

Do we have any idea about the ground motion features associated with a pre-instrumental earthquake?
We propose a protocol based on the idea that historical buildings may record ancient tremors. Their effects may be read from direct traces or deduced from reconstruction phases. The medieval church of Sant'Agata del Mugello (Tuscany, Italy) is used as a case study to illustrate the interdisciplinary approach based on building archaeology, earthquake engineering, and engineering seismology. According to archives, the church was damaged by the 1542 and 1611 earthquakes (Mw 5.8 and Mw 5.1) but resisted the 1919 earthquake (Mw 6.2). Archives data and stratigraphic analysis give the key elements to trace back the state of the building before and after each historical earthquake. The geometrical survey, stratigraphic analysis, and Ambient Vibration Testing allow calibrating of a Finite Element model of the church. An innovative static non-linear analysis provides the elastic limit of key control points to follow the response of the building to the seismic loading. The linear updated model is then used to discriminate ground motion compatible with the observed failure mechanisms of the medieval church. Finally, prospective Intensity Measures such as Peak Ground Acceleration, Arias, Housner Intensity (etc.) of the 1919 earthquake are discussed.

Damage from small and moderate earthquakes in northern Europe: An exercise in searching for historical documentary sources

DOI: 10.57757/IUGG23-0057 - LINK

Päivi Mäntyniemi[1]
[1]*Institute of Seismology- University of Helsinki, Department of Geosciences and Geography, Helsinki, Finland*

This investigation searches for contemporary written documentation on damaging earthquake consequences in intraplate northern Europe between the late 1800s and early 1900s, when the region experienced a period of elevated seismicity of earthquakes with M < 5.5. Augmenting information is expected to improve the success of intensity assignment and the subsequent determination of non-instrumental magnitude and epicenter. Ultimately, such examples would provide helpful validation of the intensity scale. This is demanding, however, because damage levels in the region can typically be linked to the masonry parts of houses, timber being resilient to ground shaking, and only ordinary buildings are recommended to be used for intensity assessment by the EMS-98 guidelines.
Once the contemporary newspapers have been exhaustively scanned, the search for archived documentation about the non-structural earthquake impact faces several challenges. Many documents were not written in the first place for dwellings that sustained some damage, but were not insured. Documentation lost over the decades is all too familiar. Earlier work on an earthquake of 1898 showed that both direct and indirect earthquake effects occurred: Ground shaking cracked unreinforced masonry chimneys and stoves, which posed a serious fire hazard in predominantly wooden towns. Additional cases from 1882 and 1904 are explored. Indirect earthquake hazards can occur at long epicentral distances, but establishing a time frame for them can be difficult. Estimates of earthquake-related costs at a few localities are attempted. A reasonable assessment of the economic impact of past earthquakes would make them more existent outside the seismological community.

Macroseismic intensity information is important in the evaluation of historical seismicity. In an effort to improve the current South African earthquake catalogue, available macroseismic information of historical and early instrumental period earthquakes were used to determine epicentres and magnitudes of 46 earthquakes. Each of them had at least eight Intensity Data Points (IDPs). The IDPs were dominated by relatively low intensity values, which are consistent with a stable continental region. The source parameters were computed using state-of-the-art 3rd generation techniques. The quality of obtained solutions was greatly influenced by the spatial distribution of the IDPs, which was not uniform for all the events, with some events having clustered IDPs whilst others were linearly distributed. As a result, a quality ranking system of the results was developed to give an indication of the confidence in the results. Of the 46 earthquakes analysed, 36 had good quality results. The methods used were also checked by comparing solutions obtained using macroseismic data to those obtained for the same events but using instrumental data. Twelve events analysed in this study are new events that were not in previous catalogues. The results obtained help in improving the earthquake catalogue of the region, as there is an increase in the number of events recorded in the historical and early-instrument period. This kind of work and results obtained highlight the value of seeking out additional contemporary sources in order to revise the source parameters of earthquakes for which no or only very limited instrumental information is available.

Coseismic and postseismic deformation associated with the 17th Century megathrust earthquake along the Kuril Trench estimated by diatom analysis

DOI: 10.57757/IUGG23-4877 - LINK

Yuichi Nishimura[1], *Takashi Chiba*[2]
[1]*Institute of Seismology and Volcanology, Hokkaido University, Sapporo, Japan*
[2]*Department of Environmental and Symbiotic Science, Rakuno Gakuen University, Ebetsu, Japan*

A method to construct the history of past crustal deformation based on diatom analysis was developed, and the amount of coseismic and postseismic deformation associated with the 17th Century megathrust earthquake in Toberi marsh, Tokachi, Hokkaido, was estimated. The cores including the tsunami deposits at an altitude of 2.5-3.0 m (TP) inferred that subside trend continued before the earthquake and it turned to uplift trend after the event. Since both of the trends are gradual, the coseismic deformation does not seem to be significant. On the other hand, Pseudopodosira kosugii, which distributes the intertidal to supratidal zone, is most abundant on the horizon of the tsunami deposits. Present habitat distribution of Pseudopodosira kosugii in the same marsh revealed that the upper distribution limit and mode were 0.8 to 1.3 m (TP) and -0.2 to 0.3 m (TP), respectively. Prehistorical uplift can be estimated from the current elevation of the limit and the mode of this diatom in the core. The amount of the uplift in Toberi march after the 17th Century event was ca. 1.5 m. That was constrained by using both the distribution limit and the mode of cores from five survey points in the marsh. Information about the crustal deformation after the 17th Century event is useful for the evaluation of source models of the earthquakes that is used for tsunami hazard assessment along the Pacific coast of Hokkaido.

Seismic activity in southern Miyagi Prefecture in the 18th century revealed from "Takano Family Record”

DOI: 10.57757/IUGG23-4735 - LINK

Sunao Urushibara[1], Yasuyuki Kano[1,2], Junzo Ohmura[1,2]
[1]The University of Tokyo, Earthquake Research Institute, Tokyo, Japan
[2]The University of Tokyo,
Collaborative Research Organization for Historical Materials on Earthquakes and Volcanoes , Tokyo, Japan

"Takano Family Record” is investigated to reveal seismic activity in southern Miyagi Prefecture in the 18th century. "Takano Family Record" is a diary recorded by the successive heads of the Takano family between 1696 and 1782 and is included in a published collection of historical documents on earthquakes in Japan. About 150 days of felt records are newly found from our investigation of microfilmed original records kept in the library of the Graduate School of Arts and Letters, Tohoku University. Comparison between the number of felt earthquakes recorded in the "Takano Family Records" that observed by modern observations shows that the author of the "Takano Family Records" recorded earthquakes of JMA seismic intensity 2 or higher, as well as some earthquakes of intensity 1. "Takano Family Records" also contains descriptions of earthquake damage. Location and magnitude of the May 4, 1767 and October 22, 1767 earthquakes are reexamined from distribution of damage and felt records as well as the number of aftershocks.

Voices of foreign residents in Yokohama and Tokyo at the time of the 1923 Kanto earthquake

DOI: 10.57757/IUGG23-0573 - LINK

Paola Albini[1], *Kenji Satake*[2]
[1]*INGV-Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Milano, Milano, Italy*
[2]*The University of Tokyo, Earthquake Research Institute, Tokyo, Japan*

On Saturday the 1st of September 1923 at a few minutes to noon, when the Kanto earthquake occurred, the foreign population of the harbor of Yokohama reached 2,500 people of different nationalities, and a similar presence was in Tokyo, which as the capital hosted the officers of embassies, consulates and trade companies. These foreign residents left impressive records of the earthquake occurrence, as well as the fire and tsunami that followed. As far as we could ascertain, their accounts have not been used yet to compile either the official reports or the published monographs on social and scientific aspects, works that mostly relied on and referenced the news press and official Japanese statements. To add a different viewpoint to the overall understanding of this earthquake, we concentrated on the considerable quantity of documents now stored at The National Archives (Kew Gardens, UK) and at the Affaires Etrangers-Archives Diplomatique (La Corneuve, Paris, France) produced by British and French diplomats as well as foreign residents of different nationalities who were in Yokohama and Tokyo at the time of the earthquake. The most significant testimonies from both cities are presented and compared, and the role in the relief actions of the British Royal Navy and of ships of other countries are put in the foreground. The immediacy of the descriptions they contain and the details they supply bring us back to the shaking and shocking moments experienced by the people living in Yokohama and Tokyo one hundred years ago.

S06b - Pre-Instrumental Earthquake Data

Recurrence of Kanto earthquakes before 1923 and probability of future occurrence

DOI: 10.57757/IUGG23-0126 - LINK

Kenji Satake[1]
[1]*The University of Tokyo, Earthquake Research Institute, Tokyo, Japan*

The Kanto earthquakes (M~8) recur along the Sagami trough, where the Philippine Sea plate subducts beneath the Kanto region. The most recent event was the 1923 earthquake which caused the worst earthquake disaster in Japan with ~105,000 casualties. The penultimate, 1703 Genroku earthquake caused larger crustal deformation and worse tsunami disasters in the southern Boso peninsula. Historical documents and tsunami deposits indicate that the 1293 Showo earthquake was also a Kanto earthquake. The 1495 Meio earthquake, considered to be confused with the 1498 earthquake along Nankai trough, may be another Kanto earthquake. Possibilities of the 878 and 1433 Kanto earthquakes have been also pointed out (Ishibashi, 2020, SRL). Marine terraces on the southern Boso peninsula indicate that the 1703 (Genroku) type earthquake recurred at approximately 2,300-year interval.

The Japanese government's Earthquake Research Committee (ERC) annually estimates and announces long-term forecasts, in terms of occurrence probability in the next 30 years. For the M~8 Kanto earthquakes, the probability was estimated as 0 – 5 %, based on historical and geological data, while the Genroku type event was estimated as 0 %. The recurrence interval is calculated as 209 years for the above six historical events, 261 years for the five (excluding 1433) events, 210 years for the four (excl. 878 and 1433 or 1495) events, and 315 years for three (1923, 1703 and 1293) events. The 30-year probabilities vary 0 – 12 % for the Brownian Passage Time model, and 9 – 13 % for the Poisson model.

The Kanto earthquakes (M~8) recur along the Sagami trough, where the Philippine Sea plate subducts beneath the Kanto region. The most recent event was the 1923 earthquake which caused the worst earthquake disaster in Japan with ~105,000 casualties. The penultimate, 1703 Genroku earthquake caused larger crustal deformation and worse tsunami disasters in the southern Boso peninsula. Historical documents and tsunami deposits indicate that the 1293 Showo earthquake was also a Kanto earthquake. The 1495 Meio earthquake, considered to be confused with the 1498 earthquake along Nankai trough, may be another Kanto earthquake. Possibilities of the 878 and 1433 Kanto earthquakes have been also pointed out (Ishibashi, 2020, SRL). Marine terraces on the southern Boso peninsula indicate that the 1703 (Genroku) type earthquake recurred at approximately 2,300-year interval.

Monitoring the plate boundary using a vertical array of borehole and seafloor seismometers in the Nankai subduction zone

DOI: 10.57757/IUGG23-2236 - LINK

Takashi Tonegawa[1], *Eiichiro Araki*[1], *Yuya Machida*[1]
[1]*JAMSTEC, Research Institute for Marine Geodynamics, Yokosuka, Japan*

We use ambient noise records obtained by a vertical array of seismometers at borehole and seafloor in the Kumano basin of the Nankai subduction zone, Japan, and examine whether S reflections from deep interfaces can be persistently detected or not. The vertical array contains a geophone at the seafloor and a borehole broadband sensor at a depth of 900 m from the seafloor. Our results show the retrieval of S reflections from the top of high velocity body above the megasplay fault, the megasplay fault itself, and the top of the subducting oceanic crust. The depths of these boundaries are 5–10 km from the sea surface. The arrival time of the S reflection for a polarization direction of N70ºE was faster, indicating that the direction is the fast polarization direction. We also investigated the temporal variation of the amplitudes of the S reflections at a slow polarization direction (N160ºE), and obtained temporal variations in amplitudes of the S reflections from the top of the high velocity body and megasplay fault for 1 year after 2016 off-Mie earthquake (Mw5.9) whose epicenter is ~30 km away from the vertical array. This may be related to fluid migration around these boundaries.

The Taiwan Milun fault zone located at the boundary between the Eurasian and Philippine Sea plates. This fault slips frequently and produced large earthquakes, as for example the Mw6.4 Hualien earthquake (6 February 2018). We map and observe the fault zone and its behavior at depth by high spatial resolution dynamic strain sensing with optical fiber. In 2021-2022, we drilled and cored the fault, and deployed a 3D multi-cross-fault fiber array comprising a borehole loop with a depth of 700 m (Hole-A, Hanging wall site, crossing the fault at depth), a surface array crossing the fault rupture zone using commercial fiber, and a second borehole loop of 500m fiber (Hole-B, Footwall site). The high spatial resolution from distributed acoustic sensing (DAS) and the retrieved core combined with geophysical logs allow us to characterize the structure on meter-scale. Within the Milun fault zone, we identified a 20-m wide fault core comprised of gray and black gouge in the core sample. DAS strain-rate records associated with the same depth as the fault core show a distinct amplification. The amplification ratio of 2.5-3 is constant as for all types of events (local, teleseismic), when compared to DAS channels at larger depth, related to a consolidated rock material. Although the fault gouge is narrow, the nature of the amplification in strain is due to its strong material contrast from fault gouge. This result may shed the light on the understanding of fault-zone dynamics in terms of remote earthquake triggering and near-fault ground motion.

Knowledge of physical and mechanical properties of subsurface faults is important for understanding the processes responsible for seismogenesis in a region. However, sampling of subsurface faults is quite challenging. Scientific drilling and downhole geophysical logging in active fault zones provide access to fault zone samples from depth as well as direct measurements of in-situ physical properties, leading to substantially improved characterization of such zones. Here, we demonstrate the wealth of information obtained from scientific drilling down to 3 km depth in the Koyna seismogenic zone and their implications for seismogenesis. Geophysical well log data has shown several fault damage zones in the basement which are characterized by low electrical resistivity, low bulk density, high neutron porosity, low Vp and Vs, high Poisson's ratio and low Young's modulus compared to the surrounding host rocks, especially below a depth of 2100 m. The data also reveal the presence of water-bearing horizons across most of the fault damage zones, indicating clear evidence of water percolation to deeper levels. Additionally, laboratory derived rock mechanical properties of intact and fault damage zone rocks also show significant variations in strength and static elastic properties of fault zone rocks from the intact host rock. Uniaxial cyclic loading tests on intact granitic rocks, located just above a fault zone, shows that elastic properties corresponding to the loading cycle close to failure is consistent with the elastic properties of the fault damage zone materials. The in-situ and laboratory datasets shed new light on the recurrent RTS in the region.

The Koyna-Warna seismic zone, located in peninsular India is characterized by persistent seismic activity within an area of 20 km x 30 km area since the impoundment of the Shivajisagar water reservoir in 1962. In general, the hypocenters lie in the depth range 2-10 km, in the ~2.4-2.7 Ga granitic basement that underlies ~1 km - thick Deccan trap cover. Fresh core samples of the basement granitoids recovered from recent scientific drilling in the area have been studied. Physical studies suggest a brittle deformation sequence from cataclasite to fault breccia and fault gouge materials. These rocks contain meso- to microscopic scale fractures which are mostly inter- or trans-granular in nature. Widths of fractures vary from micrometer to centimeter scale, and the anastomosing nature facilitates fluid channelization potentially down to the hypocentral depths. Microstructural and geochemical studies suggest most of those are partially or completely sealed by ferruginous, siliceous and carbonate materials. Such secondary materials present in both crystal and amorphous forms imply a conducive setting for mineralization. The fractures dominantly control deformations nearby the hypocentral depths and secondary mineralizations. They also can be correlated with related changes in pore pressure and temperature during earthquakes.

Scientific deep drilling in the Koyna seismogenic zone (Koyna, India), sheds new light into the prokaryotic denizens of the deep, dark, igneous crust hosted biosphere, spanning the basaltic formations of Cretaceous volcanism to the Archaean granitic horizon (59-2913 mbs) of the Deccan Traps. These enigmatic polyextremophilic oligotrophic microorganisms possess unique genetic traits that allow chemolithoautotrophic metabolism under conditions of high temperature, pressure and severe energy and nutrient limitations while driving biogeochemical cycles of carbon and other elements. Obligately anaerobic acetogenic and microaerophilic hydrogenotrophic bacteria were enriched from these rocks using specialised nutrient media under high temperature (50-70 ℃) and CO_2 concentration (2-12% v/v). Their ability to assimilate hot CO_2 gas and metabolize gaseous $H_2$was investigated. 16S rRNA gene amplicon sequencing and predictive phenotyping have revealed the most abundant and metabolically productive genera to include *Moorella, Bacillus, Anarobranca*, *Thermoacetogenia*, *Thermonaeromonas*, *Desulfofundulus*, *Desulfovibrio* and *P aracoccus*. Phylogenetic Investigation of Communities by Reconstruction of Unobserved States 2 (PICRUSt2) analysis identified the most abundant autotrophic carbon fixation pathways to be reverse Krebs cycle, Calvin-Benson-Bassham cycle and Wood-Ljungdahl pathway; and major biosynthetic products as medium- and short-chain fatty acids, alcohols and antibiotics. Our research provides new insights into the geomicrobiological processes within the active seismogenic zone of Koyna and their possible correlation with various subsurface geophysical and geochemical properties. The study provides a better understanding of the overall system of such important geological provinces, highlighting the role of microorganisms and developing improved geomicrobiological methods to study such crystalline deep biosphere.

We present ongoing experiments from the Bedretto Underground Laboratory for Geociences and Geoenergies, a unique research infrastructure in Switzerland

DOI: 10.57757/IUGG23-4314 - LINK

Domenico Giardini[1], Stefan Wiemer[2], Hansruedi Maurer[1], Marian Hertrich[1], The Bedretto Team[1]
[1]ETH Zurich, Department of Earth Sciences, Zurich, Switzerland
[2]ETH Zurich, Swiss Seimological Survey, Zurich, Switzerland

The BedrettoLab is an open and extendable research infrastructure of ETH Zurich. It is located in the Bedretto tunnel in the Swiss Alps. Its primary mission is to advance transdisciplinary research in geoenergy applications, such as deep geothermal reservoir development in crystalline rocks, and in frontier geoscience research, such as earthquake physics and predictability. Laboratories in the deep underground bridge the gap between natural scales (kilometres and above) and the research-lab scale (centimetres). This facility is extremely valuable to Earth scientists for hypothesis driven, fundamental research as well as for technology demonstrations. In a natural and realistic setting, experiments such as inducing micro-earthquakes or reservoir stimulation at the scale of tens to hundreds of meters can be conducted under controlled and repeatable conditions, observed closely by hundreds of multi-parameter sensors. Currently, about 50 scientists, engineers and technicians are part of the core BedrettoLab Team.

Within the BedrettoLab two separate reservoirs, the so called Geothermal and Earthquake physics test-beds, have been developed and instrumented. Both test-beds are equipped with numerous boreholes either for stimulation purposes or monitoring. The monitoring boreholes are equipped with a high-resolution monitoring system.

Beyond the two dedicated test-beds, the Bedretto tunnel provides smaller experimental sites, such as individual boreholes (10-40m), geological outcrops, water inflows or hydro-bio-chemical sampling at various places along the 5.2km long tunnel.

We present latest results of ongoing experiments, projects in preparation and future perspectives.

[2]*Krafla Magma Testbed Team, Geothermal Research Cluster, Reykjavik, Iceland*

The near-field source region for volcanic eruptions is magma. At present, evaluating the risk of imminent volcanic eruption is based almost entirely on untested interpretations of data from a variety of remote sensors, separated from the eruption source by kilometers of solid rock. There is not even consensus as to what the source is: a mush chimney with regions of melt segregation? An accumulation of mostly melt? Or at what pressure it exists: hydrostatic? least principal stress? lithostatic (ρgh)? lithostatic + ΔP? In contrast to currently dominant views, accidental (the only kind there have been) drilling encounters with magma have found only melt-rich magma, no mush. Given this dangerous state of ignorance, we need to explore the source of volcanic eruptions directly. What is the state of this material before eruption, as revealed by quenching it in situ under pressure? What do the signals of unrest recorded at the surface actually mean about processes in magma-hydrothermal systems? The Krafla Magma Testbed (KMT), Iceland, an ICDP project, seeks to answer these questions with a doublet of boreholes to magma. The first will core and permanently instrument the interval from brittle rock to magma, establishing physical, chemical, and mechanical source conditions. This borehole will become a monitoring post for the second well, where intentional perturbation of pressure and temperature of the magma and flow testing of the expected high-enthalpy fluid will be matched to signals at depth and at the surface. Obviously, there are implications for exploiting superhot geothermal energy as well.

Maar-diatreme volcanoes are small volcanic structures with a conical crater surrounded by a tephra-ring. They are formed by the explosive phreatomagmatic eruptions in a short time when groundwater comes into the contact with magma. We focus on the Bažina maar in the geodynamically active western Eger Rift (Czech Republic) and discuss results from multidisciplinary geophysical investigations calibrated by drilling in the frame of the ICDP Eger project (International Continental Drilling Program). Apart from the internal structure, we show how detailed pre-drill geophysical research contributed to a proper selection of the drill site which concluded in revealing unique structure of a maar volcano with several generations of eruptions. Two boreholes located in the maar crater evinced lithologies of the maar-diatreme filling and its contact with country rocks. They penetrated volcanic rocks and volcaniclastic deposits of the maar but also revealed pyroclastic cone with the olivine nephelinite feeding conduit. Such results are unique and disclose that the maar formation was followed by several subsequent eruptions within the maar. Further investigationsconfirmed long-lasting volcanic activity with very primitive magma and extremely low magma productivity, which distinguishes the western Eger Rift from other Cenozoic volcanic provinces in Europe. These results improve our understanding of volcanic processes, their significance is also general because they shed light on unique evolution of two volcanoes, one inside the other.

Assessing the timing and cause of widespread iron oxidation through scientific drilling of the Colorado Plateau

DOI: 10.57757/IUGG23-3592 - LINK

Christopher Lepre[1]
[1]*Bowling Green State University, Earth- Environment and Society, Bowling Green, USA*

The origin of red beds is a longstanding, unresolved problem that has raised many contentious discussions. Multiple hypotheses describe how red beds form yet there is still much unknown about the ubiquity, timing, and source of the hematite minerals that color the strata. These uncertainties are complicated by an absence of such mass accumulation of hematite on today's continents and the lack of a depositional model that explains why the blue, red, and purple colors rapidly alternate through stratigraphic successions. We therefore need an explanation that can account for hematite production at a regional scale and the seriation of color at the bed scale. Solving this puzzle has implications for many pursuits (e.g., paleomagnetism, redox geochemistry, organic carbon burial) and can shed light on other intervals of the geologic past (e.g., Precambrian BIFs) and perhaps Martian hematite. In this study, I examine scientific drill cores of Late Triassic red beds from the Chinle Formation in the Petrified Forest National Park, Arizona. These units have been sampled for color through high-resolution core scans conducted at the CSD facility, Minnesota, USA. I compare the color data to hematite concentrations collected through lower-resolution stratigraphic sampling with a benchtop spectrophotometer. Stratigraphic variations in color and hematite are argued to be indications of an orbital climate control on red bed formation. Comparing the core data to stratigraphically equivalent outcrop intervals provides a set of predictions to test for the timing and amount of diagenetic hematite formed in sandstones and other units of the Colorado Plateau.

[2]German Research Centre GFZ, Earth Sciences, Potsdam, Germany

Ringvent is a young shallow saucer-shaped sill intrusion emplaced in the Guaymas Basin in the Gulf of California, Mexico. It is an active hydrothermal cooling magmatic intrusion that allows the evaluation of thermomechanical processes involved in the emplacement of these structures in rift environments, practically in real-time.

This study aims to provide information about the mechanisms involved in sill emplacement by characterizing the physical properties in the contact zone between the sill and the host rock. The physical data used in this project was taken from ten logs and core samples drilled at the Ringvent site by the IODP 385 expedition. The data set includes measurements of density, permeability, p-wave velocities, and magnetic susceptibility that was analyzed, cleaned and plotted to find patterns in the sediment´s behavior around the sill contact area.

As a result of the analysis, we found that some of the factors that contribute to the emplacement of Ringvent are a porosity reduction above the sill, a decrease in the speed of the P-wave velocity, a slight decay in magnetic susceptibility, and the existence of a high-stress resistance layer above the sill.

These results were compared to another site in the Guaymas basin, where an older and deeper sill was emplaced, finding similar patterns. This correlation allows us to contribute to the discussion about the factors involved in sill emplacement and argue about if these observed changes are a result of thermal alteration by the sill, or in contrast, they are what determine the depth and shape of the sill.

Ringvent is a young shallow saucer-shaped sill intrusion emplaced in the Guaymas Basin in the Gulf of California, Mexico. It is an active hydrothermal cooling magmatic intrusion that allows the evaluation of thermomechanical processes involved in the emplacement of these structures in rift environments, practically in real-time.

This study aims to provide information about the mechanisms involved in sill emplacement by characterizing the physical properties in the contact zone between the sill and the host rock. The physical data used in this project was taken from ten logs and core samples drilled at the Ringvent site by the IODP 385 expedition. The data set includes measurements of density, permeability, p-wave velocities, and magnetic susceptibility that was analyzed, cleaned and plotted to find patterns in the sediment´s behavior around the sill contact area.

As a result of the analysis, we found that some of the factors that contribute to the emplacement of Ringvent are a porosity reduction above the sill, a decrease in the speed of the P-wave

velocity, a slight decay in magnetic susceptibility, and the existence of a high-stress resistance layer above the sill.

These results were compared to another site in the Guaymas basin, where an older and deeper sill was emplaced, finding similar patterns. This correlation allows us to contribute to the discussion about the factors involved in sill emplacement and argue about if these observed changes are a result of thermal alteration by the sill, or in contrast, they are what determine the depth and shape of the sill.

Imaging the weathering zone in Chile with active Radio-Magnetotellurics

The interdisciplinary DeepEarthShape project focusses on the weathering zone with drillings and geophysical, geochemical and geobiological approaches. The weathering zone is the uppermost part of the Earth's crust where rocks and soils experience breakdown through the impact of air/gases, water and/or biological organisms. The full picture of weathering processes and our insight into the critical zone is still limited. Since some of the properties of the weathering zone seem to be linked with climate, a set of sites is studied within the framework of the DFG Special Priority Program 1803 belonging to different climate zones and thus experience different vegetation, precipitation and erosion.
We utilised a combination of seismics and Radio-Magnetotelluric (RMT) measurements along ~200m long profiles at three study sites in Chile. For the RMT experiment, we used a horizontal magnetic dipole transmitter together with a nearby MT station. To develop the method into an applicable tool for this kind of inter-disciplinary studies, we show RMT results at different stages: Experimental layout tuned with synthetic simulations, RMT data processing using machine learning approaches. And finally, we will show and discuss 2D and 3D inversion results together with geophysical logging data and lab measurements. First results indicate that we can image precipitation and shallow fluid enhanced zones and provide crucial information for other disciplines. Minor faults and folds can be traced into the active weathering zone and linked with surface and borehole information.

S08a - Anthropogenic Seismicity

The Deccan Volcanic Province of India experiences all the three different types of earthquake sequences

DOI: 10.57757/IUGG23-0066 - LINK

Harsh K. Gupta[1]
[1]*CSIR-National Geophysical Research Institute, Seismlogy, Hyderabad, India*

Mogi (1963) broadly classified the earthquake sequences in Type 1, 2 and 3. Type 1 earthquake sequences have no foreshocks. However, aftershocks follow. In Type 2 earthquake sequences the main shock is preceded by foreshocks, and the number of aftershocks as well as the duration of the occurrence of aftershocks increases. Type 3 of the earthquake sequence is a swarm kind of activity where the number and magnitude of shocks increases with the passage of time and then decreases after some time. The Deccan Volcanic Province (DVP) of India witnessed earthquake sequences belonging Type 1 (Latur earthquake of M 6.2 on 29 September 1993), Type 2 (Koyna earthquake of M 6.3 on 10 December 1967), and Type 3 (Palghar earthquake swarm 2018-2020). It has been proposed that the change in the mechanical properties in the shallow crust due to loading of water reservoir has caused the change from Type 1 to Type 2 earthquake sequence for Koyna. Similarly, intense rain is considered to cause the change to Type 3. However, how these changes occur is not well understood. There is a need for understanding the cause leading to three different characteristics of earthquake foreshock-mainshock-aftershock sequence for a single geological domain. It is hoped that the detailed near field studies of earthquakes being undertaken at Koyna will provide an explanation.

Triggered seismicity in the Koyna region, starting soon after the impoundment of Shivajisagar water reservoir in 1962, has continued to this day. The activity, confined to 20 km x 30 km area and 10 km depth, is modulated by the annual loading and unloading cycles of the Shivajisagar and nearby Warna reservoirs. The 1967 M6.3 Koyna earthquake caused a NNE-trending surface rupture zone near Donichawadi, along which seismic activity in the past few decades is aligned.

To investigate the recurrent seismicity, a 3 km deep scientific borehole was drilled in the vicinity of the Donichawadi fault. Downhole measurements of physical and mechanical properties, borehole images, and composition of formation gases in the deep crystalline basement, combined with seismological data and laboratory geological and rock mechanical datasets provide new insights on the underlying conditions favouring recurrent seismicity: (i) Helium concentrations in the borehole suggest that the subsurface fault damage zones potentially associated with the Donichawadi fault. (ii) Drill core samples show evidences of repeated brittle deformations (iii) Water bearing zones are identified at multiple depths, providing strong evidence for percolation of water to deeper levels. (iv) Stress regime and earthquake focal mechanisms support transitional strike-slip to normal faulting environment. (v) The presence of optimally oriented, critically stressed and hydraulically conductive fractures creates conducive conditions for reactivation of faults with small changes in fluid pressure and/or frictional strength.(vi) Strain budget estimates from seismological and GPS data suggest that release of strain energy in terms of earthquake activity may continue for a longer time.

Induced seismicity has become a matter of concern for industry and nearby residents, as it poses significant risks to both property and human life. The Xinfengjiang water reservoir in China is a prime example of this, as it has induced earthquakes of magnitude greater than 6 and has experienced a yearly decline in dam stiffness. The potential safety hazards associated with induced seismicity have garnered significant attention. To address these concerns, a high-resolution 3D velocity and focal mechanism tomography study was conducted using a dense local seismic network. The study aimed to gain a deeper understanding of the underlying causes of induced seismicity in the area. The results show that fracture development beneath the dam area facilitated rapid fluid diffusion, whereas the presence of low-permeability striped bodies beneath the tail of the reservoir slowed fluid diffusion. A conceptual model was proposed linking the tomographic structure to the inducing process of the earthquakes, suggesting that an increased pore pressure is responsible for the seismic activity in both the dam and reservoir tail, while structural differences result in differing seismic activity characteristics.

S08a - Anthropogenic Seismicity

Hydro-Seismicity in the Paraná Basin, SE Brazil: events induced by the opening of water wells and rainfall.

DOI: 10.57757/IUGG23-1588 - [LINK]

Marcelo Assumpcao[1], *José Roberto Barbosa*[1], *Jaime Convers*[1], *Andrés Hincapie*[1], *marcelo Bianchi*[1], *Daniel Rosa*[1], *Luis Galhardo*[1]
[1]*University of Sao Paulo, Geophysics, Sao Paulo, Brazil*

Nine cases of earthquakes (1< M < 3.5) caused by the opening of water deep wells in the Paraná Basin, SE Brazil, are known since 1959. All occurred with wells drilled into the basalt layer to exploit confined aquifers.

The earthquakes start soon after the opening of the well, not after a long period of water extraction. The inducing mechanism is injection of water from the open surface aquifer into the confined deeper (100-200 m) aquifer. The uncased drilled well connects the surface and deep aquifers. These are clear examples of natural, gravity-driven fluid injection. The peak of seismicity occurs 2-3 months after the rainy season: rainwater recharges the surface aquifer, which in turn injects more water into the deeper aquifer increasing pore pressures at seismogenic depths. Earthquakes start near the drilled well and the active area expands with rates corresponding to seismic diffusivities from 0.02 to 0.7 m2/s, consistent with observed diffusivities worldwide.

Tens of thousands of deep wells have been drilled in the Paraná Basin: the hazard of seismicity induced by a deep well is very small. Most cases are in the NE part of the Basin close to several water reservoirs with induced seismicity, suggesting that both dam-induced and well-induced cases occur in a region of high neotectonic stresses.

The other natural earthquakes in the Basin occur mainly five months after the rainy season, especially in areas of flood basalt. Well-induced and rain-water seismicity show a common hydroseismicity character of the flood basalt layer.

We analyzed the earthquake density at the Geysers geothermal area (California) as function of time and space over a decade. We grouped parts of the volume of the geothermal area sharing similar earthquake rates over time; in this way, we found three concentric spatial domains labeled as A, B, C, moving from the inner- to the outermost domain, characterized by peculiar time-history of the earthquake rates and different Coulomb stress drops. The earthquake density decreases moving from domain A to C, and different b-values of the Gutenberg-Richter distribution appear for the domains A-B and domain C. We decomposed the mean earthquake rates into their independent components (ICs), which we model as the seismic response to some unknown triggering factors. IC1-2 appear to be straightforwardly related to the wastewater injection, while IC3 contains a secondary contribute from an unknown source. By simple modeling the earthquake source, we estimated that IC3 triggers about 1% of earthquakes of domain A and accounts for a yearly cumulative fault slip of about 7 mm. We broadly localized IC1 in the northern part of the geothermal area where most wells are located; IC2 is instead located about 4 km NW of IC1 source area. We model the earthquake pattern as principally due to stress transfer from the source of IC1 via a poroelastic mechanism.

S08b - Anthropogenic Seismicity

Rethinking historical models of induced seismicity in Rocky Mountain House, Alberta, Canada: Is brine disposal to blame?

DOI: 10.57757/IUGG23-4941 - [LINK]

Kienan Marion[1], David Eaton[1], Rebecca Salvage[1]
[1]University of Calgary, Geoscience, Calgary, Canada

Although most wells in Alberta have no correlation with induced earthquakes, the Rocky Mountain House Seismogenic Zone (RMHSZ) defies this trend. The RMHSZ is a long-lived (1970's to present) cluster of induced earthquakes located in west-central Alberta, Canada that has attracted attention following a stark increase in the regional seismicity rate after 2014. Seismicity in the RMHSZ has historically been linked to two mechanisms: poroelastic effects from gas production from the Strachan D3-A pool, a fractured Devonian reef; and natural earthquakes related to thrust faulting. The recent resurgence of seismicity brings the previously accepted poroelastic model into question, as gas production from the gas pool has ceased; new evidence suggests a nearby brine disposal scheme may be the culprit. This region is predisposed to favor induced seismicity from fluid injection based on overall sedimentology, diagenetic history, and complex structure, leading to increased seismic risk. Publicly available fluid injection data provided by geoSCOUT™ reveals the operator of the injector wells switched to a stratigraphically higher dolomitic zone, the Devonian Wabamun Group, in 2013; this timing coincides with the increase in seismicity.

We investigated the strength and nature of the relationship between recent seismicity and the production and injection history of nearby wells in the RMHSZ by applying a cross-correlation algorithm to injection volumes and earthquake counts. We found that recent seismicity does correlate with brine disposal in space and time; this method can be applied to other retroactive seismicity studies. On-site earthquake monitoring at RMHSZ should be undertaken in the future.

Stress features inferred from induced earthquakes in the Weiyuan shale gas block in southwestern China

DOI: 10.57757/IUGG23-4772 - LINK

Risheng Chu[1], *Minhan Sheng*[1]
[1]*Innovation Academy for Precision Measurement Science and Technology- Chinese Academy of Sciences, State Key Laboratory of Geodesy and Earth's Dynamics, Wuhan, China*

Stress features, particularly local stress field and earthquake stress drops, are important to understand mechanism of induced earthquakes. Since shale gas exploitations in 2015, the Weiyuan shale gas block has experienced frequent earthquakes. In this paper, we determine focal mechanisms of 257 events with M_L>1.5 by fitting three-component waveforms, invert for direction of maximum horizontal stress for two dense earthquake clusters, and then calculate stress drops for 17 earthquakes with moment magnitudes between 2.2 and 2.75 through the spectral ratio method. The focal mechanisms of all earthquakes are reverse faulting. The orientation of local maximum horizontal compressive stress is in the ESE direction, consistent with crustal movement indicated by GPS measurements. Both the focal mechanisms and microseismicity locations suggest the existence of steeply-dipping faults with dip angles of ~70º , which are relatively rare and difficult to slip under usual conditions, unlike major induced earthquakes with strike-slip or low-angle thrusting faults in the midwestern United States and western Canada. However, the steeply-dipping reverse events can be induced by large pore pressure from hydraulic fracturing. The stress drops range from 2.5 MPa to 54.7 MPa, comparable to those of potentially induced earthquakes in the midwestern United States. Our results imply earthquakes in the Weiyuan area are controlled by local tectonic stress and induced by large pore pressure from hydraulic fracturing, which advances our knowledge of reactivation of steeply-dipping reverse faults.

[1]The Chinese University of Hong Kong, Earth and Environmental Sciences Program, Hong Kong, Hong Kong

Hydraulic fracturing (HF) is a viable technique to stimulate the productivity of unconventional hydrocarbon resources. However the mobility of injected fluid in HF plays a critical role in controlling fault reactivation and consequently induced seismicity. Yet tracking the injected fluids underground remains challenging because of the limited resolution in traditional approaches. In this study, we attempt to investigate the possible controlling mechanisms of induced seismicity in the Weiyuan shale gas field in Sichuan, China using a dense temporary seismic network that was deployed between April to June 2020. We apply the frequency index to analyze the impact of injected fluid on event waveforms and classify them based on the low/high-frequency components. We assess the potential controlling mechanism of these waveforms, including source, path, or injected fluid, and evaluate with waveform analysis. Our results reveal that low-frequency waveforms (LFW) are prominent in a certain azimuth range which rules out the possibility of source effects. Meanwhile, most of these LFW are constrained temporally and spatially and unlikely to be path effects. Furthermore, waveforms from nearly collocated earthquakes at different depths have distinct frequency contents. P phases are relatively unaffected, compared to highly attenuated S phases which suggest that absorption might be a key factor, instead of scattering. We identify a zone with congregated fluid near hydraulic fracturing platforms which might be responsible for LFW when ray paths encounter. Such fluid may trigger delayed seismicity or upward fluid migration which poses challenges to establishing an effective mitigation strategy for potential seismic risk.

Since the mass production of shale gas in Changning, Southern Sichuan basin of China in 2014, earthquake activity has increased rapidly, including the destructive 2018 Xingwen 5.7 and 2019 Gongxian 5.3 earthquakes, which are among the largest induced earthquakes worldwide. Because of the limited access to the industrial fracturing parameters, we have to rely on comprehensive seismological tools to decipher what mechanisms likely induce earthquakes in southern Sichuan basin, which include seismic location, focal mechanism determination, coseismic slip inversion, and seismic tomography.

Our seismic data mainly comes from a local seismic array including 10 4.5-Hz geophones covering the Changning shale gas block that has the area of ~50 km by ~20 km. In 2019, this array detected more than 40000 seismic events by applying an STA/LTA technique. Among these events, we selected ~11600 events with clear P and S arrivals for location and tomography. The relocated events are clustered in swarms and show vertical lineations beneath the target shale reservoir layer. We also selected 30-40 events for each swarm and determined their focal mechanisms by a full waveform matching method. From these focal mechanisms, stress inversion is conducted to determine the principal stresses and excess fluid pressures for each earthquake. Three-dimensional Vp, Vs and Vp/Vs models were determined for the shale gas block by the double-difference seismic tomography method. These joint analysis results show that these earthquakes are most likely induced by increased pore pressures on the seismogenic faults due to the presence of water and/or gas.

Since the mass production of shale gas in Changning, Southern Sichuan basin of China in 2014, earthquake activity has increased rapidly, including the destructive 2018 Xingwen 5.7 and 2019 Gongxian 5.3 earthquakes, which are among the largest induced earthquakes worldwide. In 2019, this array detected more than 40000 seismic events by applying an STA/LTA technique. Among these events, we selected ~11600 events with clear P and S arrivals for location and

tomography. The relocated events are clustered in swarms and show vertical lineations beneath the target shale reservoir layer. We also selected 30-40 events for each swarm and determined their focal mechanisms by a full waveform matching method. From these focal mechanisms, stress inversion is conducted to determine the principal stresses and excess fluid pressures for each earthquake. Three-dimensional Vp, Vs and Vp/Vs models were determined for the shale gas block by the double-difference seismic tomography method. These joint analysis results show that these earthquakes are most likely induced by increased pore pressures on the seismogenic faults due to the presence of water and/or gas.

Spatial clustering of induced seismicity controlled by the pre-existing faults and fractures in the southern Sichuan Basin of China

DOI: 10.57757/IUGG23-4936 - LINK

Haichao Chen[1], Fenglin Niu[1]
[1]China University of Petroleum-Beijing, Unconventional Petroleum Research Institute, Beijing, China

The surge of seismic activity in the recent years has been attributed, at least partly, to intense hydraulic stimulation activities associated with the exploitation of unconventional natural gas resources in the southern Sichuan Basin, China. We have deployed a dense seismic array, which consists of 30 broadband seismometers with station spacing about 2 km, from December 2020 to March 2022 in the Weiyuan shale gas block within the southern Sichuan Basin. In this study, we systematically detect and locate 52210 earthquake events using LOC-FLOW framework and compute focal mechanisms of small to medium events (M>2). The enhanced catalog, with a maximum ML of 3.6 and a completeness magnitude of 0.5, generally includes two distinct prolonged earthquake sequences. The temporal migration of the earthquake sequences is highly correlated with fracking operations of two well pads both spatially and temporally. The events have focal depth ranging from 2 to 6 km, extending from the injection zone downward into the underlying crystalline basement. The focal mechanisms exhibit predominant thrust faulting, with P-axis subparallel to the maximum horizontal compressional stress direction in the region. Moreover, the lineation of earthquake clusters is also clearly associated with the apparent fault zones identified by ant tracking algorithm of a 3D seismic reflection survey, indicate reactivation of a subsurface thrust fault system. These results suggest that the spatially clustered earthquake sequences are driven by pore pressure diffusion related to hydraulic stimulation and strongly controlled by pre-existing faults and fractures.

Tectonic Strain Rate and Induced Earthquakes in Oklahoma: Implications for Regional Seismic Hazard

DOI: 10.57757/IUGG23-1357 - LINK

Innovation Academy for Precision Measurement Science and Technology- CAS, Wuhan, China

In recent decades, the magnitude and harm of injection-induced earthquakes (IIE) due to anthropogenic activities have gradually increased, which has evolved into a global problem. However, the triggering mechanism of induced earthquakes is complicated, and there are significant spatial differences and time delays between the pumping areas and the areas where the induced earthquakes are concentrated, not all injections induce earthquakes, and it is not uncommon for regions with strong injections to remain seismically silent. To explore the controls on IIE, we compare geodetically derived tectonic strain rates with seismicity in Oklahoma where injections are prevalent. Results demonstrate that induced earthquakes are high in areas with moderate tectonic strain rates, while areas with high seismic moment release are consistent with areas with moderate tectonic strain rates, indicating that the regional tectonic is the fundamental cause of IIE. Moreover, the moment rates released by induced earthquakes approach even exceed the tectonic moment rate in the IIE-rich zone. We thus argue that injections indeed causes a large number of induced earthquakes and local seismic hazard in the short term, but limits the potential for larger future earthquakes by depleting the shallow tectonic moment.

[4]OR, Reykjavík Energy, Reykjavík, Iceland

Nesjavellir geothermal field is located in the northern part of the Hengill central volcano in South West Iceland. Electricity and hot water for district heating is currently produced by OR-Reykjavík Energy at two power plants around Hengill, Nesjavellir to the north and in Hellisheiði to the southwest. The seismicity recorded in the area is due to volcano-tectonic processes, natural geothermal activity and geothermal production.

The aim of this work is to deepen the understanding of the mechanisms of generation of seismicity through the study of the properties of the medium, it's variations over time and the kinematic characteristics of earthquakes.

Below Nesjavellir low Vp/Vs ratios and low b-values are observed at shallow depth (due to low Vp). High Vp/Vs ratios and high b-values are observed between 3.5 and 6 km depths (due to high Vp and low Vs), which is in correspondence with the deepest seismicity characterized by a higher percentage of small events. Our results suggest the coexistence of distinct mechanisms that control seismicity. From 4D analysis we observe the evolution of seismicity and a corresponding variation in the elastic medium properties as a function of the depth.

This work has been supported by PRIN-2017 MATISSE project, No 20177EPPN2, funded by Italian Ministry of Education and Research.

Physical modeling of injection-induced earthquakes in fractured rocks

DOI: 10.57757/IUGG23-3111 - LINK

Adrian Bormann[1], *Mohammad Moein*[1]
[1]*Freie Universität Berlin, Geophysics Section, Berlin, Germany*

Induced seismicity has been a major challenge for engineering subsurface reservoirs. Particularly, hydraulic stimulation of Enhanced Geothermal Systems (EGS) is typically accompanied by seismic events that may be felt by public and even include damaging earthquakes. Massive fluid injection reactivates the pre-existing critically stressed faults and releases the strain energy by seismic slip. In densely fractured rocks, induced seismic sequence is jointly controlled by the fracture network geometry and the activated coupled hydromechanical processes. However, the physical linkage between geometrical attributes of fracture network spatiotemporal and magnitude distribution of induced seismicity is not fully understood. A physical understanding may define constraints over the maximum induced earthquake magnitude, which is a crucial parameter for seismic risk and hazard assessment. Here, we used stochastically generated discrete fracture networks (DFN) that represent the natural fractures as (poly)lines in a two-dimensional cross section. Various DFNs were generated over two orders of magnitude in length scales (1-100 m) to cover the observed length distribution in outcrop analogues. Then, we utilized a hydromechanical model to resolve the activated processes by fluid injection. The occurrence of seismic and aseismic slip was obtained by post-processing of the resulting displacement field. The preliminary investigations revealed the significant role of connectivity on the spatial distribution of seismic events. However, a sensitivity study is required to clarify the impact of unknown fracture network attributes (length and spatial clustering) on the characteristics of seismic sequence (b-value). The results of the analysis might have significant implications injection-related activities such as enhanced geothermal systems.

Among the key aspects for the analysis of artificial water Reservoir-Triggered Seismicity (RTS) is the adequate setting of the 4D spatiotemporal distribution of water loads, usually based on the Digital Elevation Models (DEMs) of the reservoir basin, and the observed temporal evolution of the water levels. Somehow, in some cases, the access to a detailed lake bathymetry for old reservoirs is generally limited.

Here we study the 4D spatiotemporal evolution of the stress changes as a function of the 3D configuration of the bathymetry, and the temporal changes in the water level in dams, using real and theoretical 3D DEMs. First, surface loads are modeled using 3D theoretical configurations for the bathymetry and water levels time evolution, considering the actual aspect ratio of the lakes. Stress changes (ΔCFS), are computed for an elastic halfspace, calculated using the full 3D stress tensor. Then, stress changes from theoretical models are compared with those produced by the real DEMs of the dam. The analysis is carried out for three different reservoirs: the Aguamilpa reservoir in Mexico, with a storage capacity SC=5480 hm3, the Itoiz reservoir in Spain, with a SC=418 hm3 and the Pirrís reservoir in Costa Rica with a SC=30 hm3. Stresses are compared with the corresponding seismic series occurred after the initial filling of the three dams. Results show that theoretical models adequately reproduce the main effects of surface loads even at relatively shallow depths, showing their suitability for the analysis on the possible induced shallow seismicity.

Array-derived rocking and vertical ground motion scaling relations from seismicity induced by the 2018 Espoo/Helsinki geothermal stimulation

DOI: 10.57757/IUGG23-2868 - LINK

Amir Sadeghi-Bagherabadi[1], *Gregor Hillers*[1]
[1]*Institute of Seismology, Department of Geosciences and Geography- University of Helsinki, Helsinki, Finland*

The observation of ground motions excited by induced earthquakes near urban areas is of significant engineering importance. During the 2018 geothermal stimulation in the Otaniemi district of Helsinki, Finland, five seismic arrays consisting of 3 to 25 three-component geophones were deployed with interstation distances of 50 meters to record ground motions of 6-km deep induced events. This dataset provides an opportunity to study the ground motion patterns in the low-attenuation environment of the Fennoscandian Shield. The translational seismograms are used to calculate rotational motion for ~400 events with local magnitudes ranging from -0.5 to 1.8 using the seismogeodetic method. We evaluate the relationship between array-derived ground rocking rate (GRR) and vertical ground acceleration (VGA) associated with direct body waves. The robustness of the GRR estimates in the 2-15 Hz frequency range are assessed by comparing the VGA waveforms to the GRRs from the full arrays and to the GRRs from subarrays with different wavelength-to-aperture ratios. By rotating the two perpendicular components of the GRRs, we obtained the radial-transverse coordinate system that minimizes the GRR values on the radial component. We, find different P- and S-wave propagation directions that deviate from the theoretical back-azimuth of the earthquakes, and variations in the apparent body wave velocities beneath the arrays that we attribute to local propagation effects. While the deployment of broadband rotational sensors for wavefield gradiometry analyses is anticipated to become a common practice in the near future, this study provides a low-tech and band-limited experimental verification of the theoretical scaling models.

Earthquake-induced anomalies and recovery phenomena in groundwater system from the 2017 MW 5.5 Pohang earthquake in South Korea

DOI: 10.57757/IUGG23-0401 - LINK

Jaeyeon Kim[1], Kang-Kun Lee[1], Dugin Kaown[1], In-Woo Park[1]
[1]Seoul National University, School of Earth and Environmental Sciences, Seoul, Korea Republic of

The 2017 M_W 5.5 Pohang earthquake was one of the largest earthquakes triggered by hydraulic stimulation for an enhanced geothermal system. This study aims at investigating hydrogeochemical and microbial evidence of earthquake-induced anomalies and recovery phenomena. Generally, groundwater level changes have been used as indicators, however, these have limitations for identifying the anomalies that cannot be interpreted comprehensively as pore-elastic behavior of aquifers. In this study, we analyzed hydrogeochemical data, including environmental isotopes (^{18}O, ^{2}H, Sr, and ^{222}Rn), and microbial diversity with time-series data of groundwater level. The physical modeling for pore pressure changes was also employed. The results showed that the wells near the epicenter had the notable changes in groundwater level, which are corresponded with the distribution of pore pressure changes from the modeling, whereas the other wells had abnormal patterns in the data of hydrogeochemistry and isotopes. These isotopic anomalies could suggest possible mechanisms underlying the responses to the earthquakes such as sea water intrusion, water-rock interactions, shallow and deep groundwater mixing, and deep fluid upwelling. With regard to the recovery phenomena, the hydrogeochemical and microbial results showed that shallow groundwater system has probably recovered within 2 years, whereas the geothermal well, with deep casing, did not recover to its original groundwater quality within 4 years, suggesting the management for a more extended period.

Pressure diffusion controls maximum earthquake magnitudes induced by geo-energy applications

DOI: 10.57757/IUGG23-0585 - LINK

Cornelius Langenbruch[1], *Mohammad Moein*[1], *Serge Shapiro*[1]
[1]*Freie Universität Berlin, Fachrichtung Geophysik, Berlin, Germany*

It is an open question if maximum induced earthquake magnitudes can be determined based on knowledge about operational parameters, subsurface conditions and physical process understanding. We analyzed a global compilation of earthquakes induced by hydraulic fracturing, geothermal reservoir stimulation, water disposal, gas storage and reservoir impoundment. Our analysis showed that maximum magnitudes scale with the characteristic length of pressure diffusion in the brittle Earth's crust. An observed increase of the nucleation potential of larger magnitude earthquakes with time is likely governed by diffusion-controlled growth of pressure perturbed fault sizes. Numerical and analytical fault size modelling confirmed the findings. Finally, we derived scaling laws for the maximum possible and maximum expected magnitude for induced seismic hazard and risk forecasting and management.

Induced earthquakes have peculiar characteristics such as relatively shallow depths, small-to-moderate magnitude, correlation with field operations, non-GR recurrence law, and eventually non-homogenous Poisson recurrence time. Thus, when dealing with induced seismicity, the standard Probabilistic Seismic Hazard Analysis (PSHA) has to be modified.

This work aims at exploiting the information carried by the ongoing induced seismic sequence in quasi-real time to provide spatio-temporal predictions of ground shaking in a prescribed forecasting interval (in the order of days). First, the workflow adaptively updates the seismicity forecasts based on the incoming information as it becomes available. The clustering of seismic events in volume (3D seismicity) and time is modelled based on an Epidemic Type Aftershock Sequence (ETAS) model. The proposed 3D ETAS model encompasses a decoupled depth-area volumetric probabilistic kernel. The ETAS parameters will be re-calibrated to take into account non-GR long-term temporal boundary conditions in case of induced seismicity.

Second, the PSHA is performed using proper ground motion prediction models (GMPE). By combining the time-dependent seismicity rates provided by ETAS model and the mentioned GMPE, PSHA in a prescribed forecasting interval is adopted for calculating the mean rates of exceeding certain ground-shaking levels.

The procedure is demonstrated through retrospective hazard forecasting of induced seismicity recorded at the Geysers geothermal field in northern California in the time period of 2011-2015 during fluid injection in the vicinity of Prati 9 and Prati 29 injection wells.

This work has been supported by PRIN-2017 MATISSE project No 20177EPPN2, funded by Italian Ministry of Education and Research.

A Coulomb Stress response model for time-dependent earthquake forecasts: Application to the Groningen gas field

DOI: 10.57757/IUGG23-0926 - LINK

Sebastian Hainzl[1], *Torsten Dahm*[1]
[1]*GFZ German Research Centre for Geosciences, Geophysics, Potsdam, Germany*

We have recently developed a new physics-based seismicity model assuming pre-existing populations of faults that respond to changes in Coulomb stress. In contrast to the traditional Coulomb Failure (CF) model, which assumes instantaneous triggering when stress exceeds a threshold value, the new model replaces instantaneous triggering with an average time to failure that depends exponentially on the absolute stress value. The prediction for critical pre-stress conditions is identical to the widely used rate-state (RS) friction model. Thus, CF and RS predictions are both special cases of the new model. However, the new stress response model can also account for subcritical initial stress conditions, which are particularly relevant for induced seismicity in intraplate regions.

Here we show the application of the new model to the Groningen gas field, which is one of the largest onshore gas fields in production in Europe and a frequently considered site for the study of induced seismicity. The long delay between the start of production and the onset of seismicity indicates subcritical pre-stresses. We estimate the pre-stress distribution based on the background stress field and the existing fault structure. Using this pre-stress distribution and the estimated temporal evolution of the 2D stress field in the reservoir, we show that the delayed onset, the peak in 2013-2015 and the recent decline in observed seismicity are well explained by the model.

Magnitude complexity of earthquake sequences resulting from anthropogenic activities

DOI: 10.57757/IUGG23-0572 - LINK

Anastasios Kostoglou[1], *Beata Orlecka-Sikora*[1], *Stanislaw Lasocki*[1]
[1]*Institute of Geophysics- Polish Academy of Sciences, Department of Seismology, Warsaw, Poland*

Human activities exploiting geo-resources can cause moderate to strong earthquakes and result in significant economic and social impacts. It was shown (Urban et al. Pure Appl. Geophys. 173, 2016) that because such anthropogenic seismicity was controlled by complex technological factors, its magnitude distribution might deviate from the exponential distribution of the Gutenberg–Richter (G-R) law. Here, we investigated the deviation of the magnitude distributions from the G–R law for twelve earthquake sequences of anthropogenic seismicity, accessible on the "EPISODES" platform of EPOS Thematic Core Service Anthropogenic Hazards (https://tcs.ah-epos.eu/). The sequences include earthquakes induced by reservoir impoundment and hydraulic injection, as well as acoustic emissions induced by repetitive cooling cycles. We examined the magnitude distributions of space–time clusters of seismicity following variations of the inducing processes, ensuring the stationarity of the seismic process by appropriate temporal window selection. Subsequently, we assessed the deviation from the G–R law via the Anderson – Darling test.

The results showed that the magnitude distribution of anthropogenic seismicity deviated from exponentiality regardless of the causative technological factors. They point to the need to consider alternative magnitude distribution models when calculating seismic hazard parameters, as incorrect models can impose unacceptable errors on hazard estimates.

Geophys. 173, 2016) that because such anthropogenic seismicity was controlled by complex technological factors, its magnitude distribution might deviate from the exponential distribution of the Gutenberg–Richter (G-R) law. Here, we investigated the deviation of the magnitude distributions from the G–R law for twelve earthquake sequences of anthropogenic seismicity, accessible on the "EPISODES" platform of EPOS Thematic Core Service Anthropogenic Hazards (https://tcs.ah-epos.eu/). The sequences include earthquakes induced by reservoir impoundment and hydraulic injection, as well as acoustic emissions induced by repetitive cooling cycles. We examined the magnitude distributions of space–time clusters of seismicity following variations of the inducing processes, ensuring the stationarity of the seismic process by appropriate temporal window selection. Subsequently, we assessed the deviation from the G–R law via the Anderson – Darling test.

The results showed that the magnitude distribution of anthropogenic seismicity deviated from exponentiality regardless of the causative technological factors. They point to the need to consider alternative magnitude distribution models when calculating seismic hazard parameters, as incorrect models can impose unacceptable errors on hazard estimates.

Waiting times distributions between successive earthquakes have extensively been studied to provide insights into the physical mechanism of seismogenesis and to effectively assess seismic hazard. While in tectonic seismicity the waiting times distribution is well-defined as the superposition of Omori-like aftershock sequences on correlated and/or random background activity, in induced seismicity associated with fluid-injections in the subsurface, the underlying physical mechanism remains ambiguous. Herein, we analyze the waiting times distributions in various cases of fluid-injection induced seismicity in deep geothermal reservoirs, as in the Cooper Basin (Australia), Basel (Switzerland), Soultz-sous-Forêts (France) and Espoo (Finland). In all cases that we study, the probability densities of waiting times present broad distributions with asymptotic power-law behavior, indicating clustering effects at intermediate and long-time scales. At short-time scales, however, clustering effects in most of the cases are either weak or absent, suggesting that seismic clustering due to aftershocks is missing. In the Habanero field (Cooper Basin), on the other hand, short-term clustering is also present, implying the interplay of various physical mechanisms in the evolution of induced seismicity. The observed scaling behaviour, in all the cases, can well be described with a stochastic model that incorporates nonstationarities and memory effects in the evolution of seismicity, contrasting a random Poisson process.

Anthropogenic seismicity is an unwanted by-product of the technological operation of humans. The socio-economic impact of the induced seismicity is significant. Induced earthquakes can cause material loss, injuries, and fatalities. Data access is necessary to assess and mitigate the associated hazards. To respond to the need of the scientific community, the Thematic Core Service Anthropogenic Hazards (TCS AH) has been created within the framework of the European Plate Observing System, a solid earth science European Research Infrastructure Consortium (ERIC). TCS AH is a consortium of 14 institutions from Europe and beyond. TCS AH provides access to a novel e-research infrastructure, the EPISODES Platform, to foster research and training on induced seismicity and geo-hazards related to the exploration and exploitation of geo-resource. The EPISODES Platform is connected to international data nodes which offer open access to multidisciplinary datasets called episodes. Episodes comprise geoscientific and associated data from industrial activity along with a large set of embedded applications for their efficient data processing, analysis, and visualization. The EPISODES Platform also opens the possibility to create new applications and combine implemented applications with the user's codes. We present the current results of the TCS AH research infrastructure integration indicating the benefits of their usage for science, education, and innovation.

This work was conducted in the frameworks of (1) the TCS Governance and Coordination Collaboration Agreement 2021-2023 between EPOS-ERIC and the Institute of Geophysics, PAS (NUMBER 01– CA-TCSGOV-AH), and (2) the project "TCS AH," financed by the Polish Ministry of Education and Science, (Number 2021/WK/09).

Many Swiss microearthquake sequences have been analyzed using relative location techniques, which often allowed constraining active fault planes and tectonic processes that drive seismicity. Yet, often the number of located earthquakes was too small to infer details of the space-time evolution of the sequences or their statistical properties, and thus resolve clear seismicity patterns and their driving mechanisms.

We present a nearly automatic workflow that combines well-established seismological analysis techniques to improve the completeness of detected and located earthquakes of a sequence. Starting from a manual catalog (magnitude of completeness, Mc ≈ 1.0−1.5), we assemble a template set and perform a matched filter analysis on a single station with highest SNR. This allows us to detect events of local magnitude $M_L < 0.0$. The waveform similarity is further exploited to derive detection magnitudes. The enhanced catalog is then statistically analyzed to derive high-resolution temporal evolutions of the Gutenberg−Richter a- and b-values, and consequently the occurrence probability of larger events. Strong events are located using relative double-difference, which usually improves the number of well-relocated events by a factor of 2−5.

This workflow allows us to significantly enhance the analysis of spatiotemporal behavior of natural and induced microearthquake sequences, which we use to monitor commercial and scientific fluid injections in near real-time. We implemented this workflow in the open-source Python/PostgreSQL toolbox **QuakeMatch**. We discuss the capabilities of QuakeMatch with examples of induced microearthquake sequences associated with various geothermal projects monitored by the Swiss Seismological Service in the framework of the GEOBEST2020+ project.

The Fault Activation and Earthquake Rupture (FEAR) project aims at activating a natural granitic fault zone in the BedrettoLab at the 100m scale. The goal is to observe and study earthquake rupture phenomena in a natural setting from unusually close distance.

The Bedretto Underground Laboratory for Geosciences and Geoenergies is a research laboratory in a 5km long tunnel in the southern Swiss Alps, with an overburden of up to 1.5km. At 2.4km into the Bedretto tunnel we have identified a ~2m thick natural fault zone. The fault zone consists of multiple distinct quartz and biotite shear fractures, some of which contain gauge layers of up to 5mm thickness. The fault zone is favourably oriented for rupture in the estimated present day background stress field.

In autumn 2023, we plan to excavate a side tunnel that runs parallel to the fault zone for ~125m. This tunnel will facilitate the installation of a very dense multi-domain geophysical monitoring system, directly on and around to the fault zone. After a detailed characterization of the fault zone and the host rock, and with the monitoring system in place, we plan to activate the fault via water injection in multiple injection boreholes, in a suite of experiments. If successful, the experimental setup will allow us to study a wide range of seismic and aseismic crustal deformation phenomena from up close, including rupture preparation and precursory signals, rupture nucleation, coseismic strain localisation, rupture growth and termination as well as the post-seismic response of the fault zone.

Seismic repeaters are a well-known phenomenon in natural seismotectonic environments but have been rarely observed in underground mines. Recent studies in the Garpenberg excavation mine (Sweden) have shown that repeaters may represent significant part of the total number of microseismic events (> 80 %). Accurate analysis, involving multiplet clustering, relocation, source parameter and mechanism estimation, and inter-event time analysis, suggest that seismic repeaters represent brittle frictional components of creeping, planar shaped, pre-exiting structures of several meters' length.

The accessibility and high recurrence rates of these repeaters provide a great opportunity to study and monitor repeaters in situ and to improve our understanding on seismic-aseismic coupling mechanisms in fault zones and potential pre-seismic precursory slip on faults asperities. In the framework of the FIMOPTIC project, we aim at monitoring the full seismic cycle of certain repeater targets using standard in situ strain monitoring combined with recent optic fiber technologies. In the first phase of the project, we currently investigate the exact location of some target repeaters using dense seismic arrays, as well as DAS and DTTS campaigns along optic fibers installed along the mine galleries. Once a accurate location is obtained and the geo-structural nature of the phenomena better understood, we aim at performing detailed in situ strain measurements along boreholes cross-cutting the faults zone (asperities) including a high resolution Faby-Pérot optical strain-meter with sensitivities in the nano-strain range at low frequencies (< 10 HZ). The presented study provides an update on these investigations and shares preliminary results.

Exploring the potential of surface monitoring networks for induced seismicity in the Utah FORGE geothermal project

DOI: 10.57757/IUGG23-2796 - LINK

Enhanced geothermal systems are a cornerstone in transitioning from fossil to renewable energy sources. However, applications of its potential are still rare, either due to economic reasons or concerns about induced seismic activity. The large-scale Utah FORGE project (Milford, Utah, USA) with a planned well-doublet reaching a depth of 2.5km in crystalline basement rock addresses both issues. Detailed microseismic monitoring of deep geothermal projects remains challenging and expensive when using additional deep monitoring boreholes. We explore the potential of cost-efficient surface or shallow-borehole (tens of meters) monitoring networks regarding the detection and characterization of injection-induced seismicity during three stimulation stages at Utah FORGE in 2022. The analysis relies on full-waveform-based methods for detecting, locating, and classifying events and inversions for focal mechanisms of the largest events. It also includes exploiting information from a multi-patch geophone nodal deployment via waveform stacking, which helps further lower the surface network's detection threshold. We compare our surface monitoring catalog to the official deep borehole monitoring catalog, which comprises ~2500 events between M -2.09 and 0.52. Preliminary results indicate that despite the higher noise level at the surface and the increased distance to the source area, we can reliably detect events down to M -0.7 using the surface networks. In the ongoing work, we investigate the resolution of seismicity patterns and evaluate the applicability of such cost-efficient surface networks for monitoring geothermal projects.

Macroseismology plays a crucial role in earthquake hazard and risk analyses, tying earthquake occurrences and impacts from the past with those of the present and future. The use of macroseismic intensity has grown as the hazard layer within essential USGS and others' real-time information products and even in presenting hazard maps in a form friendlier to nontechnical users. However, even with best practices, there are limitations to modern macroseismic data collection approaches. Whereas crowd-sourced intensities are robust for lower levels, they are poorly defined above intensity VII, where damage assessment requires knowledge of each building's structural system. Likewise, the United States, New Zealand, and others employ the Modified Mercalli Intensity (MMI) scale, which is consistent with—yet inferior to—the more recently developed European Macroseismic Scale (EMS-98). We report on an IMS Working Group meeting held in October 2022 at the USGS Powell Center to address these and other issues and to work towards an IMS. Workshop goals were, first, to harmonize the MMI scale with EMS-98 for the US and NZ—which share several similar building types—by considering those structures and associated damage grades not well represented in the current EMS-98 building vulnerability table. Second, formalize the process of augmenting EMS-98 with vulnerability classes appropriate for building types in other countries, thus promoting a scale that can be employed globally. Such efforts require expanding the EMS-98 explanatory documents. Lastly, we discuss how standardized earthquake-damage data collection worldwide—as part of an IMS—could facilitate hazard and risk analyses.

Rapid assessment of an earthquake’s impact on the affected society is a crucial first step of disaster management, determining further emergency measures.
We demonstrate that macroseismic observations, collected as felt reports via the LastQuake service of the European Mediterranean Seismological Center, can be utilized to estimate the probability of a felt earthquake to have a “high impact” rather than a “low impact” on the affected population on a global scale. In our fully data-driven, transparent, and reproducible approach we compare the distribution of felt reports to documented earthquake impact in terms of economic losses, number of fatalities, and number of damaged or destroyed buildings. Using the distribution of felt-reports as predictive parameters and an impact measure as the target parameter, we infer a probabilistic model utilizing Bayes’ theorem and Kernel Density Estimation, that provides the probability of an earthquake to be “high impact”. For 393 felt events in 2021, a sufficient number of felt reports to run the model is collected within 10 minutes after the earthquake. While a clean separation of “high-impact” and “low-impact” events remains a challenging task, unambiguous identification of many “low-impact” events in our dataset is identified as a key strength of our approach. We consider our method a complementary and inexpensive impact assessment tools, that can be utilized instantly in all populated areas on the planet, with the necessary technological infrastructure. Being fully independent of seismic data, our framework poses an affordable option to support disaster management in regions that currently lack expensive seismic instrumentation.

To estimate a potential source fault after an earthquake is important for seismic hazard assessment (e.g., FinDer). Using pre-calculated ground motion time histories will be useful for earthquake evaluation to grasp which scenario earthquakes are similar to each other within a few hours to half a day when an earthquake occurs. We develop a method to compare observed ground motions by NIED K-NET/KiK-net with simulated ground velocities from the NIED J-SHIS database that for the Scenario Seismic Hazard Maps in the National Seismic Hazard Maps 2020, targeting active faults in Japan. Based on the comparison of velocity ground motion time histories with a 0.1-1 Hz band-pass filter, cross-correlation coefficients with/without amplitude normalization were obtained, and scenario fault candidates were ranked. We applied this method to the 2016 Kumamoto earthquake sequence. The fault selection for the foreshock worked well, supporting the proposed method. However, the mainshock did not select the ruptured fault identified by the ground truth. One of the reasons is the different dominant frequency between the observation and pre-calculated ground velocities, indicating the necessity of further adjustment.

On November 11th, 2019, a moderate M_W 4.9 earthquake occurred in Le Teil in the southeast of France, inducing significant damage (VIII on the EMS98 intensity scale in some localities). This moderate earthquake occurred at a very shallow depth of 1-2 km and induced a surface rupture up to 15 cm uplift. Good quality recordings of this earthquake are available at numerous stations well distributed around the epicentre, with the nearest station 8 km from the rupture. These recordings were analysed to highlight any specific ground motion features related to the shallow depth of the earthquake with a focus on the residuals between observations and ground motion model predictions. The first trend emerging from the residual analysis is that observations are higher than predictions at 0.5 Hz and on the contrary, they are lower above 5 Hz. Looking at the spatial distribution of residuals, we highlight that their amplitude is closely related to their location. For example, at high frequencies, residuals are lower for sites in the southeast of France, which is consistent to the first order with regional attenuation maps. Source properties and regional geological characteristics could also be explored to explain the residual amplitudes in different frequency ranges. Finally, different phenomena could be involved to explain residuals, but it is not straightforward to conclude that one factor is dominant.

The aim of the study is to analyze the existing ground motion prediction equations (GMPEs) applicable in Albania for horizontal peak ground acceleration (PGA) and spectral acceleration (SA). We present four sets of GMPEs evaluated for Albania using a dataset of instrumental strong-motion records from the November 26, 2019, Mw6.4 Durres earthquake. Besides the mainshock, the models are tested for foreshock and aftershock events of magnitude Mw>5.0. The GMPEs from Boore et al., (2014), Chiou and Youngs (2014), and Kotha et. al., (2020), provide a better fit to the ground-motion attenuation observed for the mainshock at distances up to 400 km, while Akkar et. al., (2014) fit better at a short distance. Along with the seismological aspects of the earthquake, we give an overview of the damages and social consequences, considering the engineering seismology source of data known as “Did You Feel It?” (DYFI) and the 1360 DYFI online citizen responses collected after the Durres event. The DYFI data are higher than instrumentation data, better represented using SA at 0.3s. By integrating the instrumentally observed data with the macroseismic observed data, we explore the importance of human response to the concept of ground shaking, demonstrating how this type of information can indeed reduce the gap in regions with a limited number of near-field stations. Therefore, this study makes a major contribution to the selection of GMPEs and provides a useful reference for the logic tree structure in subsequent seismic hazard assessment on both national and regional scales.

We are leading an effort to develop international standards and guidelines for curating, disseminating, and validating simulated ground-motion data. This effort is organized as a working group within the Consortium of Organizations for Strong Motion Observation Systems (COSMOS). In 2022 we held online workshops on 7-8 June and 20 October. The first workshop focused on curating and disseminating simulated ground-motion data. The second workshop focused on validating simulated ground-motions for engineering applications. We intend to form a technical committee to draft international guidelines and standards while continuing to engage stakeholders from across the globe through online and in-person meetings.

The key points from workshops include: (1) Numerous groups are generating simulated earthquake ground motions and making them openly available, however there is very little coordination among groups to provide consistent interfaces for searching and retrieving data; (2) Standardizing interfaces for metadata and data access should consider agile approaches that can adapt to changing capabilities and user needs while building upon existing efforts; (3) Participants advocated for a distributed architecture that would allow institutions to host and manage their own data while broadcasting their holdings to a combined catalog; (4) Validation of ground-motion simulations applies to the entire workflow for simulating earthquake ground-motions, including the rupture model, seismic velocity model, and seismic wave propagation software; (5) Metrics to evaluate the validation are application dependent; more research is needed to tie structural response characteristics to ground-motion characteristics; and (6) Validation results should provide a clear, transparent, quantitative assessment of the simulated ground motions.

The BELSHAKE project aims to compile a database of ground motion in Belgium and to develop the capacity to model earthquake ground motion based on that. This database contributes to existing databases by increasing the coverage of low-seismicity regions. The current BELSHAKE database contains ~7000 records from 362 natural and induced earthquakes in Belgium and adjacent areas since 1985 with $M_L \geq 2$. It includes records from broadband, accelerometric, and short-period sensors operated by the Royal Observatory of Belgium. For each event, the relevant source parameters and station metadata are extracted from the ROB database, event-station metadata computed and waveforms capturing the complete event downloaded. The waveform library is structured in folders corresponding to each event, containing one file for each station. The metadata and ground-motion parameters are collected in a relational database. A dedicated python library provides a programming interface with the database and waveform archive, allowing reading and writing of metadata, and streamlining data import. All records have been visually checked to correct or eliminate problematic waveforms such as low signal-to-noise ratio, timing problems, disturbances, clipping, missing or incomplete phase windows, interruptions, and the presence of foreshocks or aftershocks. We use a combination of two windowing procedures, one to define P, S and coda windows, and the other to define noise windows. We are currently implementing a semi-automatic workflow to process the waveforms in a uniform way, which will allow to determine ground-motion parameters following international standards. In this contribution, we discuss the database and processing steps in more detail.

Moment-Magnitude Definition for Pan-European Shallow Crustal Earthquakes: Impact on Fourier Ground-Motion Variability

DOI: 10.57757/IUGG23-4296 - LINK

Aurore Laurendeau[1], Sreeram Reddy Kotha[2]

In a probabilistic seismic hazard assessment (PSHA) the estimated likelihood of rare/large ground-motions is controlled by the aleatory variability of the Ground-Motion Model (GMM). This variability is partly from the poor modelling of earthquake physics, and partly from the poor quality of GMM parameters. Here, we investigate the impact of the definition of moment magnitude (M_W) on GMM variability. Indeed, M_W can either be estimated directly from the moment-tensor inversion or deduced from other magnitude scales. However, for the same event, even the moment-tensor based M_W estimates provided by different agencies often differ – due to differences in computation methods, inverted data, and network configuration. Various strategies have been proposed to define a unique M_W value for each earthquake. In this study, we developed Fourier Spectrum GMMs using the pan-European Engineering Strong Motion database using two disctinct strategies to define M_W: (1) the EMEC approach (ranking of the M_W sources) preferring M_W from event-specific studies, and (2) the IRSN approach (ranking + unification) in which all M_W values are unified with those from the Global and Regional Centroïd Moment Tensor catalogs. We observe that the IRSN unified M_W achieves a 18% smaller between-event variability at low frequencies (e.g. 0.3Hz) compared to EMEC M_W. Such reduction in GMM variability makes a strong case for the use of M_W unification approaches in GMMs and in earthquake catalogs – the two blocks of PSHA.

Reducing the standard deviation of ground motion models (GMMs) is a challenge that has engaged the seismic hazard scientific community for many years with results that unfortunately do not match the dedicated efforts. The work of the last few years, allowing the processing of an ever-increasing amount of data with machine learning approaches, has allowed great progress towards the reduction of these uncertainties, nevertheless, the high frequency uncertainty remains large, especially for GMMs developed in the Fourier domain.

While these machine learning approaches are particularly promising, it is nevertheless necessary for the seismologist to provide them with the relevant parameters to test. In this work, we inventory a set of phenomena that disturb high frequency signals and that are not or rarely taken into account. We present a synthesis of recent results on different phenomena: small-scale soil-structure interaction generated by slabs or pillars often used to couple seismometers and accelerometers, depth effect, small-scale topography effect, seasonal variations. We discuss the interest of a better documentation of the installation conditions within the metadata associated to seismic motion databases.

The kappa (κ) parameter represents the rate of high-frequency decay of recorded earthquake ground-motion spectra with respect to a theoretical source model. Its value at zero distance, κ_0, is usually used to isolate the site component of decay from the path-related attenuation. κ_0 has significant implications in ground motion simulations, adjusting ground motion models to different geological conditions, and site response analyses. κ measurements from regional seismograms at various site-to-source distances are often used to estimate the site-specific, zero-distance value of κ_0 through regression with distance. When combining several stations, there are two ways to do this, which we call here 'fixed-slope' and 'free-slope' methods. The 'fixed-slope' method enforces a common slope (i.e., distance dependence function) for a given region, as that is strongly related to the regional path attenuation characteristics (e.g., quality factor), and then allows for individual estimates (zero-distance intercepts) per station. In contrast, the 'free-slope' method allows for a station-specific intercept (κ_0) as well as slope. This study compares the two methods, using Turkey and California as study regions, and discusses the potential problems associated with both, such as the effects of variation in station density and number of records at each station. We propose using mixed effects regression as a way to overcome some of the limitations of the fixed- and free-slope methods, and to achieve reductions in the variability and bias of estimated κ_0.

The computation of time series for hard-rock site conditions, either as input motion for site response calculations or for applications to installations constructed on this site type, is a crucial step for seismic hazard assessment. The current state-of-the-art is to apply physics-based corrections to surface motions to eliminate the influence of site effects for retrieving the underlying bedrock motion. Here we evaluate the application of the generalized inversion method (GIT) for deconvolving surface recordings to obtain hard-rock time series at the amplification-free seismic bedrock. The method includes an event-specific phase scaling approach on the surface recordings that takes changes in the signal duration between the surface and the seismic bedrock into account.

We choose a total of 90 KiK-net surface-downhole sites for validation which do not have a significant velocity contrast below the downhole sensors and with the latter being located at sufficient depth so that they are not significantly impaired by downgoing waves. By comparing the empirical predictions from surface recordings with time series that have been recorded at the downhole sensors, we assess the accuracy of the predictions. In contrast to empirical and one-dimensional modelling approaches, which significantly overestimate the level of hard-rock ground motion for frequencies greater than a few Hz, we find quite high correlations and small variations in both spectral shape and amplitude over the entire frequency range. This approach delivers a data set that facilitates the development of reference ground-motion models.

Toward a regionalized ground motion model for shaking scenarios in Italy

DOI: 10.57757/IUGG23-4070 - LINK

[1]Instituto Nazionale di Geofisica e Vulcanologia, Milano Section, Milano, Italy

Several studies, conducted over the last 20 years, have shown that ground motion in Italy is characterized by a strong regional variability and, in particular, tectonic and geological factors play key roles in the definition of the observed differences. In the early 2000s, several researches (Castro et al. 1999, Malagnini et al., 2000; 2002) were focused on conducting systematic studies of the regionalization in Italy using local dataset of small magnitude recordings of the seismic sequences that occurred in Italy in the early instrumental epoch.

Recently, the availability of a large number of records from moderate-to-strong earthquakes on the entire Italian territory allowed us to review previous results, with the final aim of producing a new generation of Ground Motion Models (GMM) models for the calibration of shaking scenarios. In this work, the analysis of the residuals (logarithm differences between observations and GMM predictions) was exploited to describe the regional differences in terms of source and path effects across the country (Brunelli et al. 2023), confirming the results of the previous studies conducted in Italy. Based on these results, we developed a regionalised model for Italy, using an approach similar to that of Kotha et al. (2020) for source effects, and a zoneless approach for propagation effects. We also improved the near-source predictions, integrating the dataset with records from the NESS database (https://ness.mi.ingv.it/), and through the introduction of the explicit dependence on focal depth.

S09c - Earthquake Ground Motion and Seismic Hazard

Non-ergodic ground-motion model for path effects due to 3-D velocity structure

DOI: 10.57757/IUGG23-4498 - LINK

Maxime Lacour[1], *Karen Sung*[1], *Norman Abrahamson*[1]
[1]*University of California- Berkeley, Civil and Environmental Engineering, Berkeley, USA*

Current non-ergodic ground-motion models for path effects only capture the effects due to anelastic attenuation (δP2P_Q); however, at longer periods (T >1s), the majority of path effects is due to the 3D velocity structure. Using a Gaussian processes (GP) regression, Sung et al. (2023) found systematic path effects for T=3 sec spectral acceleration due to the 3D velocity of up to 0.5 natural log units.For modeling non-ergodic path terms using GP, a key issue is how to measure the difference between two ray paths for input into Gaussian process models. Sung et al. (2023) parameterized the path differences by the vector sum of the distance between the two source locations and the distance between two the site locations. However, this metric does not capture the main differences between ray paths pairs. We develop a new metric for measuring ray paths differences based on difference in azimuth, rupture distance, and site locations. This metric has a better physical basis, giving us more confidence in application to scenarios outside the range of empirical data. Compared to non-ergodic ground-motion models that do not include the path effect due to the 3D velocity structure, the aleatory variability is reduced from about 0.5 to 0.4 ln units. Additionally, we combine our model with efficient numerical methods (SKIP) that can accommodate large datasets with 100,000 of ground motions. Using SKIP, we can condition forward predictions of path effects at thousands of new source-site locations within a minute using traditional laptop computers with standard memory.

In current approaches for developing non-ergodic ground-motion models (GMMs), the non-ergodic path effect is through the cell-specific linear-distance scaling (Dawood & Rodriguez-Marek, 2010) that mimics the effects from a 2-D Q structure, but the significant Q effects on the ground-motion amplitudes are mainly limited to short-period ground motion at large distances. The path effects due to 3-D velocity structures are not captured by the cell-specific distance scaling approach. In this study, we adopt the new methodology from Sung et al. (2023) and Lacour et al. (2023) to estimate the spatial distribution of non-ergodic path effects using residuals from the Morikawa and Fujiwara (2013) GMM to model path effects related to 3-D velocity structures using the varying coefficient model (VCM). The epistemic uncertainty of the non-ergodic term is given by the posterior distribution in the VCM, which is small in regions with data and large in regions with spare data. The dataset is from the dense strong-motion observation networks in Japan (e.g., K-NET and KiK-net). The standard deviation of non-ergodic path terms is approximately 0.15 LN units when only considering 2-D Q path terms, whereas the standard deviation is much larger (about 0.30-0.35 LN units) if both Q and 3-D velocity structure non-ergodic terms are included. Fully non-ergodic models lead to an aleatory variance of residuals for GMMs that is reduced by 40-70% compared to ergodic GMMs. The combined effect of the shift in the median with the reduced aleatory variability can significantly affect seismic hazard calculations for the Japan region.

The ESHM20 ground-motion model (GMM) is developed using the pan-European Engineering Strong-Motion (ESM) dataset, and is applicable for earthquakes of 3 < Mw ≤ 7.4. This model accounts for regional variability of path and source effects via regionally adjustable anelastic attenuation and offset components, respectively, in its functional form. In low-moderate seismicity regions, such as France and Germany, events with lower Mws and paths of slower crustal attenuation could be of interest in seismic hazard assessments. For this purpose, we have performed a Bayesian update of the ESHM20 GMM using the French RESIF-RAP dataset containing ground-motion data from 2 < Mw ≤ 5.5 earthquakes. This procedure extends the GMM's applicability to smaller earthquakes and apparently slower attenuating regions of France. The updated GMM, however, predicts larger median ground-motions with a larger aleatory variability – which together would aggravate the hazard estimates in France (compared to ESHM20). Here, we present our approach, outcome, and understanding of these systemic changes in GMM coefficients and predictions following the Bayesian update. Revision of attenuation regionalisation model of France and moment-magnitude estimates of French earthquakes are in process, and may help evaluate the procedure. We anticipate that such checks and refinements would become necessary before adapting the ESHM20 GMM in seismic hazard assessments of other low-moderate seismicity regions of pan-Europe.

Large earthquakes are among the most destructive natural phenomena. Fast estimation of the ground shaking intensities is a crucial task for hazard assessment after a large earthquake occurs.

The Machine Learning Estimator for Ground Shaking maps (MLESmap) is proposed as a novel methodology that exploits the predictive power of Machine-Learning (ML) algorithms to estimate ground acceleration values a few seconds after a large earthquake occurs. The inferred information can produce shaking maps of the ground providing quasi-real-time affectation information to help us explore uncertainties quickly and reliably.

MLESmap utilizes physics-based seismic scenarios to feed the algorithms.

Moreover, as our synthetic catalogs will never contain all possible future events, we aim at having models capable of successfully interpolating non-trained events accurately.

To set up the MLESmap technology, we used simulated ground motions from CyberShake Study 15.4, a physics-based Probabilistic Seismic Hazard model for Southern California at 1 Hz. In particular, this CyberShake study is focused on the Los Angeles basin region. Los Angeles sits on top of large sedimentary basins. These soft foundations can amplify the amount of damaging shaking these cities experience during an earthquake. Our approach (i.e. simulate, train, deploy) can help produce the next generation of ground shake maps, capturing physical information from wave propagation (directivity, topography, site effects) at the velocity of simple empirical GMPEs. In this work, we will present the MLESmap workflow and its application in the Los Angeles region as a use case.

Despite the continuous increase in the number of ground motion stations and the amount of recorded ground motion data in recent years, we still face observational gaps in earthquake records for large-magnitude and small-distance events. Physics-based simulations of recent earthquakes have been capable of reproducing the ground shaking recorded by near-field accelerometric stations but also predicting ground motions in other locations. In this work, we first develop a hybrid database combining calibrated ground shaking simulations and real-world observed ground motions. This hybrid dataset consists of 83864 real and near-source events records (from 1200 events) and physics-based simulations (from 20 events).

In the second step, a generative model is trained based on this hybrid dataset. The model simulates nonstationary ground-shaking recordings. It combines a conditional generative adversarial network to predict the amplitude part of the time-frequency representation (TFR) of ground-motion recordings and a phase retrieval method. This model simulates the amplitude and frequency contents of ground-motion data in the TFR as a function of earthquake moment magnitude, source-to-site distance, and a random vector called latent space. After generating the phaseless amplitude of the TFR, the phase of the TFR is estimated by minimizing all differences between the observed and reconstructed spectrograms.

The simulated accelerograms produced by the proposed method show similar characteristics to conventional ground-motion models in terms of their mean values and standard deviations for peak ground accelerations and Fourier amplitude spectral values. We finallly compare the generative model predictions with the data of the 2023 Turkey-Syria seismic sequence.

Korea is in a stable continental region (SCR), where large earthquakes do not occur frequently. However, Korea has suffered from infrequent yet damaging earthquakes in the past. Among the instrumented earthquakes, the largest was the 2016 M5.5 Gyeongju earthquake. The 2017 M5.4 Pohang earthquake was the second largest; but it was the most damaging one, due to its proximity to urban areas, shallow hypocentral depth of 5km, and the amplification of ground motions due to the dynamic response of the Pohang basin.

Being in an SCR with a short history of instrumentation, South Korea has not collected sufficient instrumental data for data-driven ground motion models. To address this limitation, we implemented the hybrid ground motion simulation method of Graves and Pitarka (2010, 2015) to simulate earthquakes in South Korea, accounting for the crustal velocity structure and seismological characteristics of the Korean peninsula. We implemented a three-dimensional velocity model by Kim et al. (2017) and a one-dimensional velocity model by Kim et al. (2011). To model the earthquake source, we implemented Graves and Pitarka's rupture generator with a magnitude-area scaling relationship developed for SCR by Leonard (2014).

Using the implemented simulation platform, we simulated the 2016 M5.5 Gyeongju earthquake and the 2017 M5.4 Pohang earthquake and compared results with recorded ground accelerations at strong motion stations. Our study demonstrated the potential of physics-based ground motion simulation in South Korea, but it also suggested the need for further validation of the simulation method for earthquake engineering applications in South Korea.

Ground motion variability is often left aside in the validation framework of physics-based ground motion simulation. In this study, we evaluate how the distributions of model parameters control ground-motion variability, and whether the simulations are consistent with the empirical ground-motion model in terms of both median and standard deviation.

Our analyses consist of two main steps. First, we establish a database that contains a series of simulated ground motions from a stochastic catalog (i.e., a set of earthquake scenarios consistent with the source model developed recently for the German Probabilistic Seismic Hazard map) that could occur in the Rhine Graben area. Ground-motion simulations are performed adopting the simulation method of Graves and Pitarka (2010, 2015) implemented in the Southern California Earthquake Center (SCEC) broadband platform (BBP), which we have tailored for use in the Rhine Graben. In a second step, we ablaze ground motion variability by deconstructing it into its between-event and within-event components

The analyses are performed through six different modeling assumptions reflecting various choices of stress parameters, velocity structure, site effects, and source parameters. The residual analysis through random-effect splitting captures the main components of the variability of resulting simulations. The between-event variability, for instance, is mainly controlled by stress parameter distribution at short-period and by the source parameters and slip distributions at long-period. If these distributions are well-chosen the simulations reproduce the variability of empirical models. Our results however highlight that simulations based on one-dimensional velocity models cannot reproduce the observed within-event (path-to-path) variability.

S-net is a large-scale seafloor network in the Japan Trench area, consisting of inline-type 150 observatories with seismometers and pressure gauges. We analyzed the strong-motion data recorded at the S-net sites from earthquakes with magnitudes between about 4 and 7 with focal depths lower than 70 km. To minimize the effects of nonlinear site response and weak-couplings between the seabed and sensor houses, recordings with vector peak accelerations lower than 50 gals were selected. More than 6,000 recordings with high S/N ratios from about 600 earthquakes were used. Using the spectral inversion technique, we obtained some fundamental properties of the earthquake source spectra, path attenuation, and site factors from the horizontal-component S-wave portions of the recordings. The source spectra followed the ω^{-2} source model generally well, and the estimated magnitudes were similar to the catalog magnitudes. The stress drops increased systematically with the focal depths, and the stress-drop values differed between the earthquake types. The path-averaged quality factors were somewhat larger than those in the past studies. The peak site frequencies ranged between about 0.2 and 10 Hz, while the peak amplification factors were between about 10 and 50. A moderate regionality was also observed in the distribution of site amplification factors. At some stations which were not buried, spurious site spectra were recognized. We discuss the above results and their implication in the presentation.

[2]Swiss Seismological Service SED at ETH Zurich, Earthquake Hazard & Risk Assessment, Zurich, Switzerland

Earthquake ground-shaking recorded at the surface is influenced by local site conditions. At stiff sites and for small ground motions, this soil response behaves linearly, at soft sites and for larger ground motions, however, the site effects starts to become nonlinear. The complex phenomena of nonlinear site-amplification remain a challenge in seismic hazard assessment, mainly because there are still few recorded observations. In this study we use the comprehensive Japanese KiK-net network to systematically capture the empirical effects of nonlinear soil response. Here the nonlinear soil-response is measured in the stations' surface-to-borehole ratios as the change in amplitude and shift in frequency between strong-motion events and the linear site-response. We then derive station-specific parameters for nonlinearity using the measurements for each station and explore the correlation between the station nonlinearity and a selection of geotechnical and geological parameters. Our results show that finding site parameters suitable for predicting nonlinear site-effects remain challenging as the nonlinear soil-behavior is largely site specific.

Nonlinear site response, which occurs when the soil strength is affected by the amplitude of the incident wavefield, is of primary interest in seismic risk assessment due to its effects in strong ground motion prediction. Nonlinear soil behavior is widely been studied mainly using laboratory experiments. However, it is still difficult to detect nonlinear site response in seismic records, in particular, in the absence of a nearby reference site. In this article, we introduce the use of the predominant frequency to characterize nonlinear effects in earthquake data recorded in Japan (KiK-net), California (DesignSafe) and Italy (ESM) regions. The principle follows the fact that nonlinear effects produce a shift of the frequency content in acceleration time histories. Traditionally, this is expected at the fundamental resonance. However, we show that the predominant frequency is more sensitive due to its higher frequency value. Moreover, the predominant frequency indicates the frequency band where a site is more responsive to the incident wavefield, which may further contribute to a higher seismic hazard. Using this method to study multiple events in seismic stations help deriving the spatial distribution of possible nonlinear effects inside a given seismic network. These observations are expected to provide much more relevance to studies of earthquake engineering and hazard analysis in the future.

Seismic wave amplification in the foreland basin of the Himalaya from CIGN network data

DOI: 10.57757/IUGG23-0051 - LINK

Rajender Chadha[1]
[1]*Raja Ramanna Fellow, CSIR-National Geophysical Research Institute, Hyderabad, India*

In the sediment filled foreland basin of the Himalaya data from CIGN network was analyzed to estimate seismic wave amplification using Standard Spectral Ratios (SSR) and Ratio of Source Spectrum (RSS) methods. The recordings of three largest aftershocks of M_w 7.2, 6.7 and 6.7 of the 2015 Gorkha earthquake at soft sites in the Indo Gangetic Plains (IGP) are used. Our analysis show that fundamental frequency (f_0) of the sites increase from 0.12 Hz near the foothills of Himalaya to 2.0 Hz at the southern edge of the basin and the amplification reaches about 10. But at several sites the (f_0) if difficult to select and amplification of ~5 is broadband in 0.12-0.17 Hz range. At only four sites a comparison of both the methods was possible where spectral amplifications showed both resemblance and significant differences. These differences arise because the reference spectrum in the RSS method is the geometric mean source spectrum calculated from data at many hard sites. The reference spectrum in the SSR technique, on the other hand, is obtained from the recording at a hard site located in the vicinity of the target site. Therefore, SSR method is preferable if the input motion at the target soft site is compared to a nearby hard site, otherwise in the absence of a hard site in near vicinity of a target site RSS method is more suitable as in this method ground motion can only be specified at a generic hard site that is often the case

While probabilistic seismic hazard assessment (PSHA) is well-established as the principal methodology for characterizing earthquake shaking at site or across region, quantitative validation (or even simply comparison) of hazard models against recorded ground motions remains challenging. Focusing on recent models from France and Germany, alongside the 2020 European Seismic Hazard Model, we exploit the vast database of weak and strong motion observations provided by the European Integrated Data Archive (EIDA) to compare predicted and observed exceedance of shaking in regions of low-to-moderate seismicity.

EIDA vastly expands the number of records and stations available for model-to-data comparison, especially in regions of low seismicity. However, the database of usable accelerations from these stations is not a complete archive of the shaking that has occurred, even at sites in longer operation. We overcome incompleteness using observed seismicity to predict expected distributions of shaking at times and locations where gaps exist, calibrated according to inferences from the distributions of recorded motions.

With this joint observed-inferred archive we explore the opportunities for quantitative model-to-data comparison using stations from France, Germany and Italy. The analysis begins with an overview of established methods for quantitative comparison before delving further to assess the influence of non-ergodic PSHA. We also aim to relax the constraint of independence between observation sites by introducing spatial correlation into both the hazard calculation and testing metrics. This effort highlights how systematic seismic data archiving can be vital to help demonstrate the relative suitability of hazard models for application in a region.

While probabilistic seismic hazard assessment (PSHA) is well-established as the principal methodology for characterizing earthquake shaking at site or across region, quantitative validation (or even simply comparison) of hazard models against recorded ground motions remains challenging. Focusing on recent models from France and Germany, alongside the 2020 European Seismic Hazard Model, we exploit the vast database of weak and strong motion observations provided by the European Integrated Data Archive (EIDA) to compare predicted and observed exceedance of shaking in regions of low-to-moderate seismicity.

EIDA vastly expands the number of records and stations available for model-to-data comparison, especially in regions of low seismicity. However, the database of usable accelerations from these stations is not a complete archive of the shaking that has occurred, even at sites in longer operation. We overcome incompleteness using observed seismicity to

predict expected distributions of shaking at times and locations where gaps exist, calibrated according to inferences from the distributions of recorded motions.

With this joint observed-inferred archive we explore the opportunities for quantitative model-to-data comparison using stations from France, Germany and Italy. The analysis begins with an overview of established methods for quantitative comparison before delving further to assess the influence of non-ergodic PSHA. We also aim to relax the constraint of independence between observation sites by introducing spatial correlation into both the hazard calculation and testing metrics. This effort highlights how systematic seismic data archiving can be vital to help demonstrate the relative suitability of hazard models for application in a region.

S09e - Earthquake Ground Motion and Seismic Hazard

Framework for Deterministic Earthquake Ground Motion Maps in Germany using Machine Learning

DOI: 10.57757/IUGG23-3261 - LINK

Andreas Steinberg[1], *Manuel Hobiger*[1], *Peter Gaebler*[1], *Hannes Vasurya-Bathke*[2], *Aida Azari Sisi*[1]

The surface effects of an earthquake are typically evaluated using ground motion maps. These ground motion maps are often based on empirical ground motion prediction equations (GMPEs), which however largely neglect source physics and, therefore, the radiation pattern of seismic energy. We present a framework for evaluating seismicity in Germany in which we calculate physics-based deterministic ground motion maps based on forward modeling of full seismic waveforms for different sources; isotropic sources for smaller earthquakes and full seismic moment tensors and finite rectangular sources for larger earthquakes.

We use 1-D and 2-D Green’s function databases to rapidly consider a large number of statistically significant scenarios, including variations in Earth structure models, site effects, and source parameters. Basin effects are explicitly modelled. We apply machine learning to generate the ground motion maps even faster and incrementally improve the accuracy of our results with each earthquake based on a comparison between expected and measured peak ground velocity.

To evaluate the accuracy of our approach, we compare the ground motion predictions from our waveform simulations to those obtained from regionalized probabilistic ground motion prediction equations (GMPEs) for a variety of synthetic cases. We quantify the differences between the two approaches. We carry out specific tests for an area in southern Germany with induced earthquakes around the two geothermal power plants of Insheim and Landau in the Upper Rhine Graben. We use locally measured passive measured velocity profiles to incorporate site effects in the form of $V_{S30.}$

S09e - Earthquake Ground Motion and Seismic Hazard

Seismicity, seismotectonics, and seismic hazard assessment for Western Mexico

DOI: 10.57757/IUGG23-0800 - LINK

Rashad Sawires[1], José A. Peláez[2], Miguel A. Santoyo[3]
[1]University of Assiut, Geology, Assiut, Egypt
[2]University of Jaén, Physics, Jaén, Spain
[3]National Autonomous University of Mexico, Institute of Geophysics, Mexico City, Mexico

Western Mexico is characterized by a complex seismotectonic setting, exposing the interaction among four tectonic plates. This region suffered several damaging earthquakes in the past, and subduction earthquakes occurring along the Mexican subduction zone have been also strongly felt. Consequently, this area is highly exposed to future earthquakes that may cause significant damage.

Herein, we assessed the seismic hazard in terms of PGA and SA values, for a 10% and 5% probability of exceedance in 50 years, for B, B/C and C NEHRP soil classes. To conduct such assessment, an updated earthquake catalog, as well as a focal mechanism database, were compiled for this work. In addition, two alternative seismic source models were considered in the assessment, within a logic tree scheme, each model covering the potential seismic sources in and around the studied region: shallow crustal, subduction interplate and intraplate earthquakes. The designed logic tree has also included other parameters: the Gutenberg-Richter *b*-value, the maximum expected magnitude, and the ground-motion attenuation models for the subduction seismic sources.

Concerning the most significant results, seismic hazard on the southwestern coast (parallel to the Middle America Trench) presents the highest values. For instance, the city of Lázaro Cárdenas displays mean PGA and SA (0.2 s) pair values, for a 475-year return period, equal to 0.73 and 1.60 g, 0.83 and 1.90 g, and 0.89 and 2.05 g, for B, B/C, and C site conditions, respectively. It is worth noting that the September 19 (Mw 7.7) and the September 22, 2022 (Mw 6.9) Michoacán earthquakes occurred where the highest hazard values have been obtained. Results, together with the occurrence of such large events, suggest that this assessment is accurately foreseeing the seismic hazard for one of the most active regions in Mexico.

No in-depth seismic hazard (SH) study for West Africa (WA) has ever been conducted, as the regional earthquake catalogues are incomplete. Such lack of comprehensive SH study has negatively affected planning and development of critical infrastructure and disaster risk management in WA. This study aims to bridge the knowledge gap by applying modern techniques to updating the existing catalogues and assessing the seismic hazards for the region. We updated the current catalogue for WA from International Seismological Centre, publications and data from seismic stations in WA. Different studies considered the seismotectonic setting of WA as stable continental crust and a region of shallow crustal seismicity. We investigated both schools of thought and compared results. For each scenario, three different ground-motion models (GMMs) were combined to produce each hazard map using logic tree formalism with equal weights. WA was divided into five source zones for the computation of earthquake recurrence parameters and for the entire WA region. Computed Gutenberg–Richter b-value, activity rates(λ), and regional maximum possible magnitudes(mmax) for the zones ranged from 0.84 to 1.0, 0.3–2.1, and 5.2–7.0, respectively. Calculated b-value, λ, mmax for the region were 0.77, 4.1, and 7.2. The estimated b-value (0.77) falls within generally accepted range for tectonic seismicity. SH predicted by GMMs for stable continental areas was higher than that predicted for shallow crustal seismicity. Therefore, our results confirmed that WA is characterized by a stable continental crust. The highest hazard levels were observed in parts of Ghana, Togo, Cameroon etc., ranging between 0.02g and 0.03g.

The Iranian Plateau is one of the most seismic regions in the world and contains several seismotectonic provinces. Azerbaijan is one of these provinces with high seismogenic potential and has experienced many earthquakes to date. Khoy M_w 5.9, [Ma1] 2023, and Ahar-Varzaghan M_w 6.4 and 6.3, 2012 double earthquakes are the most recent. Their Peak Ground Accelerations (PGA) are 0.29g, 0.43g, and 0.53g, respectively. The PGA value for Khoy is 0.35g and 0.30g for Ahar-Varzaghan, for the 10% Probability of Exceedance (PoE) in 50 years According to the Iranian design code (Standard 2800), which has a good agreement with the Khoy earthquake while it has an underestimated amount for Ahar-Varzaghan. The Iranian design code was obtained from traditional Probabilistic Seismic Hazard Analysis (PSHA) and the aim of this study is to evaluate the sufficiency of the current code represented PGAs for the case study of Azerbaijan province. For this purpose, the code amounts are compared with the results of Deformation Based Hazard Model of the Iranian Plateau (DBHM). Traditional PSHA uses the earthquakes catalogs whereas DBHM utilizes the latest Iranian combined data sets (i.e., seismicity, geodetic, and Geological data). The PGA values derived from DBHM for 10% and 2% PoE in 50 years are 0.5g and 0.82g for Khoy, and 0.38g and 0.65g for Ahar-Varzaghan, respectively, which are higher than the current design code amounts. The results show this area is prone to earthquakes with long recurrence times and higher PGA values, which not consider in the Iranian design code.

This presentation describes the activities provided by the ARISTOTLE (All Risk Integrated System TOwards Transboundary hoListic Early warning, http://aristotle.ingv.it) consortium to the Emergency Response Coordination Centre (ERCC) of the European Civil Protection and Humanitarian Aid Operations Directorate (DG ECHO) for the realization of the European Natural Hazards Scientific Partnership (ENHSP). The service provided by the ARISTOTLE consortium responds to the needs of the ERCC to coordinate very rapidly the delivery of assistance to disaster-stricken countries within the EU Civil Protection Mechanism both within and outside the Union. It features a 7/24H operational system capable of assembling within a few hours relevant information on natural events that have just occurred (e.g., geo unforecastable hazards), are ongoing or that are developing (e.g., meteorological forecastable hazards). ARISTOTLE harnesses operational expertise from nationally mandated scientific institutions and agencies across Europe to provide multi-hazard, rapid assessment on natural disasters related to volcanoes, earthquakes, tsunami, severe weather, flooding and forest fires. Each hazard brings together experts to deliver a "collective analysis" which is then fed into the partnership multi-hazard discussions to provide the sought assessment. ARISTOTLE includes partner institutions from EU and non-EU Countries and from European international organizations operating in the Meteorological and Geophysical domains. They constitute the European Natural Hazards Scientific Partnership, ENHSP. This presentation describes the organization of the service in its various modes (e.g., emergency activation, routine weekly assessment, ...), its challenges and achievements, and the interaction model developed between the scientists and the ERCC disaster risk managers.

[4]University of Oslo, Department of Geosciences, Oslo, Norway

The Alna district in Oslo, Norway is a high profile (residential, commercial and industrial) area exposed to multiple hazards, in particular to quick clay landslides. Quick clay is a marine clay sediment where the salt that binds the clay together has been washed away over time. Thus, the structure becomes unstable, and increased point loads or erosion of waterways can trigger landslides. In case of a landslide, the quick clay becomes liquefied, and major material damage and danger to life can occur. To support the authorities in selecting the optimal risk-mitigation action, this study develops the multi-criteria decision-making methodology, which accounts for the stakeholders' preferences. The Decision Support System framework includes three key steps: 1) Identify criteria for assessing the impacts of multi-hazard scenario; 2) Identify possible measures that can reduce the impacts; 3) Give objective/subjective weighting of the identified criteria, reflecting the stakeholders' preferences. The framework is demonstrated in a multi-hazard scenario (i.e., quick clay, flood and fire) of interest to the Oslo stakeholders. The impact of the considered scenario is evaluated in terms of five categories (i.e., life and health, nature and environment, economy, societal stability, and governance and control) and 13 single criteria. Through workshops with stakeholders, possible alternatives as well as the respective cost and mitigated impacts were estimated, and stakeholders' preferences were collected. The optimal action under given circumstances is identified quantitatively and is highly dependent on stakeholders' preferences. Further details of the impact analysis are needed to understand the risk landscape of different alternatives.

An updated exposure model for the City of Johannesburg, South Africa

DOI: 10.57757/IUGG23-2714 - LINK

Tebogo Pule[1], Vunganai Midzi[1], Brassnavy Manzunzu[2]
[1]Council for Geoscience, Infrastructure and Land use, Pretoria, South Africa
[2]National University of Science and Technology, University, Bulawayo, Zimbabwe

Johannesburg city is one of the most advanced commercial cities in Africa and the engine room of the South African and regional economy. It is a city with world-class infrastructure in the fields of telecommunications, transportation, water and power, and with globally-competitive health care and educational facilities. However, the city is also one of contrasts, home to both the wealthy and poor, residents and refugees, global corporations and emerging enterprises. Though, several moderate to large earthquakes have occurred throughout South Africa, yet few comprehensive exposure models exist for the country. The high population growth and rapid pace of urbanization within the City of Johannesburg (CoJ) entails a significant potential for increased economic and human losses in the event of a damaging earthquake. This study introduces a new exposure model using national datasets with a uniform approach across the municipality. The exposure model was derived with ward level statistics. This refined spatial resolution allows the model to reflect a population distribution within each ward and thereby better characterize the potential risk to earthquakes and allow identification of disaster risk hotspots. The results indicate the current concentrations of building stock in CoJ. This study provides an updated exposure model towards the probabilistic seismic risk assessment for the CoJ which involves the estimation of the probability of damage and losses resulting from potential future earthquakes. This damage and loss might occur to buildings, infrastructure, people or even the environment. The exposure model in this study covers the population, residential, commercial and industrial buildings.

Digital platform to assess risk to natural hazards in Mexico city, Mexico

DOI: 10.57757/IUGG23-0313 - LINK

David A. Novelo Casanova[1], *Gerardo Suarez*[1]
[1]*Instituto de Geofisica- Universidad Nacional Autonoma de México, Sismologia, Ciudad de Mexico, Mexico*

To build disaster resilience, the National Autonomous University of Mexico and the Mexico City's Secretariat of Education, Science, Technology, and Innovation, supported a project to develop a digital platform to assess risk to natural hazards in Mexico City. This platform is based on a Geographical Information System (GIS) and its main purpose is to identify the associated risk to the following natural hazards: earthquakes, volcanic eruptions, floods, mass movement processes, forest fires, and land subsidence. Besides characterizing the local hazards for different return periods, social vulnerability was determined using thirteen indicators from data of the 2010 Mexican Census of Population and Housing. We recognize social vulnerability as those social conditions that make a community susceptible to be damaged by a hazard and it is an inherent characteristic of society. Population and critical facilities (hospitals, schools, telecommunications, etc.) were considered as exposed elements. "Social risk" is expressed using a qualitative spatial multi-criteria evaluation technique by superimposing the calculated GIS's raster of the social vulnerability over individual hazard rasters. The resulting values measure the "*likelihood of risk*". Both, vulnerability and hazard, were classified into five categories with values from 1 to 5, where 1 is low and 5 very high. As a result, we obtain a meshing array that reflects the likelihood of social risk for specific hazards. The main purpose of this tool is to provide local authorities elements for land use regulations and urban development by strengthening their prevention and mitigation actions.

S10a - Multi-Hazard Risk Assessment

Seismic loss assessment sensitivity study based on building-specific exposure models

DOI: 10.57757/IUGG23-4542 - LINK

Tara Evaz Zadeh[1], *Laurens Jozef Nicolaas Oostwegel*[1], *Lars Lingner*[1], *Simantini Shinde*[1], *Fabrice Cotton*[1], *Danijel Schorlemmer*[1]
[1]*GFZ-Potsdam, Section of Seismic Hazard and Risk Dynamics- Department of Geophysics-, Potsdam, Germany*

Seismic exposure models are the most uncertain component in the chain of seismic loss assessments and aim to describe the built environment with information about buildings, their types and the population in them. Aggregated Exposure Models (AEM) are the most common type of exposure models, describing the built-environment in aggregates over administrative regions in which neither location nor type of individual buildings is precisely described. By combining AEMs with building parameters available from OpenStreetMap (OSM), an *open geographic database updated by volunteers*, we can improve the exposure model by providing location, occupancy type and also numbers of stories for many individual buildings, resulting potentially in a more precise characterization of buildings.

Because seismic losses highly depend on both the location and type of each building, we explore how these OSM building parameters may alter the distribution of building types and how this can accordingly affect loss assessments. We also aim to understand the impact of each building parameter on describing building types more precisely for different countries in Europe. This impact depends on the the underlying AEMs and the local/national OSM mapping activities. Both vary strongly within Europe, so that the impact on both the exposure model and the loss assessment results are country-dependent. Our preliminary results suggest that the widespread occupancy parameter helps characterizing many buildings while the not so frequent number-of-stories parameter is more capable of deciding the building type ins many countries.

Seismic exposure models are the most uncertain component in the chain of seismic loss assessments and aim to describe the built environment with information about buildings, their types and the population in them. Aggregated Exposure Models (AEM) are the most common type of exposure models, describing the built-environment in aggregates over administrative regions in which neither location nor type of individual buildings is precisely described. By combining AEMs with building parameters available from OpenStreetMap (OSM), an *open geographic database updated by volunteers*, we can improve the exposure model by providing location, occupancy type and also numbers of stories for many individual buildings, resulting potentially in a more precise characterization of buildings.

Because seismic losses highly depend on both the location and type of each building, we explore how these OSM building parameters may alter the distribution of building types and how this can accordingly affect loss assessments. We also aim to understand the impact of each building parameter on describing building types more precisely for different countries in Europe. This

impact depends on the the underlying AEMs and the local/national OSM mapping activities. Both vary strongly within Europe, so that the impact on both the exposure model and the loss assessment results are country-dependent. Our preliminary results suggest that the widespread occupancy parameter helps characterizing many buildings while the not so frequent number-of-stories parameter is more capable of deciding the building type ins many countries.

Propagating uncertainties from tsunami hazard to risk for Coquimbo Bay

DOI: 10.57757/IUGG23-3976 - LINK

Fatemeh Jalayer[1]*, Hossein Ebrahimian*[2]*, Patricio Catalan*[3]

Tsunami hazard and risk analysis are examples of multi-hazard and multi-risk assessments. The procedure for probabilistic tsunami risk analysis (PTRA) involves characterization, quantification, and propagation of uncertainties from sources to the consequences. A forward and modular probabilistic framework for risk assessment, known as the PEER-type approach was originally developed for single-hazard risk assessment. However, given its practical appeal, it has also been adapted to multi-hazard and multi-risk analysis. We focus on the application of this framework for tsunami risk analysis and demonstrate how the uncertainties are going to be propagated from the hazard to the risk level. The advantage of using this approach, compared to fully simulation-based approaches for tsunami risk assessment, is that it can use already-available hazard, fragility, and consequence models. More specifically, the interval of confidence for the hazard curves can be used as a proxy for epistemic uncertainties. The procedure also considers the epistemic uncertainties in the tsunami fragility curves and the consequence functions. We demonstrate how hazard and fragility curves and their confidence intervals, and the loss models (consequence functions) can be integrated to obtain loss curves for certain locations of interest. An application of this procedure is demonstrated for PTRA for Coquimbo Bay in Chile affected by the 2015 Illapel tsunami which was a near-field tsunami generated by a subduction earthquake of 8.3 Mw rupturing a 240 km section of the Nazca–South American plate interface. We consider fragility functions already developed for mixed (masonry and wood) buildings.

In view of the historically devastating earthquakes in Ghana, this study employed regional satellite gravity data to reveal the extension of the crustal network of fractures emanating from the seismically active zone in the Gulf of Guinea and its implications on Coulomb stress transfer of the June 22nd, 1939 Accra earthquake. The Accra earthquake (M=6.5), Ghana is one of the most devastating intra-plate earthquakes in sub-Sahara west African region. In order to carry out the Coulomb stress transfer study, we utilized the Fault Plane Solutions (FPS) obtained from the waveform inversion of Yarwood and Doser (1979), which revealed that the earthquake composed of two events (6.1 Mw and 6.4 Mw). This study resolved the static Coulomb Failure Stress (CFS) change onto the finite fault models of the 6.4 Mw and 6.1 Mw earthquakes and its effect on associated receiver faults. The gravity study revealed swarms of fractures emanating from the gulf of Guinea and connected with the Akwapim and Coastal boundary faults favored the enhanced CFS to generate the 6.1 Mw due to transmission of stress from the seismically

active zones in the Gulf of Guinea (boundary between the African plate and the South-American plate). The 6.4 Mw main shock was explained to correlate with release of seismic energy from the associated secondarily stressed prominent strike-slip (Akwapim) fault and strike-slip (coastal boundary fault). The direction of Coulomb stress transfer and the receiver faults of the 6.4 Mw main event have been mapped for the next big magnitude earthquake preparedness.

Earthquake-Induced Landslide Hazard Assessment of Uttarkashi using Analytical Approach

DOI: 10.57757/IUGG23-4250 - LINK

Raju Sarkar[1], *Ashi Dwivedi*[1]
[1]*Delhi Technological University, Civil Engineering, New Delhi, India*

Earthquake has played a major role in current landslide scenario of Uttarkashi since past few decades. Moreover Uttarkashi lies in the seismically active part of India based on Indian seismic zonation map (zone IV). It has become necessary to determine the earthquake induced landslide hazard with increasing magnitude and area of earthquake. The objective of this study is to prepare an earthquake-induced landslide hazard map using Analytical Hierarchal Process (AHP) and GIS for Uttarkashi, Uttarakhand. Over 65 Earthquake epicenters (ranging from a magnitude of 3.5 to 6.8) along with landslide points in and around the study area have been considered. Further, 12 factors are taken into consideration including tectonic framework, earthquake magnitude distribution, distance to epicenter, fault/focal mechanism, topography along with other landslide factors. Shake maps are used for the peak ground acceleration (PGA) and peak ground velocity (PGV) analysis. The consistency ratio (CR) determined for AHP is 0.075(<0.1), which indicates an acceptable preference matrix for the associated factors. The weights assigned to the above factors are validated using Relative Frequency Ratio method. Earthquake induced landslide susceptibility map is prepared and the zones are classified accordingly. The validation of these maps was accomplished by the area under the curve (AUC) method.

Testing machine learning models for building damage assessment applied to the Italian Database of Observed Damage (DaDO)

DOI: 10.57757/IUGG23-3062 - LINK

Subash Ghimire[1], *Philippe Gueguen*[2]
[1]*ISTerre- Université Grenoble Alpes/CNRS/IRD/Université Gustave Eiffel, ISTerre, Gières, France*
[2]*Université Grenoble Alpes/CNRS/IRD/Université Gustave Eiffel, ISTerre-, Grenoble, France*

Assessing or forecasting seismic damage to buildings is an essential issue for earthquake disaster management. In this framework, we tested six machine learning models on the DaDO database of observed damage from Italian earthquakes to assess their efficacy in characterizing seismic damage. The models included random forest, gradient boosting, and extreme gradient boosting. The input features were all or a subset of the structural features provided by DaDO, as well as macroseismic intensity. Extreme gradient boosting classification performed best, especially when using basic structural features (age, number of storeys, floor area, building height) and grouping damage according to the traffic-light-based system used, for example, during the post-disaster period (green, yellow, and red). The machine learning-based model had similar efficacy to the traditional Risk-UE method. Finally, the importance of structural features varied depending on the level of damage considered.

Responses of a cantilever retaining wall subjected to mainshock-aftershock sequences

DOI: 10.57757/IUGG23-2226 - LINK

Seong Jun Ha[1], *Byungmin Kim*[1]
[1]*Ulsan National Institute of Science and Technology, Urban and Environmental Engineering, Ulsan, Korea Republic of*

A mainshock is typically followed by a train of aftershocks. Aftershocks were as strong as mainshocks in some previous cases, leading to catastrophic seismic damage by sequential excitations. Seismic designs for structures have been carried out so far based on single-ground motion. The seismic design considering earthquake sequences may be required for high seismic regions. In this study, we investigated the responses of a cantilever retaining wall under mainshock-aftershock sequences by performing finite-difference-based numerical simulations. We collect a suite of the mainshock-aftershock sequential ground motions, used as input ground motions, with a wide range of intensities from the KiK-net database, in Japan. Each mainshock-aftershock sequential motion is prepared by paring mainshock and aftershock motions recorded at the same recording station from actual earthquake sequences. It turns out that relative wall displacements developed by the mainshock-aftershock sequential motions can be much larger than those by the single mainshock motions. However, the ratio of the relative wall displacement by the aftershock motions under the sequence to that by the single aftershock motions decreases as the intensity of the aftershock motions increases. In addition, post-mainshock responses depend on the intensity of the mainshock motions. The responses by the weak mainshock motions barely affect the responses by the aftershock motions. The post-mainshock responses are pronounced with the strong mainshock motions.

S10c - Multi-Hazard Risk Assessment

Downward counterfactual analysis as a multi-hazard risk tool

DOI: 10.57757/IUGG23-0167 - LINK

Gordon Woo[1]
[1]*Moodys/RMS, Research, London, United Kingdom*

In the historical record, disasters arising from multi-hazard events are comparatively rare. However, far more common are near-misses, where a disaster tipping-point was narrowly averted. What happened historically, is only one realization of what might have happened. Due to psychological outcome bias, people pay far less attention to near-misses than to actual losses. A downward counterfactual is a psychological term for a thought about the past, where things turned for the worse. Exploration of downward counterfactuals enhances risk awareness and can contribute to risk preparedness. There are no databases of multi-hazard near-misses, but insights can be gained from downward counterfactual analysis.

Downward counterfactual analysis is a generic risk tool, universally applicable to all types of hazard combinations. Consider earthquake fatality risk in California. Since 1950, there have been several hundred earthquake-related deaths in California. This number might have been higher by several orders of magnitude if the Lower San Fernando Dam had been overtopped on 6 February 1971. The dam was badly damaged by the M6.7 San Fernando earthquake, and if the water had been at its maximum height, as it had been the previous year, the valley would have been flooded, with massive downstream consequences. A combination of heavy rain and strong seismic ground motion might have triggered an extreme engineering disaster. This is one of a range of historical examples which will be presented from the accumulating library of multi-hazard near-misses.

Towards Exposure-Centered Multi-Hazard Risk Assessment: A Case Study For The Adriatic

DOI: 10.57757/IUGG23-3253 - LINK

Chiara Scaini[1]*, Hany M. Hassan*[2]*, Antonella Peresan*[1]

Earthquake-induced tsunamis are relatively infrequent in the Adriatic, but their occurrence might cause substantial damages, in particular if no mitigation measures are put in place. Assessing earthquake and tsunami-induced damages and how they interact in time and space is therefore crucial in order to enhance emergency response. Damage assessment procedures are based on the knowledge of location, type and characteristics of exposed assets (namely, the exposure) and their vulnerability. Exposure datasets are commonly developed based on remote sensing products and ancillary data (e.g. census, land use), but they are often developed separately for different hazards. We discuss the role of exposure to support multi-hazard damage assessment procedures for earthquake and tsunami. The proposed approach is demonstrated considering earthquake-induced tsunami scenarios for the Adriatic, modeled based on the available active faults database and historical records. Specifically, we consider scenarios computed for the Albanian coastline and the city of Durres, which experienced a M6.5 earthquake on 26 November 2019 and a related tsunami alert (canceled later on). However, exposed assets include not only buildings and infrastructure, but also population which might dramatically increase during tourist season. We discuss the possibility of complementing exposure datasets with crowdsourced data collected by citizens. This activity would increase citizens' awareness while developing up-to-date multi-hazard exposure datasets. We present the experience of a cooperation project developed between Italy and Albania involving civil protection officers, journalists and university staff, addressing a broad range of stakeholders and supporting the development of future disaster risk reduction strategies.

Space and time play a crucial role in multi-hazard damage assessment. When two or more natural hazards occur simultaneously in the same location or within a short time frame, the physical integrity of infrastructure can be compromised, leading to two scenarios: (i) 'spatial-temporal overlapping impact', when the damage results from the combined impact of both hazards, and (ii)' overlapping spatial impact with residual and subsequent damage', in case of cumulative damage from consecutive hazards.

Current literature highlights the lack of clear frameworks for multi-hazard impact assessment. Complexity in formalising quantitative aspects and understanding feedback loops between hazard, exposure and vulnerability emphasises this gap. This research aims to develop a generalised mathematical framework for quantitatively assessing multi-hazard physical damage on exposed assets, such as buildings or critical infrastructures, over time. The proposed framework covers both cases of compound and consecutive hazards. Specifically, in the "overlapping spatial impacts with residual and subsequent damage" scenario, the framework considers the reduction in exposure value, modification of vulnerability, and recovery dynamics. A sensitivity analysis has been conducted to evaluate how the duration of recovery and its functional shape (linear, exponential, and logarithmic) affect the asset's resilience.

The framework is tested through a series of real and virtual case studies, demonstrating its applicability. Observing real scenarios allows the assessment of socioeconomic and institutional factors influencing the single and multi-hazard recovery process. By incorporating dynamic analysis into the recovery phase, we can offer decision-makers a comprehensive understanding of the impacts caused by compound and consecutive events.

Remarkably, the existing multi-hazard risk models that assess the physical vulnerability of exposed assets lack validation and do not offer the disaggregated effects per hazard scenario. We track that shortcoming while relying on the assumption that locally calibrated single-hazard vulnerability models available in the literature can be reused for multi-hazard risk assessment for building portfolios. This is done through a holistic method that probabilistically harmonises such single-hazard fragility models and allows us to assess the differential and cumulated damage that are expected from residential building stocks affected by cascading hazards. This is a modular approach that is composed of: (1) exposure models that classify the buildings into individual sets of classes for each hazard; (2) their spatial aggregation onto optimal geographical units whose variable resolution is compatible with the variability of the hazard intensities; (3) the probabilistic compatibilities between such sets of building classes and the damage states within their fragility models; (4) the use of state-dependent fragility functions for the second hazard. We test this methodology on the residential building stock of Lima (Peru), a coastal mega-city. Damage distributions and direct economic loss estimates are calculated for six independent mega-thrust-earthquake scenarios (main-shock) ranging from Mw 8.5 to 9.0. Thereby, the resultant distribution of damage states after the first earthquake is probabilistically converted to the reference frame of the tsunami and is later used to assess the cumulative damage using state-dependent fragility functions. This setting allows disaggregating the direct economic losses of each individual hazard to the entire cascading sequence.

[2]*International Centre for Earth Simulation Foundation, Seismology, Geneva, Switzerland*

Based on our new catalogue of 2,795 fatal earthquake for the world, covering the period 856BC to March 2022 not including tsunami deaths, we estimate that the reporting of fatal earthquakes is complete for events with more than 16 fatalities since 1927. The total number of fatalities recorded is 8,336,526. 117 countries have reported at least one earthquake with one fatality or more. 77 and 52 countries have reported more than 100 and 1,000 earthquake fatalities, respectively. We introduce the ***earthquake potency*** for a country, defined as the sum of recorded fatalities divided by the number of earthquakes that it took to accumulate them, which equals the average earthquake disaster size in a given country, in units of fatalities per event. A key measure of the earthquake problem in a country is the ratio of fatalities to population size. We propose that the new parameter ***earthquake fatality load per year*** objectively measures the level of the population suffering in seismically active countries, that is, it indicates the average annual cost in lives. Ecuador, Iran, Peru, Turkey and Chile have experienced the greatest loads during the last five centuries. We suggest that in multi-hazard analyses the parameters ***potency*** and ***load*** could be introduced for floods, storms and other geohazards.

S11a - Site Response in Urban Areas

Perspectives on the state of practice in site characterization for site response analyses

DOI: 10.57757/IUGG23-2489 - LINK

Alan Yong[1]
[1]*US Geological Survey, Earthquake Science Center, Moffett Field, USA*

I present perspectives on the use of noninvasive single- and multi-station site characterization methods and their impact on estimating site response, including the so-called double "A"s inherent within site effects phenomena: amplification and attenuation. I describe the current state of knowledge and practice using traditional independent array-based techniques through results from the 2015–2021 Consortium of Organizations for Strong Motion Observation System (COSMOS) Site Characterization Project (Yong *et al*., 2022)[1]. I also compare results for *S*-wave velocity (V_S) profiles from single-station methods—such as the earthquake horizontal-to-vertical spectral ratio (eHVSR; Nagashima *et al*., 2014)[2] technique—against those by traditional approaches (Stephenson *et al*., 2022)[3]. Through recent investigations, including results by Asten *et al*. (2022)[4], I propose optimal procedures for applying single-station and array-based methods to acquire: V_{S30}, the time-averaged V_S of the upper 30 meters, and the fundamental (f_0) and dominant (f_d) site frequencies. For V_{S30}, I show that V_{R40}, the Rayleigh-wave phase velocity at the 40 m wavelength, is suitable to estimate V_{S30} for the majority of cases encountered. Through our Wang *et al*. (2023)[5] article, I show how selections of f_0 or f_d are affected by analyst bias and propose how to address such uncertainty. Finally, I discuss the importance of measuring the site *S*-wave quality factor (Q_S) as described by our Parolai *et al*. (2022)[6] review paper, and propose methods that will advance the current practice towards a more accurate understanding of the two "A"s of site effects.

Using single-station six-component measurements and numerical simulations for site response estimation in Munich, Germany

DOI: 10.57757/IUGG23-0349 - LINK

Sabrina Keil[1], *Joachim Wassermann*[1]
[1]*Ludwig-Maximilians-Universität München, Geophysik, München, Germany*

Recent progress in seismic instrumentation has opened new opportunities for using wavefield gradients (strain and rotation) for several seismic applications. We show that single-station six-component (6C) measurements, combining three translational and three rotational motions, can be used to investigate the shallow velocity structure. A remarkable advantage of this single-station 6C approach is its simpler way of deployment compared to array measurements, which especially eases the application in urban areas. We performed ambient noise measurements in Munich, Germany, using an iXblue blueSeis-3A rotational motion sensor together with a Nanometrics Trillium Compact seismometer. From the 6C data we were able to compute Love and Rayleigh dispersion curves, which are inverted together with H/V spectral ratios to obtain 1D P- and S-wave velocity profiles of the upper 100 m. The resulting velocity structure is implemented with additional geological and geophysical data into a 3D subsurface model. This model is used to perform 3D seismic simulations of induced earthquakes using the spectral element code SALVUS. The simulations help to quantify the amplification effect of the shallow low velocity sediments in the Munich area. In addition, the maximum ground motion and its spatial distribution can be estimated, which is important to evaluate the seismic risk in this densely populated area.

S11a - Site Response in Urban Areas

Comparison of near-surface attenuation estimated from seismic noise surface data and weak motion recordings in a borehole

DOI: 10.57757/IUGG23-3263 - LINK

Ilaria Dreossi[1], *Stefano Parolai*[2]
[1]*National Institute of Oceanography and Applied Geophysics - OGS, OGS, Sgonico, Italy*
[2]*University of Trieste, Department of Mathematics and Geosciences, Trieste, Italy*

Within the framework of the seismic site response assessment, ambient seismic noise analyses have increasingly spread over the years, mostly to retrieve the shear-wave velocity (V_S) and the fundamental frequency of the subsoil. On the contrary, less studies focused on their potential to estimate the seismic-wave attenuation and the associated shear-wave quality factor (Q_S). Recent works conducted at a local scale proposed a linear inversion, based on a least squares algorithm, to retrieve the 1D Q_S structure of the subsurface from seismic noise measures using microarrays. This inversion requires trial-and-error tests for choosing an ad-hoc damping factor and to set a positivity constraint to the solutions. Later studies showed that the Simultaneous Algebraic Reconstruction Technique (SART) could simplify the procedure (e.g., by avoiding the introduction of a positivity constraint), still providing reliable results.
To test the capability of seismic noise for a robust estimation of the near-surface attenuation, an experiment was conducted at a test site where a 100-m-deep instrumented borehole exists. The selected site is situated in north-east Italy and is equipped with two permanent seismic sensors at 0.5m and 100m depth, respectively. Nearby the borehole, a seismic noise measurement in microarray configuration was carried out and the results were compared with those derived from the inversion of seismograms collected by the two sensors. The outcomes show a reasonable agreement, considering both the diverse spatial resolution of the techniques and the difference among the parameters estimated in the depth range where a comparison can be attempted.

We use a number of machine learning models to predict the seismic site amplifications of shallow bedrock sites calculated from one-dimensional ground response analyses. We compare the results with a regression-based model that are conditioned on V_{S30}, site period, and peak ground acceleration. We show that use of the array type of information for the ground motion and site profile in machine learning training produces excellent predictions of the surface response. In contrast, employing parameters typically used for the site amplification models widely employed in ground motion prediction equations produces only marginal improvement compared with a regression-based model. The fit can be improved through utilization of additional parameters, although the improvement is not as dramatic as when using the array data.

We use 24 km of telecommunications fiber in Athens, Greece, to explore the use of ambient noise correlations and the construction of a shallow 2D velocity model. Models of the shallow subsurface are especially important for hazard and site-response characterisation, yet traditional measurement campaigns in dense, urban environments can be challenging. Using pre-existing telecommunications fiber provides an efficient and easy way to construct such high-resolution models.

The fiber was provided by the Hellenic Telecommunications Organization (OTE), over 36 days in the Autumn of 2021, and in cooperation with the National Observatory of Athens (NOA). Using a Silixa iDAS interrogator, we measure strain-rates every 4 meters along the fiber to provide dense observations of wave propagation. Strong anthropogenic noise gives clear Rayleigh-wave signals in cross-correlations in the frequency band of 5-30 Hz. We discuss our efforts to efficiently stack multiple virtual sources' record sections and construct dispersion curves. We then invert for numerous 1D velocity profiles of the top ~100 m, comparing different approaches, and finally present a 2D model over the entire line.

Reexamination of the subsurface velocity structure and estimation of amplification factor of Yangon, Myanmar estimated from microtremor data

DOI: 10.57757/IUGG23-4849 - LINK

Shinichi Matsushima[1]
[1]*Kyoto University, Disaster Prevention Research Institute, Uji, Japan*

In order to understand the subsurface velocity structure of the city of Yangon, Myanmar, microtremor observations were conducted in and around the city. Data was obtained during the period of 2015 to 2018. Triangular array observations were conducted at seven locations within the study area in order to estimate the phase velocity and the velocity structure at each location. On the other hand, in order to estimate the depth distribution of the subsurface layers, single-station observation was conducted at over 150 sites to obtain Microtremor horizontal-to-vertical spectral ratios (MHVRs) (Hirokawa et al., 2016; Matsushita et al., 2018).

These data will be reinvestigated to reexamine the subsurface structure of the city of Yangon. The S-wave velocity and thickness of the layers is estimated from the phase velocity and P-wave velocity and density are estimated from the S-wave velocity using the relation by Ludwig et al. (1970). The velocity structure at singe-station observation points are estimated by fitting the observed MHVRs with the theoretical MHVRs calculated according to the diffuse field concept (Sánchez-Sesma et al., 2011) using the velocity structure estimated at the array observation locations as initial models. The S- and P-wave velocities and number of layers are fixed and only the thickness of the layers are changed to fit the data. The estimated velocity structure will be interpolated to construct a three-dimensional velocity structure and the amplification factor due to the subsurface structure is estimated.

Site response analysis is essential for evaluating seismic hazard and risk assessment and for providing useful data for land use planning. However, current regional site amplification models do not have the necessary resolution for sites such as alpine valleys, where site response is characterized by complex effects. In this study, the site response of the lower Sarca Valley (northern Italy) was first evaluated at a limited number of sites corresponding to the locations of earthquake recordings. Then, the site response (in terms of spectral amplification curves and duration lengthening) was spatially extended where recordings of earthquakes were not available, by the application of cluster and a correlation analysis, using the noise NHV recorded throughout the valley by single-station noise measurements. In this way, could finally zonate the area into three parts with different site response characteristics: the area where the bedrock outcrops, characterized by a flat response; an area around the valley axis where the sediments reach a thickness of about 450 meters, characterized by high amplification values (up to 10) and ground motion lengthening of several tens of seconds at frequencies below 1 Hz; an area at the valley margins where the sediments become thinner, characterized by spectral amplification at frequencies between 1 and 10 Hz. The results obtained can provide useful information for hazard and risk scenarios and for improving lower resolution regional maps at the local scale.

In the framework of the Risk Model Switzerland, Risk Model Basel and Urbasis projects, selected areas in Switzerland were used to derive local amplification models combining geological, seismological and geophysical data. The chosen sites are Visp and Sion located in the Canton of Valais in southwest Switzerland, Lucerne a densely populated city located in central Switzerland and Basel located in the northwest of Switzerland.

In the area of Visp, different amplification models are derived by means of 3D simulations and statistical correlation of horizontal-to-vertical spectral ratio and empirical amplification functions. Additionally, a further strategy for the prediction of amplification is presently being calibrated using the quarter wavelength method as a direct empirical modelling approach to estimate amplification from synthetic S-wave velocity profiles extracted from the 3D model. Instead, in the Sion, Basel and Lucerne areas beyond the statistical correlation of horizontal-to-vertical spectral ratio with empirical amplification functions as in Visp, also a method combining noise and earthquake standard spectral ratio is used.

Thanks to the available database of geophysical data and empirical amplification functions Switzerland is a good laboratory in which different techniques to map amplification can be tested and compared highlighting the advantages and limitations.

Estimation of amplification factors (AFs) at the local or regional scale is an important task in land planning and seismic design, especially in areas with high seismic hazards and complex geological and geomorphological structures of the territory, such as Italy. When multiple seismic recordings at a single site are available, they can be exploited to estimate AFs empirically through many methods, such as: a) spectral ratios between i) the horizontal and vertical ground-motion components and ii) the shaking observed at the site and at a reference rock site, both for acceleration response and Fourier spectra; b) parametric or non-parametric generalized spectral inversion techniques; and c) decomposition of residuals of a nonergodic Ground Motion Model (Rodriguez-Marek et al., 2011; Priolo et al., 2020, among the others) to estimate repeatable within-site terms (δS2S).
In this study, we exploited the estimates of δS2S provided by Lanzano et al (2022), through the ITACA (ITalian ACcelerometric Archive) web portal (https://itaca.mi.ingv.it/ItacaNet_32/#/products/itacas2s_flatfile), to compute the AFs for about 800 recording sites in Italy. We then compare AFs estimates with different proxies for predicting the site effects, such as Vs profile, resonance frequency, cover geology and topographic slope. Moreover, we also employed the empirical AFs to validate the estimates provided by 1D, 2D and 3D numerical modeling of the site response. Later, we investigate spatial correlation of the AFs in urban areas, where dense networks are installed.

Site response in urban areas is influenced by the presence of buildings and their interactions with the soil. The simplified dynamic response of buildings, and especially their fundamental period of vibration, can be determined by empirical characterization. However, a large variability is observed between buildings located at different sites, even if they belong to the same building typology. Our study focuses on the impact of the main characteristics of buildings (i.e., the construction materials) and soil (i.e., rigid or soft), and thus soil-structure interaction, on the structural response of buildings. For this purpose, the main characteristics of 312 buildings (constructed of reinforced concrete, unreinforced masonry or mixed materials) and their associated foundation soils were collected from different surveys in southern and northern Italy and published in an open-access database called FRIBAS (https://doi.org/10.5281/zenodo.6505442). It contains a total of 37 parameters, such as different structural and geometrical characteristics of the building (e.g., construction material, number of floors, shape) and soil properties (e.g., outcropping geology). Moreover, the fundamental vibration periods of the buildings and soil were estimated using the Horizontal-to-Vertical spectral ratio from ambient vibration measurements. FRIBAS gave us the opportunity to investigate the influence of construction materials and soil types on building periods. Our results suggest that a general T-H relationship is not sufficient, but that it is necessary to develop building-site-specific T-H relationships. FRIBAS is a fully public database that allows the entire scientific community to analyze the influence of various building and soil properties on the dynamic behavior of buildings.

S12a - Recent Devastating Earthquakes Including the Feb. 6, 2023 Turkey Sequence

Insights into Subduction Zone coupling from the 2020 - 2021 Alaska (Shumagin) earthquake sequence

DOI: 10.57757/IUGG23-1254 - LINK

Kevin Furlong[1], *Matthew Herman*[2]
[1]*Penn State University, Geosciences, University Park, USA*
[2]*California State University Bakersfield, Geological Sciences, Bakersfield CA, USA*

Prior to July 2020, the Alaska-Aleutian subduction zone near the Shumagin Islands had not experienced a large, Mw7.0+ earthquake in over 75 years. The previous major events in this region were the great (Mw8.0+) 1938 and 1946 earthquakes. These events occurred on either side of the “Shumagin Seismic Gap”, a region that has not hosted a great megathrust earthquake in recorded history. Attention to this region was renewed with the occurrence of three large earthquakes: the 22 July 2020 Mw7.8 Simeonof megathrust event, the 17 October 2020 Mw 7.6 Sand Point intraslab (strike-slip) event, and the 29 July 2021 Mw8.2 Chignik megathrust event. The two 2020 events and subsequent aftershock activity were shown to be consistent with a transition from high plate interface coupling east of the Shumagin Gap to a generally uncoupled megathrust in the Shumagin Gap. The 2021 Chignik earthquake was located in a section of the subduction zone that hosted previous large earthquakes and that was brought closer to failure by the seismicity of the previous year. Analyses of the Chignik earthquake sequence and the previous large earthquakes provide additional constraints on the transition from coupled to uncoupled along the Aleutian megathrust and implications for earthquake processes. In particular, the evolution of events in this sequence is compatible with occurring in the stress field produced by the coupling transition, which also allowed more complete elastic strain release during the large earthquakes.

We continue analysing earthquake sequences in terms of their variability and scaling properties, including the behaviour of the control parameter η of the unified scaling law for earthquakes (USLE), along with a detailed analysis of the surface wave records for reconstruction of the source in approximation of the second moments of the stress glut tensor to obtain integral estimation of its length, orientation, and seismic process development over time. In particular, we present the analysis of the cases of the three recent earthquakes in Southern Alaska – 22 July 2020, Mw7.8 at 105 km SSE of Perryville, 19 October 2020, Mw7.6 at 97 km SSE of Sand Point, and 29 July 2021, Mw8.2 at 99 km SE of Perryville – that have occurred right at the western edge of the rupture zone of the 1964 Great Alaska, M9.3 mega-earthquake and contribute to apparent activation of the region started with the three major earthquakes (24 January 2016, Mw7.1, 23January 2018, Mw7.9, and 30 November 2018, Mw7.1) at its north-western and southern borders.

Due to yet rather small number of case studies, it seems premature to discuss if the observed quantitative characteristics of seismic variability and their scaling properties disclose clear patterns useful in operational earthquake forecasting of seismic catastrophes including the extreme mega-earthquakes. However, our studies give a new insight into better understanding of seismic dynamics in the Pacific Northeast.

The study is carried on in the framework of the Russian State Task of Scientific Research Works of IEPT RAS (0143-2019-0006, 0143-2019-0007).

Historical earthquakes, rupture zones and the earthquake cycle along the East Anatolian Fault

DOI: 10.57757/IUGG23-4114 - LINK

Ioanna Triantafyllou[1], *Gerassimos Papadopoulos*[2]

[2]*International Society for the Prevention & Mitigation of Natural Hazards, Natural Hazards Department, Athens, Greece*

The region of the East Anatolian Fault (EAF) experienced several strong earthquakes during the instrumental period of seismology, i.e. after AD 1900. However, the devastating earthquake (Mw7.8) of 6 February 2023, that ruptured along the EAF, is the first to occur with such a large magnitude in that time interval. Then, some questions of fundamental importance for the earthquake cycle in the EAF raise. When earthquakes of similarly large magnitudes occurred in the past? Which segments of the EAF ruptured? What is the mean repeat time of the large EAF earthquakes? To respond to such challenging issues we organized a data base of historical earthquakes that caused significant damage in the region of EAF and assigned macroseismic intensities in terms of MMI scale. Earthquake magnitudes were calculated from empirical magnitude/intensity relationships. Mapping of lateral rupture zones along the EAF was based on higher degree isoseismal curves (e.g. degree VIII) and on evidence of surface-fault traces and other ground failures. Preliminary results showed that rupture zones of the large magnitude earthquakes abut and do not overlap, while the repeat times are of the order of several hundred years.

The ISC Seismic Event Bibliography: An asset for studying recent earthquakes

DOI: 10.57757/IUGG23-0475 - LINK

Domenico Di Giacomo[1]
[1]*International Seismological Centre, ISC, Thatcham, United Kingdom*

Since its launch in 2014 (Di Giacomo *et al.*, 2014), the International Seismological Centre (ISC, www.isc.ac.uk) Seismic Event Bibliography service has been very popular with researchers worldwide. Indeed, this service differs from other literature search engines since it is based on the association between seismic events in the ISC Bulletin and bibliographic records. As such, web searches (www.isc.ac.uk/event_bibliography/bibsearch.php) are not only based on bibliographic parameters (e.g., author, journal title, year of publication) but also on event parameters (e.g., origin time, location). In addition, the literature considered is not limited to seismology but includes a broad range of disciplines (e.g., earthquake engineering, geodesy and remote sensing, tectonophysics and volcano-tectonics, monitoring research, tsunami, landslides, geology, geochemistry, hydrogeology, atmospheric sciences), a feature that makes the service useful also for multidisciplinary studies. Hence, the ISC Seismic Event Bibliography is an asset both to researchers studying specific events as well as editors and reviewers during every stage of the publication process.

The bibliographic record of this service has grown significantly in recent years, and new papers related to recent significant earthquakes (e.g., May 21, 2021, Maduo; 29 July, 2021, Chignik; 6 February, 2023, East Anatolian) as well as other types of seismic sources (e.g., the 15 January 2022 Hunga Tonga Hunga Haapai eruption) are published at increasing speed. In such a context, with this contribution we aim to showcase the usefulness of the ISC Seismic Event Bibliography, how the community can use it best and, at the same time, help improve it and facilitate its maintenance.

On September 5, 2022, an *M*s6.8 earthquake hit the Luding County in Sichuan Province, China, and caused 93 deaths and 24 people missing. The spatial distribution of the relocated Luding earthquake sequence reveals an NNW-trending aftershock zone with long axis about 55 km along Moxi segment, the southern segment of Xianshuihe fault zone (XSH). The aftershock zone is wider in the middle and narrower in the southern and northern sections. The *M*s6.8/*M*w6.44 mainshock with centroid depth at 3.0 km and the two *M*s≥5.0 aftershocks occurred in the middle section. The strike, dip and rake angles of the nodal planes I and II of the focal mechanism for the mainshock are 75°/90°/155° and 165°/65°/0°, respectively. The areal strains *A*s exhibit a pure strike-slip faulting style both for the mainshock and the aftershocks in the southern and northern parts, while the aftershocks in the middle section are of pure or oblique extensional. Based on the spatial distribution of aftershocks, the focal mechanism solutions of the entire sequence and the structural trending in the aftershock zone, we conclude that the seismogenic fault of the *M*s6.8 Luding earthquake is the NNW-trending Moxi fault on the southern segment of XSH. The seven *M*s≥3.1 aftershocks in the middle section of the aftershock zone and the four *M*s≥3.4 events in the 2016 Luding earthquake swarm with pure or oblique extensional behaviors imply the possible existence of a series of SSE (NNW)-striking normal faults, some of which might contribute to the occurrence of aftershocks there.

The 2021 M_w 7.4 Maduo earthquake that occurred within the Bayan Har block provides us with a unique opportunity to understand the lithospheric mechanical properties in northeastern Tibet. We retrieve the coseismic displacements and time series of postseismic deformation associated with the Maduo earthquake from Sentinel-1 InSAR data. We estimate the detailed coseismic slip distribution from the coseismic deformation fields and analyze possible postseismic processes by modeling the six-month postseismic deformation. The coseismic rupture is dominated by sinistral strike-slip motion and concentrated at 0-15 km depth with a peak of ~4 m. Our optimal afterslip-poro-viscoelastic model is not only physically more reasonable, but also has the best data fit. The postseismic deformation is dominated by afterslip located at depths of 10-20 km, revealing a complementary pattern with the updip high coseismic slip. Yet ignoring poroelasticity and viscoelasticity will result in errors in the afterslip of >12 cm locally. Poroelastic rebound contributes significant postseismic LOS deformation, up to ~14 mm, near the northwest and southeast fault segments. The steady-state viscosities in the lower crust and upper mantle are 4×10^{19} Pa·s and 2×10^{20} Pa·s, respectively, agreeing with the “Jelly Sandwich” model, but not with the crustal-flow models featuring much lower viscosity.

Fault zone head waves (FZHWs) are an essential diagnostic signal which can provide high-resolution imaging of fault interface properties at seismogenic depth. In this study, we investigate the existence of bi-material interfaces along the rupture zone of the 2022 Mw6.8 Luding earthquake at the southern Xianshuihe Fault and determine the cross-fault velocity contrast. We employ a semi-automatic workflow to detect FZHWs and the direct-P waves. We improve the identification ability of potential FZHWs in the automatic picking process with a combination of STA/LTA functions and a kurtosis detector in a “forward-detecting and backward-picking” strategy. We confirm 206 FZHWs at two stations. Results indicate average velocity contrasts of ~5 % along the northern segment of the rupture zone while it decreases to ~3% in the south, with the northeast side having a faster P-wave velocity, in agreement with tomographic results. We also noticed that some direct-P waves do not polarize parallel to the back azimuth, indicating a complex site effect beneath the station. The distribution of FZHW-generated events indicates the existence of a single continuous interface in the seismogenic zone with length about 100km, which might be conducive to the preparation of large earthquakes and further influence the dynamic rupture processes. The velocity contrast across the rupture zone indicates a statistically preferred NW propagation direction for typical subshear ruptures. However, the rupture direction of the Mw6.8 Luding earthquake was primarily from NW to SE, suggesting that other factors, such as heterogeneous stress distribution along the fault, might impact the rupturing direction.

The tourist town of Joshimath in the west of Indian Himalayas, is bounded by NNW-SSE Munsiari Thrust in the north and Main Central Thrust Faults in the south. The study of tectonic structural configuration indicates that these two faults caused differential fragmentation of Joshimath slab. Like many other parts of a young mountain building system, the town is prone to various types of landslides, subsidence, slope failures, avalanches, debris and mud flows. The surface geological materials are composed of heterogeneous piedmont deposits in northern slope of the mountain facet, consisting of weathered boulders of gneisses and schistose rocks amalgamated with silty-sandy matrix. This study finds that the Alakananda River strongly smack the north-east foothill of Joshimath cliff from the north and cause severe scour, erosion of the ground and infiltration of running water before merging into a structurally controlled vertical gorge. The remaining volume of water is carried out by Dhauliganga river. The existence of number of active NS trending short gravitational (Normal) faults and deep fractures in the east and west side of the Joshimath town, caused northward slip of the Joshimath slab. Our mathematical modelling suggest that tensile stresses generated in compressive thrust wedge under low friction on boundary thrust of wedge causes shallow subsidence. Unplanned construction activities and inconsistent modification of natural topography add on to the impact of natural degradation and damages urban structures. A planned urban construction consistent with geological and geomorphological environment and aligned to the seismic and meteorological conditions is recommended in Himalayas.

Newly discovered faults in Indonesia revealed by recent destructive earthquakes

DOI: 10.57757/IUGG23-0610 - LINK

Pepen Supendi[1], *Nicholas Rawlinson*[1]
[1]*University of Cambridge, Earth Sciences, Cambridge, United Kingdom*

Indonesia is one of the most earthquake-prone countries in the world. Its highly complex tectonics setting is the result of collision between the Australian and Sunda blocks, and the interaction of the Pacific and Philippine Sea plates. Prior to 2017, the National Center for Earthquake Studies of Indonesia database recognised 295 active faults throughout Indonesia. The additional seismic stations operated by the Agency for Meteorology, Climatology, and Geophysics over the past 5 years has greatly improved the detection of small earthquakes from previously unidentified faults. In this study, we investigate recent destructive earthquake sequences in Indonesia along with their associated foreshock and aftershocks. We find, using a variety of techniques including relative relocation of hypocenters, focal mechanism determination, and Coulomb stress modelling, that the main shocks occurred on previously unknown faults, including the Majene Fault in West Sulawesi, the Kalaotoa Fault in the Flores Sea, a small graben system in Semangko Bay (Southern Sumatra), the Kajai Fault in Pasaman (West Sumatra), and a conjugate fault in Cianjur (West Java). Mapping these active faults is very important for updating seismic hazard maps and understanding their implications. The Turkey earthquake on February 6, 2023, serves as a reminder that shallow crustal earthquakes caused by active terrestrial faults located near large population centers pose a major natural hazard.

[6]University of California Santa Cruz, Department of Earth and Planetary Sciences, Santa Cruz, USA

On 6 February 2023, an M_W 7.8 earthquake occurred on the southwestern part of the East Anatolian Fault zone (EAF), followed by an M_W 7.5 at ~100 km away on the East-West striking Sürgü fault 9 hours later. The W-Phase inversions indicate major strike-slip with dip angles of 60° for both events. A notable difference in seismic waveforms between two major earthquakes suggests different rupture characteristics. High-frequency back projection images for the M_W 7.8 event from the dense broadband ChinArray shows a NE unilateral rupture from the onset for 40 sec with the expansion to the EAF trace since ~20 s and stopping at the junction of EAF and Sürgü fault, along with some late radiation at ~40-60 s to SW at the Amanos segment of EAF. The back projection image for the M_W 7.5 event shows a main high-frequency coherent energy release for the first 10 sec over ~40 km and late weak radiations to the west near the curved Cardak fault and to the east near the Malatya fault. Preliminary slip models inverted from teleseismic data indicate a complex rupture for the M_W 7.8 event predominantly on the EAF and a localized slip for the M_W 7.5 event. The difference also exhibits in body-wave magnitude with m_B=7.5 for the M_W 7.5 and m_B=7.2 for the M_W 7.8 events. We are exploring InSAR images, hr-GNSS, and strong-motion data to constrain details in the rupture process of both events.

On 6 February 2023, an M_W 7.8 earthquake occurred on the southwestern part of the East Anatolian Fault zone (EAF), followed by an M_W 7.5 at ~100 km away on the East-West striking Sürgü fault 9 hours later. The W-Phase inversions indicate major strike-slip with dip angles of 60° for both events. A notable difference in seismic waveforms between two major earthquakes suggests different rupture characteristics. High-frequency back projection images for the M_W 7.8 event from the dense broadband ChinArray shows a NE unilateral rupture from the onset for 40 sec with the expansion to the EAF trace since ~20 s and stopping at the junction of EAF and Sürgü fault, along with some late radiation at ~40-60 s to SW at the Amanos segment of EAF. The back projection image for the M_W 7.5 event shows a main high-frequency coherent energy release for the first 10 sec over ~40 km and late weak radiations to the west near the curved Cardak fault and to the east near the Malatya fault. Preliminary slip models inverted from teleseismic data indicate a complex rupture for the M_W 7.8 event predominantly on the

EAF and a localized slip for the M_W 7.5 event. The difference also exhibits in body-wave magnitude with m_B=7.5 for the M_W 7.5 and m_B=7.2 for the M_W 7.8 events. We are exploring InSAR images, hr-GNSS, and strong-motion data to constrain details in the rupture process of both events.

Rupture processes of the 2023 Türkiye earthquake sequence: Main- and aftershocks

On February 6, 2023, southeastern Turkey was hit by two of the most devastating earthquakes in the instrumental period of the country, with Mw 7.8 and Mw 7.5, respectively. Both earthquakes caused massive damage in Turkey and Syria. In this study, we analyze the rupture processes of main- and aftershocks by combining different seismic source characterization techniques using teleseismic, regional, and local data. We perform finite source inversion and back projection-based analyses for the two main shocks and invert for probabilistic centroid moment tensor solutions of both main and aftershocks (M≥4). The first earthquake was bilateral and ruptured a seismic gap along the East Anatolian Fault, with rupture first propagating to the north-east for ~200 km, and in a latter phase propagating to the SSW, probably coming to a halt only on a branch extending into the Mediterranean Sea. The total length of the rupture likely exceeds 500 km. The second event ruptured the EW-oriented Sürgü-Misis Fault to the NW of the first event. It shows a highly concentrated rupture near the epicenter, Rupture directivity analyses for M≥5.3 earthquakes provide additional insights into dynamic source aspects. Preliminary moment tensor solutions of numerous aftershocks indicate a remarkable variability of rupturing mechanisms, suggesting stress changes and the activation of multiple faults in the vicinity of the main ruptures. With our work, we aim to shed light onto multiple aspects of the complex rupture evolution and hope to provide new insights towards a better understanding of the devastating 2023 Türkiye earthquake sequence.

Two earthquakes struck eastern Turkey and caused severe damage on 6th February 2023. The magnitudes are Mw7.8 and Mw7.7, respectively. The rupture processes of the two earthquakes are significantly different. The Mw7.8 earthquake has a gradual initial rupture, resulting in a longer duration time. In addition, the epicenter is located at a small branch.

We focus on the initial rupture constrained by teleseismic data. We set up fault planes based on preliminary online geodetic and seismology results by other researchers. After a series of tests, we could not simulate the initial rupture well based on the uniform sub-fault size (6x4km).

We carry out a two-step inversion strategy. Firstly, we used a rectangle fault with a length of 26km and a width of 30km to simulate the first 12s teleseismic P waveforms. The sub-fault size is 2x2km. The strike and dip angles are 220° and 70°, respectively. The residual teleseismic waveforms between synthetic and the whole observed teleseismic waveforms are calculated.

Secondly, Two rectangle segments with larger sub-fault sizes and different strike angles (220° and 235°) are applied to simulate the residual teleseismic waveforms. The sub-fault size is 6x4km.

The result indicates that the initial rupture propagated downward along the dip-slip direction which is a nearly pure strike-slip event. The moment is 1.3x10^19 Nm, and the corresponding moment magnitude is Mw6.7, about 2% of the total moment.

A significant normal component could be observed at the shallow depth between the initial pure strike-slip patch and the body patch, which is consistent with the tectonic background.

On February 6, 2023, two large earthquakes with moment magnitudes of 7.8 and 7.5 occurred in Southeastern Turkey. These two earthquakes caused significant damage and a high number of fatalities in the provinces of Kahramanmaras, Hatay, Adiyaman, Osmaniye, Gaziantep, Kilis, Sanliurfa, Diyarbakir, Malatya, Adana, and Elazig. A dense array of seismograms close to the fault ruptures recorded both earthquakes. Some of these records are observed to have very large amplitudes with peak ground acceleration values over 1 g and peak ground velocity values over 150 cm/s. This study provides a detailed analysis of the recorded ground motions and investigates potential reasons behind the significant structural damage and observed extreme motions with very high amplitudes. These reasons include multi-segment fault ruptures, multiple high-amplitude wave packets observed in the records, rupture directivity effects, and the occurrence of strong velocity pulses. The recorded ground motions are also compared to the current and previous seismic codes of Turkey for various return periods. Next, shaking intensities in terms of the Modified Mercalli Intensity (MMI) scale are estimated using empirical models which relate peak ground motion parameters to the felt intensity. These estimates are then compared to the reported intensity values from field observations. Discrepancies between the estimated and reported intensity values are investigated.

Within the proximity of the source of medium-to-large earthquakes, seismic ground motion exhibits peculiar characteristics that can hardly be reproduced by global and regional empirical models (GMMs), usually adopted for hazard assessments and shaking scenarios.

High amplitudes (in terms of peak values and spectral ordinates), velocity pulses, vertical motions greater than their horizontal counterparts, and permanent displacements are some of the characteristics observed during strong worldwide earthquakes.

The paucity of near source observables does not allow the calibration of robust empirical models for their prediction, and to overcome this limitation, adjustment factors have recently been calibrated to be applied to classical GMMs for several ground motion parameters using the NESS recording dataset.

The recent earthquake sequence in Turkey produced a large amount of near source recordings close to the different activated fault segments, which provide an opportunity on the one hand to validate the previously calibrated adjustment factors and on the other hand to investigate the characteristics of additional shaking parameters related to energy content and release mode, such as waveform envelopes, arias intensity and duration.

Keywords: Turkish event, ground motion models, near source features and intensity measures.

An earthquake sequence occurred along the East Anatolian fault (EAF, Mw 7.8) and Sürgü fault (SF, Mw 7.6) in the Kahramanmaras region (Southern Turkey). Both earthquakes show strike-slip mechanisms and shallow hypocentre (<15 km), with NE-SW trending Kahramanmaras and Karasu fault segments reaching ~300 km and E-W trending 150 km Sürgü fault length, respectively. An analogue seismic event according to historical catalogue is the 29 November 1114 that severely affected Antachia, Marash and Urfa with about 40 000 victims. Christian and Muslim chroniclers report the occurrence of two large seismic events, a comparable situation to the 2023 events. Field investigations conducted in 2005 in the frame of the EC-Funded APAME project show ~4 m to ~80 m left-lateral offset streams along the fault zone south of Kahramanmaras city. InSAR results from Sentinel images provide an accurate mapping of the Kahramanmaras and Karasu fault traces with estimated ~3 m to ~8 m left-lateral slip along strike. Repeated GPS measurements from 1991 – 2004 allow us to determine horizontal velocities of 22 stations located across the EAF in southern Turkey. By using a simple locked fault model, we estimate that the relative left-lateral plate motion across the EAF is 9.7 ± 0.9 mm/yr., and 4.4 ± 0.4 mm/yr across the Karasu fault. The ~900 year of interseismic relative quiescence and 9.7 mm/yr left-lateral block velocity, surface faulting geomorphology and paleoseismic results along the EAF may explain the occurrence of the Mw 7.8 event.

Fault slip distribution in the February 2023 Kahramanmaraş earthquake sequence from Sentinel-1 and ALOS-2 image offsets

DOI: 10.57757/IUGG23-4488 - LINK

Gareth Funning[1]
[1]*University of California- Riverside, Department of Earth and Planetary Sciences, Riverside, USA*

The 6 February 2023 Kahramanmaraş earthquake sequence involved two major earthquakes (M7.8 and M7.5) within 12 hours on separate faults, causing widespread damage and loss of life in SE Turkey and NW Syria. Dense image offsets, computed from Sentinel-1 and ALOS-2 SAR images, provide robust measurements of the surface deformation of both events; I use them here to estimate the distributions of slip on their causative faults.

I use the ISCE software to produce both range and azimuth offsets, for multiple ascending and descending tracks, and use them to map the major fault traces and splay faults involved in the earthquakes. To downsample the offsets into a useable form for modelling, I first use a distance-based sampling approach to produce a preliminary model, and then use a quadtree decomposition based on the modelled displacements to sample the offsets, employing a median filter to reduce the influence of noise originating from false image matches. Finally, I use the Okada-based slipinv software to invert for the slip distribution.

Preliminary results show a heterogeneous pattern, with up to 8 m of slip on a ~250 km rupture of the East Anatolian Fault (EAF) corresponding to the first event, and a ~125 km rupture of the Sürgü Fault, peaking at 9 m of slip, to the second. Both faults have splays that highlight possible complexities of both events, including a splay that likely initiated the first event, connecting to the centre of the main asperity on the EAF.

The February 6 2023 earthquake sequence in the East Anatolian Fault Zone (EAFZ) was dominated by events of magnitudes (Mw) 7.8, 6.7, 7.5, and 6.0 within an 11-hour window. The EAFZ falls within the CORS-Tr, the Turkish national network of 167 GNSS stations with a spacing of 80-100 km, delivering carrier phase data every 1 s. This dense network allows us to estimate the displacement field during this devastating earthquake sequence with unique spatio-temporal resolution and precision. This presents the opportunity to understand this sequence in ways that are uniquely enabled by GNSS: (1) CORS-Tr data started in 2008 which, together with global data, provides a long-term context on plate rotations, interseismic strain accumulation, co-seismic strain release, and post-seismic relaxation. (2) GNSS effectively extends the temporal sensitivity of seismology from seconds to decades, enabling detection of aseismic deformation that is not associated with the seismic radiation field. (3) In contrast to InSAR, GNSS provides temporal resolution between the events, and unambiguously samples displacements in 3 dimensions. Given these unique capabilities, scientific interpretation can be strongly enhanced by considering the GNSS data together with data from seismology and geodetic imaging techniques such as InSAR, pixel tracking, and optical methods. Here we present results that highlight the strengths of the CORS-Tr GNSS data for constraining all aspects of the seismic cycle, including pre-seismic strain accumulation, the permanent co-seismic displacement field including far-field motions that are sensitive to the deepest part of slip, post-seismic relaxation, and aseismic moment release in between episodic events.

AgLoc: Acoustic-GNSS Location Methods for Earthquake First Responders

DOI: 10.57757/IUGG23-5011 - LINK

Can Xue[1], *Qiang Han*[1], *Wang Zhi*[1]
[1]*Zhejiang University, Control Science and Engineering, Hangzhou, China*

Recent Earthquakes happening in Turkey can have devastating impacts on human communities, while the ability to locate missing persons quickly is crucial to reducing the death toll. However, this task can be challenging when earthquake victims are sparsely distributed in large, GNSS-blocked fields. In this paper, we propose a solution that combines GNSS and acoustic signals to accurately locate missing persons in earthquake ruins. Requiring no infrastructures, our method utilizes accurate acoustic ranging to compensate for the loss of the GNSS carrier phase to achieve higher localization accuracy, especially in complex half-blocked environments or in areas where GNSS signals are weak or even unavailable. The proposed method is not only effective but also shows unparalleled compatibility, making it widely applicable in various disaster response scenarios. Offering a flexible and versatile way of signal combination, AgLoc can be easily compatible with different types of end-equipment, dedicated to providing a solution that enables high-precision localization of first responders and survivors.

Geophysics: Seismic Hazard and Risk Dynamics, Potsdam, Germany

After large damaging earthquakes, fast and well-informed help efforts can save lives. The key information are the location and extent of damage and losses, in particular for disasters that affect large areas. Space-borne imaging methods, together with building-wise exposure data, can enable rapid damage assessments, delivering damage proxy maps for an entire affected region within hours.
Space-borne damage proxy maps are generated e.g. from repeated synthetic aperture radar (SAR) imaging of the ground before and after an event to detect changes in the radar backscatter. Such changes are expressed in a drop of interferometric (InSAR) coherence. Dense human infrastructure, like building agglomerations, shows long-term stable backscatter characteristics and high coherence compared to many natural surfaces. Therefore, a sudden drop in coherence between pre- and post-earthquake images can be attributed to damage on the ground. However, without further information a detected damage tells little about the involved severity concerning human lives. Also, less dense settlement structures like villages may not show as long-term coherent areas and may not be included in damage maps even if strongly affected.
Based on InSAR damage proxy maps from the 2023 Turkey Syria earthquakes, we present an approach to augment InSAR damage maps with information from exposure models combined with open building data. This combination can improve guiding rescue efforts by highlighting approximated damage with exposure models. Also, the building data help revealing blind spots in damage proxy maps, which are method-related, and should not go unnoticed.

We provide a preliminary report on seismicity before and after the 2023 *M*7.8 and *M*7.5 earthquake sequence.

One feature for seismicity during 2013-2022 was the 2020 *M*6.8 earthquake (data from KOERI-RETMC, in Bogazici University). Aftershocks since the *M*6.8 earthquake suggest that the south end of the *M*6.8 rupture was close to the north end of the *M*7.8 rupture. Another feature is a seismic swarm on and around the fault segment, from which the *M*7.8 rupture was initiated. On this segment, an area of large slip (~1.3 m) was overlapped with this swarm. Since late 2022, this swarm was activated, with a clear decrease in the Gutenberg-Richter *b*-value to *b*=0.7~0.8, indicative of an increase in stress. In-depth analyses to verify whether the *b*-value in the large-slip area pronouncedly decreased preceding its occurrence need to be performed, as in the case for the 2011 *M*9 Tohoku-oki earthquake in Japan (Nanjo et al., 2011).

Comparing with the stress imparted by the *M*7.8 and *M*7.5 earthquakes (Toda et al., 2011, 2023), we noted the lack of post-*M*7.5-quake seismicity at the zone of increase in stress beyond the north end of the *M*7.8 rupture and that this area lacking in seismicity closely matched to the area of the *M*6.8 rupture. Future activation that extends to the north on the East Anatolian Fault is unlikely. We will tackle the question whether parts of this fault farther to the north, beyond the *M*6.8 rupture area, and next to the south of the *M*7.8 rupture area, may show future activation.

We provide a preliminary report on seismicity before and after the 2023 *M*7.8 and *M*7.5 earthquake sequence.

The February 6, 2023 Kahramanmaras- Gaziantep Turkey M7.8 Earthquake, was one of the largest earthquake to hit Turkey in several decades. The event caused large number of death in Turkey and Syria. The earthquake resulted in thousands of totally collapsed building and thousands of damaged to the degree that are beyond repairs. The economic loses is not yet estimated but it can be said it is enormous in both countries. The quake devastated several provinces in south central Turkey and northwestern Syria. A fault rupture of 290 km long has been reported. The fault rupture correspond to several segments of East Anatolian Fault Zone. Intensity of ground shaking in the Mezoseismal zone is reported to exceed XI on MMI scale. Ground deformation is vast in Syrian side especially along the Al-Asi River flood plain. Liquefaction features is mapped and observed in serval bends in the flood plain. These liquefaction features are also observed inside village house in the developed part of the flood plain area. Sagging and subsidence of riverbank is observed and river rapids is reported. Subsidence along the Euphrates river flood plan is reported as far as 500 km at the Syrian Iraqi border.

Key words: Liquefaction, Al-Asi river flood plain

On September 5, 2020, an Mw 6.7 earthquake occurred in Luding of Sichuan, China, which is located in the southern part of the Xianshuihe Fault Zone. This earthquake provides a new opportunity for studying the fault movement characteristics of this area. Reliable seismic cycle displacement results obtained by geodetic observation are the basis for the above study. Due to the dense vegetation coverage of the Luding area, the decorrelation is serious and it is difficult to obtain high-quality coseismic displacements by traditional 2-pass differential InSAR. To address this issue, we processed multi-interferometric pairs of Sentinel-1A of ascending and descending orbital directions by time-series InSAR method and extracted pre- and co-seismic information using a polynomial. The results show that: 1) The left region of Xianshuihe Fault moved toward SSE relative to the right region during the pre-seismic or interseismic period, moreover, the Gongga Mountain moved at a high rate. 2) The Luding earthquake caused significant surface displacements. Obviously, high-quality observations are more than the ones by traditional differential InSAR. Therefore, the technological process can be used to obtain seismic cycle displacements of other earthquakes with similar environments and conditions of observation.

The 6 February 2023 Türkiye Earthquakes: Insights for the European Seismic Hazard and Risk Models

DOI: 10.57757/IUGG23-4297 - LINK

Graeme Weatherill[1], Fabrice Cotton[1], Laurentiu Danciu[2], Helen Crowley[3], Eser Cakti[4], Karin Sesetyan[4], Abdullah Sandikkaya-[5], Ozkan Kale[5], Türker Elif[1]

The earthquakes that struck eastern Türkiye and Syria on 6 February 2023 force us to evaluate the models of seismic hazard and risk developed at the European scale for the region, specifically the 2020 European Seismic Hazard Model (ESHM20, Danciu et al.. 2021) and European Seismic Risk Model (ESRM20, Crowley et al.. 2021).

We first verified that the ruptures associated to the two main earthquakes are present within the inventory of ruptures within the source model (the earthquake rupture forecasts or ERFs) for the East Anatolian Fault (first event) and Sürgü-Cardak Fault (second event. Ruptures close in magnitude and dimension to those observed were present in the ESHM20 ERFs.

Preliminary ground motion observations were found to be consistent in their prediction of the expected shaking and its attenuation. Recorded near-fault ground motions also suggest strong pulse-like behaviour, indicating the need for such phenomena to be better captured in the GMMs.

We have finally run scenario risk calculations using the ESRSM20 site, exposure and vulnerability models for the two main earthquakes. Expected fatalities were lower than those reported at the time of writing; however, many factors contribute to this. Further analysis is on-going to understand the difference, but critical areas for future improvement to the risk models should include state-dependent fragility, modelling of further epistemic uncertainty in exposure and vulnerability, and inclusion of spatial- and temporal correlations in ground motions across a region.

On February 6th, 2023 at 01:17 UTC, a devastating M_W 7.8 earthquake nucleated on the Pazarcik segment of the East Anatolian Fault Zone (EAFZ) bounding the Arabian and Anatolian tectonic plates. The fault rupture included nucleation on a secondary fault branch of the EAFZ towards the SE of the main fault and a subsequent rupture propagation towards the NE and SW on the main EAFZ. This event was followed 9 hours later by an M_w 7.5 event on the Sürgü Fault about 100km to the North.

We evaluate the regional earthquake catalog provided by the Turkish Disaster and Emergency Management Presidency in the years leading up to the first mainshock and identify an acceleration in seismicity rates and seismic moment release in the very vicinity of the mainshock epicenter a few months before the earthquake in comparison to surrounding areas. First results show that this activity is concentrated in earthquake clusters on the secondary as well as main fault branch exhibiting low b-values around 0.6-0.7.

We develop an enhanced event catalog in the surrounding of the earthquake doublet spanning the time interval 01/01/2023-11/02/2023 using the Phasenet package and perform automatic P- and S-wave phase picking. Picks are associated into events using GaMMA software and single event and relative event locations are performed using NLLoc and hypoDD. The resulting enhanced event catalog presents the detailed view of the spatio-temporal evolution of seismic actvity around the mainshock epicenter framing the last stage of the preparatory process and the first few days of aftershock activity.

The recent M7.8 - 27 km E of Nurdağı and M7.5 - 4 km SSE of Ekinözü, Turkey earthquakes provide another case history of the intermediate-term real-time prediction by the M8 algorithm (Healy et al. 1992, https://pubs.er.usgs.gov/publication/ofr92401; Kossobokov & Soloviev 2021, https://doi.org/10.1007/s12594-021-1907-8). The algorithm aimed at magnitude range M8.0+ determined Times of Increased Probability (TIP's) starting from July 2021 in the only three out of 262 circles of investigation that spread over most of the global seismic belts; the alert in one of them was confirmed in the next semi-annual updates, most recently in January 2023, eventually being marked by devastating earthquakes that hit Turkey on February 6, 2023. Note that (i) the epicentres of the two coupled events and their aftershocks are just outside the territory, where M8 algorithm aimed at M7.5+ magnitude range is applicable, while (ii) well inside the area of TIPs alerted for M8.0+ events, and (iii) some determinations of the first shock magnitude are equal 8.0 (e.g. GEOSCOPE Mw8.0, GS RAS Ms8.0, RETMC Mwp8.0).

The M8 prediction results accumulated over more than three decades of rigid real-time experiment provide reliable empirical constrains for modelling earthquake sequences and evidence that distributed seismic activity is a problem in statistical physics. Their accuracy is already enough for undertaking earthquake preparedness measures, which would prevent considerable part of damage and human loss, although far from the total.

The study is carried on in the framework of the Russian State Task of Scientific Research Works of IEPT RAS (0143-2019-0006).

The earthquake (Mw=7.7) on 06 February 2023 (01:17 UTC) in Kahramanmaras, Turkiye caused a tsunami in the Eastern Mediterranean despite its strike-slip characteristic and epicenter (37.1123N 37.1195E) ~90 km inland. The earthquake ruptured at a shallow depth (~5) striking about NE-SW on the East Anatolian fault zone and having a devastating impact in southeastern Türkiye. Kandilli Observatory and Earthquake Research Center (KOERI), which is one of the Tsunami Service Providers of the UNESCO IOC NEAMTWS issued four tsunami messages with a tsunami warning 15 min after the earthquake with expected tsunami amplitudes more than 0.5 m. The generated tsunami was recorded at four tide gauge stations, (Iskenderun-Arsuz, Erdemli, Gazimagusa (Famagusta), and Girne (Kerinya) in the Eastern Mediterranean. The recorded water level fluctuations were analyzed after detiding to extract the arrival time of the wave and its profile. For the assessment of the 06 February 2023 tsunami, numerical simulations were performed using the tsunami numerical model NAMI DANCE to understand the generation mechanism and possible location. It is important to identify those features for future preparedness in the area. This small-scale tsunami has been an important reminder in this regard and a test for the effective working of the early warning system. A field survey was also performed on 11-13 February 2023 to investigate the tsunami traces, conduct eyewitness interviews and coastal structure performance evaluation. The simulations are repeated using the survey findings and the modeling results are compared with the measurements. The results will be presented with discussions.

The Epidemic-Type Aftershock Sequence (ETAS) model is the most effective mathematical model to describe the short-term space-time clustering. The setup of the ETAS model is complicated by the high number of unknown and correlated parameters. The most recent ETAS parameterizations introduce the space-time variability of some parameters that make the model calibration even more arduous. Here, we investigate the ETAS model in an opposite perspective; we look for the simplest ETAS parametrization that can satisfactorily describe the short-term space-time earthquake clustering in crustal tectonic regions; we name this model simplETAS. Owing to its simplicity, simplETAS is easy applicable in almost all crustal tectonic regions. This ease of use leads implicitly to some important features that are worth being remarked; simplETAS provides i) important physical indications on which clustering parameter is mostly region and time-independent; ii) a reference model that can be used as benchmark to measure the relative forecasting skill of other models in earthquake forecasting experiments; iii) a simple but effective approach to generate synthetic earthquake catalogs of different length that can be used in seismic hazard and risk analysis, overcoming all problems related to the declustering and the Poisson assumption. Finally, we show that the simplETAS model calibrated with the Italian seismicity of the last decades is able to describe satisfactorily the space-time occurrence of the out-of-sample largest earthquakes in historical catalog.

3D-ETAS model with depth-dependent trigger potential

DOI: 10.57757/IUGG23-0576 - LINK

Behnam Malekiasayesh[1], Sebastian Hainzl[1], Gert Zöller[2]
[1]GFZ German Research Centre for Geosciences, Section 2.1, Potsdam, Germany
[2]University of Potsdam, Institute of Mathematics, Potsdam, Germany

In the past decades, the Epidemic Type Aftershock Sequence (ETAS) model has been widely used for describing the occurrence and clustering of earthquakes in space and time. Because of large depth uncertainties in the past, this model is two-dimensional and uses only epicentral information. Current earthquake catalogs provide high-precision depth values that contain valuable information. Thus, we extend the spatiotemporal ETAS model to 3D versions exploiting the full hypocentral information of earthquake catalogs by incorporating a depth-dependent kernel into the trigger function. To explore its most appropriate parametric form, we first examine different triggering functions for the depth difference of the aftershock-mainshock pairs identified by the Nearest-Neighbor (NN) method, showing that a magnitude-dependent power-law kernel fits best the earthquakes data in Southern California. Therefore, in order to incorporate the earthquakes' depth information in the ETAS model, we extend the established 2D spatial power-law kernel by using hypocentral instead of epicentral distances. Furthermore, in our extended 3D-ETAS model, we consider space-dependent background activity, where we additionally allow for depth-dependent aftershock productivity. A first application to data from Southern California shows a good performance of the 3D model. We also find that the aftershock productivity strongly depends on depth, similar to the seismic moment released by the mainshocks, which may be related to depth-dependent seismic coupling.

Long-term recurrence pattern and stress transfer along the Kefalonia Transform Fault Zone (KTFZ), Greece: Implications in seismic hazard evaluation

DOI: 10.57757/IUGG23-0266 - LINK

Christos Kourouklas[1], Eleftheria Papadimitriou[1], Vassilios Karakostas[1]
[1]Aristotle University of Thessaloniki, Geophysics Department, Thessaloniki, Greece

Large earthquakes ($M^{3}6.0$) recurrence pattern on specific faults is one of the key parameters for constructing Earthquake Rupture Forecast (ERF) models. These models are based on characteristic earthquake hypothesis and return the likelihood of the occurrence of a large earthquake in a specific time span either as a time-independent or an elastic-rebound motivated renewal process. Large earthquake occurrence is characterized by short- and long-term clustering segments due to the permanent and temporal stress changes and transfer as a potential factor to influence their recurrence by moving a fault towards or away from failure. We aim to investigate the long-term recurrence behavior of large ($M_w^{3}6.2$) earthquakes associated with the major fault segments of the KTFZ, which exhibits the highest moment rate release in Greece, with frequent occurrence of strong earthquakes with magnitudes $M_w^{3}6.0$ during both the instrumental and the historical era of seismicity. This data sample enables the detailed study of these earthquakes recurrence times, considering the effect of stress field evolution and stress transfer among the segments of the local fault network. Then, the Poisson and the Brownian Passage Time (BPT) distributions are applied, aiming at the development of both time-independent and renewal statistical models for earthquake generation associated with the KTFZ fault segments.

Funded by the European Union. Views and opinions expressed are however those of the author(s) only and do not necessarily reflect those of the European Union or European Commission – Euratom. Neither the European Union nor the granting authority can be held responsible for them.

We aim to investigate the long-term recurrence behavior of large ($M_w^{3}6.2$) earthquakes associated with the major fault segments of the KTFZ, which exhibits the highest moment rate release in Greece, with frequent occurrence of strong earthquakes with magnitudes $M_w^{3}6.0$ during both the instrumental and the historical era of seismicity. This data sample enables the detailed study of these earthquakes recurrence times, considering the effect of stress field evolution and stress transfer among the segments of the local fault network. Then, the Poisson and the Brownian Passage Time (BPT) distributions are applied, aiming at the development of both time-independent and renewal statistical models for earthquake generation associated with the KTFZ fault segments.

Enhancement of medium-term earthquake forecasting in New Zealand by incorporating strain-rate into the EEPAS model

DOI: 10.57757/IUGG23-0747 - LINK

Sepideh J Rastin[1], David A. Rhoades[2], Annemarie Christophersen[2]
[1]GNS Science I Te Pū Ao GirdAKL-, Earthquake Physics and Statistics, Auckland, New Zealand
[2]GNS Science I Te Pū, Earthquake Physics and Statistics, Lower Hutt, New Zealand

The “Every Earthquake a Precursor According to Scale” (EEPAS) model provides the medium-term component of public earthquake forecasts in New Zealand (NZ). EEPAS employs the “precursory scale increase” (Ψ-) phenomenon to forecast future earthquake occurrence rates with time-horizons up to a few decades. Ψ is the rate and magnitude increase of minor earthquakes preceding major earthquakes. Three associated predictive-scaling relations link mainshock magnitude , precursor time and precursory area .

Studies of Ψ in synthetic catalogues showed that the expected is inversely proportional to an overall reduction of fault slip rates. The slip-strain rate connection therefore motivates us to enhance EEPAS forecasts by incorporating strain-rate.

We allow the time distribution in EEPAS to depend on the strain-rate and introduce an additional parameter to quantify this dependence. Optimising the new parameter for the New Zealand catalogue confirms an inverse proportionality between the local strain-rate and the local precursor time. The information gain over the original EEPAS model is small because few target earthquakes occur where the strain-rate is low.
The forecast should be compensated for incompleteness of precursory earthquake contributions due to the limited lead-time from the start of the catalogue to the occurrence of target earthquakes. The incompleteness is especially severe for low strain-rate areas where is longer. Further incompleteness can result from the precursory area for some target earthquakes extending outside the region covered by the catalogue. Such considerations should improve forecasting for low strain-rate areas.

The global Collaboratory for the Study of Earthquake Predictability (CSEP, https://cseptesting.org) advances rigorous research into earthquake forecasting through open science practices. These include, foremost, a dedication to testing forecasts in a truly prospective manner, along with strict standards for reproducibility, community-endorsed model evaluation approaches, and open-source software. Now operating for over 15 years, CSEP recently re-invented itself with a modern community-developed open-source Python software toolkit (pyCSEP), a broader range of model classes and evaluations, and better open access to models, data and test results through reproducibility packages. This reinvention facilitated a surge in new research, driven largely by a global and engaged early career researcher community. In this overview talk, I will review the progress and new insights this has generated.

A powerful seismic sequence struck the Turkey-Syria border on Feb. 6 with three earthquakes having M>6.5. At 01:17 UTC, a M7.8 earthquake occurred that was followed 11 minutes later by a M6.7, and around nine hours later by a M7.5. In the first 24 hours, 20 aftershocks with M>5 and 68 events with M>4 have been registered.

Recently, we have improved and tested a Bayesian simulation-based workflow for spatio-temporal early seismicity forecasting based on ETAS model. It exploited the versatility of the Bayesian inference to adaptively update the forecasts based on the incoming information from the ongoing sequence. This workflow is demonstrated and verified through retrospective early seismicity forecasting of Central Italy 2016 and the 2017-2019 western Iran seismic sequences.

We test this workflow to predict the spatial distribution of events and their uncertainties for various forecasting intervals within this seismic sequence. Bayesian updating is first employed to learn the ETAS model parameters conditioned on the registered events (that already took place). Then, plausible sequences of events during the forecasting interval are adaptively generated. To this end, we strive to simulate those plausible sequences by embedding a branching process formulation inside the proposed workflow as an alternative to the piece-wise stationary integration of the conditional rate. The latter could be a new feature to the forecasting workflow, while its efficiency in providing early forecasts is explored during this study.

This work has been supported by PRIN-2017 MATISSE project No 20177EPPN2, funded by Italian Ministry of Education and Research.

Future scenarios for induced seismicity at the Groningen gas field, Netherlands

DOI: 10.57757/IUGG23-1188 - LINK

Section 2.1: Physics of Earthquakes and Volcanoes, Potsdam, Germany

The Groningen gas field is one of the most frequently considered sites for studying induced seismicity. The public concern about seismic activity increased drastically with the M3.6 Huizinge earthquake in 2012. Since then gas production has been reduced and is planned to be terminated soon. In our study we first present statistical estimates of the maximum possible magnitude based on the earthquake catalog from 1991 until present. Second, future scenarios for seismicity are calculated for various statistical and physical models using gas production scenarios and simulated stress values until 2052. We find that a model based on rate-and-state dependent friction with additional aftershocks fits best to the data. Despite the overall decreasing earthquake rate resulting from decreasing production volumes, the findings indicate a considerable probability that the maximum expected magnitude in the next 30 years exceeds the maximum observed magnitude from the past 30 years.

Estimating the size of future earthquake disasters by fatality numbers (Fat) is possible with a useful accuracy. Governments, first responders and the population in a seismically active region can be told whether they must be prepared for major, medium, or small numbers of earthquake fatalities. Most of the fatality calculations with the tool QLARM made within minutes after earthquakes worldwide have been correct within factors of 2 to 3, or better. We expect that estimates of future numbers of fatalities are also in this range of accuracy. We follow these steps. 1) We verify that QLARM fatality estimates are correct to better than a factor of 2 for historic earthquakes. 2) We identify an active fault segment, L(local), that has not ruptured recently, and that may break in one event. 3) We estimate the magnitude, M(local), from the known relationship between L and M. 4) We calculate the number of fatalities for a line rupture of L(local), with M(local) and the local attenuation determined in step (1). 5) The data on building stock quality is contained in the program. We have estimated future earthquake fatalities in the Himalaya, China, Kirghizstan, Greece, Italy, Haiti, Portugal, Algeria, Spain, and Morocco. We have found that some regions contain only short faults typically $L \leq 30$ km, implying $M \leq 6.5$ and resulting in Fat < several hundreds. In regions with $L \approx 100$ km and 300 km, respectively (M7+ and M8) ruptures result in several thousand and several tens of thousand fatalities, respectively.

The maximum likelihood estimation of the earthquake frequency-magnitude parameters (the Gutenberg–Richter *b*-value, the mean seismic activity rate and the area characteristic maximum possible earthquake magnitude is provided in the case of a time-varying level of completeness. In several recent studies, the catalogue with the time-varying level of completeness is defined as one that can be divided into sub-catalogues, each with a sharp jump of. This work provides a maximum likelihood estimator of the earthquake frequency-magnitude parameters when the time-varying level of completeness is a continuous, smooth function without "jumps" and abrupt changes.

Statistical earthquake forecast models are a critical component of several products released by the U.S. Geological Survey as part of its mission to deliver actionable information to decision makers in the US. These include the National Seismic Hazard Model (NSHM) and Operational Aftershock Forecasts (OAF), the latter of which can include swarm forecasts. Both products require earthquake forecast models that are applicable on different timescales, ranging from days to years (OAF) to decades (NSHM). OAF uses short-term forecast models that are based primarily on catalog statistics and include clustering behavior, such as encompassed in Reasenberg and Jones (1989), the ETAS model (Ogata, 1988), and swarm models (Llenos and van der Elst, 2019). The NSHM uses a long-term (50-year) earthquake forecast, one component of which is a smoothed seismicity model based on an earthquake catalog. Clusters are removed when forecasting the location of future seismicity but retained when estimating the future earthquake rate. Both OAF and the NSHM face challenges in catalog incompleteness, in both the short term and the long term. And both may be affected by anomalous earthquake rate changes, such as natural earthquake swarms, human-induced seismicity, or volcanic events. In this presentation, I will give an overview of the statistical models that are used for these two products, updates that have been made to address some of these challenges, future updates that could be considered such as the use of machine learning methods, and how the forecasts are used and presented to the public.

Developing guidance to communicate global aftershock forecasts

DOI: 10.57757/IUGG23-4869 - LINK

The U.S. Geological Survey (USGS) is responsible for public aftershock forecasts following US earthquakes. An automated system produces forecasts for most M5+ earthquakes. While this system is not operational for earthquakes outside the US, the USGS has received requests for forecasts following damaging earthquakes worldwide, particularly those with a high number of fatalities (orange or red level on the PAGER scale). However, aftershock forecasting globally has the inherent challenge of communication across different languages and cultures. Further, aftershock forecasts made from outside the affected region can be a challenge for local science communicators because they may need to respond to questions about a forecast that they may not be familiar with themselves. Effective communication of aftershock forecasts for earthquakes across the world requires developing products that can serve non-English-speakers, and providing local science communicators with tools to help them respond to questions about the forecasts. To support the communication of aftershock forecasts globally, the USGS is developing additional public tools for local science communicators. A communication guide will accompany the forecast template and will be translated into multiple languages. To develop this communication guide, we are facilitating meetings with science communicators in different countries to solicit feedback on its components. Additionally information regarding protective action will be updated. The USGS currently recommends "Drop, Cover, and Hold On", which may not be appropriate in countries with poorly constructed buildings. By developing additional communication tools, aftershock forecasting will be more effective and accessible to reduce seismic risk worldwide.

Researchers from New Zealand have engaged in developing and testing earthquake forecasting models for many decades. The existing earthquake forecasting models can be classified into three categories, (1) short-term or aftershock models that describe the decay of the earthquake occurrence rate following a large event, (2) medium-term models that are variations of the Every Earthquake a Precursor According to Scale (EEPAS) model, which is based on the observation that the size and frequency of earthquake occurrence tends to increase in the vicinity of an upcoming large earthquake and aims to forecast upcoming large events in the coming months to decades, and (3) long-term models.

In 2010, following the M7.1 Darfield earthquake that initiated the Canterbury earthquake sequence, GNS Science began to provide earthquake forecasts to the public. There were several further earthquake responses over the years, the largest being the 2011 M6.2 Christchurch earthquake and the 2016 M7.8 Kaikoura earthquake.

A new automated seismic processing software, introduced in 2012, caused inconsistencies in the earthquake catalogue, especially with magnitudes. It has been a slow process to resolve these issues. In the meantime, we have been limited to forecast earthquakes of magnitude 5 and larger.

In the future, we envisage to have an automated system provide regular earthquake forecasts to the public, and to engage more with users to provide the information that they need for decision-making in a seismic crisis and for planning for earthquake resilience.

Good practices in developing, testing and communicating earthquake forecasts: an expert elicitation

DOI: 10.57757/IUGG23-5039 - LINK

Leila Mizrahi[1], *Irina Dallo*[1], *Lorena Daphna Kuratle*[1]
[1]*Swiss Seismological Service, ETH Zurich, Zurich, Switzerland*

Strong earthquakes are followed by numerous aftershocks, which themselves can be strong and devastating, sometimes even stronger than the initial main event. Although earthquakes cannot be predicted, the occurrence of aftershocks in space, time, magnitude and numerosity follows several universally observed empirical laws. Operational earthquake forecasting (OEF) systems aim to provide a probabilistic assessment of expected earthquake occurrence in near-real time, enabling informed decision-making for civil protection, authorities, the public, or other user groups.

While few agencies worldwide have OEF systems in place, most countries, even those in regions of high seismic hazard, only estimate the time-independent, long-term earthquake probability as part of their seismic hazard and risk assessment, which serves a different user group involved in long-term decision making. This lack of OEF systems may be due to a lack of data, knowledge, resources, or guidance required to build them. With a plethora of forecasting models and testing schemes published every year, it is difficult to choose the most appropriate ones. On top of technical choices involved in the development and testing of forecasting models comes the additional challenge of communicating forecasts to users.

In our study, we conducted an elicitation of expert views on these topics, aiming to provide good practice recommendations for the development, testing and communication of earthquake forecasts. We applied the Delphi method – with two surveys and one workshop – to identify consensus and dissent among a group of 20 international earthquake forecasting experts on these issues, and here present the results of this elicitation.

Mega-thrust earthquake potential along the subduction zone of Peru based on the earthquake energy-budget

DOI: 10.57757/IUGG23-3817 - LINK

Nelson Pulido[1], *Juan Carlos Villegas-Lanza*[2]
[1]*National Research Institute for Earth Science and Disaster Resilience, Earthquake and Tsunami Research Division, Tsukuba, Japan*
[2]*Instituto Geofísico del Perú, Ciencias de la Tierra Sólida, Lima, Peru*

We investigate earthquake potential of megathrust earthquakes in Peru based on the interseismic coupling model at the subduction interface (ISC) (Villegas-Lanza et al. 2016). Northern Peru displays a shallow and weak ISC, whereas Central and Southern Peru are highly coupled. Recent studies in the Nankai-Tonankai subduction region in Japan indicate that slip deficit regions do not directly reflect the local frictional strength characteristics controlling fault slip behavior at the plate interface (Noda et al. 2021). Therefore, to investigate the necessary conditions for megathrust earthquake generation we calculate the difference between accumulated strain energy during the interseismic period, with fault fracture energy (G), for a given slip scenario. A scenario cannot occur unless the accumulated strain energy exceeds G. To calculate G we use a scaling between average fault slip and G for subduction interface earthquakes, obtained from the NEIC global dataset of finite fault slip rupture models (Hayes et. al, 2017), and the 2D finite width slip dynamic rupture model (Pulido 2022).

We calculated the shear stress accumulation rate and total accumulated shear stress at the Peruvian subduction margin, based on the slip deficit rate model, and interseismic periods since the largest historical earthquakes for the Northern, Central and Southern segments of the subduction interface. Our results indicate that the Central segment in Peru has currently accumulated the largest amount of shear stress, corresponding to an earthquake up to Mw~8.8. Using the earthquake energy balance we quantified the necessary conditions for megathrust earthquake generation across the subduction margin in Peru.

We investigate earthquake potential of megathrust earthquakes in Peru based on the interseismic coupling model at the subduction interface (ISC) (Villegas-Lanza et al. 2016). Northern Peru displays a shallow and weak ISC, whereas Central and Southern Peru are highly coupled. Assessing seismicity and magnitude distributions for NE Brazil earthquake catalog for Seismic Hazard Analysis purpose

DOI: 10.57757/IUGG23-0141 - LINK

José Fonsêca[1], Stanisław Lasocki[2], Aderson do Nascimento[1]
[1]Federal University of Rio Grande do Norte,
Seismological Laboratory of the Department of Geophysics, Natal, Brazil
[2]Institute of Geophysics Polish Academy of Sciences, Department of Seismology, Krakow, Poland

Results of the probabilistic analysis of stationary seismic hazard considerably depend on the quality of the data declustering and the reliability of distribution models for the earthquake occurrence and magnitude. We studied the NE Brazil catalog to optimally perform the aftershock removal and select the best distribution models. For such analysis, events from 1990 onward were collected from the Brazilian Earthquake Catalogue (SISBRA). First, we determined the magnitude completeness (mc) using maximum curvature, 90%, and modified goodness of fit approaches. Subsequently, we applied two declustering methods of Gardner and Knopoff (1974) and Reasenberg (1985) and compared the results. Reasenberg's (1985) declustering algorithm was chosen as being less conservative. The Anderson-Darling test was applied to test the exponentiality of both the interevent time and magnitude distribution. We tested the complete dataset and separately the data from the time periods in which monitoring setups had been different. In every case, the test rejected the exponentiality of the interevent time distribution. The magnitude distribution of earthquakes from the complete dataset also disagreed with the exponential distribution. However, separate tests of the data from selected spatially subsets unveiled nonrejection of exponentiality for 3 out of 4 most seismically active areas.

This study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior - Brasil (CAPES) - Finance Code 001, and CNPq (Brazil) grants. It was also partially supported in the framework of the statutory activity from the subvention of the Ministry of Science and Higher Education of Poland.

Seismicity Analysis and Probabilistic Hazard Assessment of earthquakes in a circular region of 2005 Kashmir Earthquake of the North-West Himalaya

DOI: 10.57757/IUGG23-0087 - LINK

Uma Ghosh[1]
[1]*SIDDHINATH MAHAVIDYALAYA, MATHEMATICS, BELUR MATH, India*

ABSTRACT
Spatial distribution of seismicity and seismic characteristics like b-value, fractal dimension, energy release and recurrence period are assessed for the circular region of radius 400 km, taking epicenter of 2005 Kashmir earthquake (34.45°N -73.65°E) as Centre. The EHB relocated earthquakes $M_b \geq 3.8$ are selected for the period 1964-2020 from the International Seismological Centre catalogues.

The Maximum Likelihood Method (MLM) and Least Square Method are used for calculating b-value. The fractal dimension is estimated using the correlation integral method. The events are also used for estimating radiated energy in the region. The probability of occurrence of moderate earthquakes ($M_b \geq 6.0$) during a specified interval of time has been estimated on the basis of four probabilistic models namely, Exponential, Weibull, Gamma and Lognormal. The cumulative and conditional probabilities are estimated using the above four probabilistic models. The model parameters have been estimated by the Maximum Likelihood Estimates (MLE). It is estimated that there is a 99% probability for occurrence of at least one earthquake of magnitude $M_b \geq 6.0$ in this region in a time window of four-five years from the year 2019.

Probability density function maps, using Poisson distribution for the magnitude $M_b \geq 6.0$, were prepared. These maps are used to estimate the percent probability of occurrence of next event with different return periods. The vulnerable zones identified by different spatial distribution maps are further corroborated with the probabilistic models to assess the seismic hazards in the region.

Scientists frequently used stress changes to evaluate seismic hazards. A 3D mechanical model of the Indian plate has been considered to simulate the stress and strain distribution using finite element method (FEM). The model is divided into 19 geological regions, and each 19 parts is sub-divided into five layers, and for each layers different elastic parametric values are given and the effect of the material heterogeneity is studied. It is observed that in comparison to homogeneous model, heterogeneous model shows close correlation with GPS measurement. Also, the stress distribution contour estimated by the homogeneous model is compared with the seismotectonic map of the Indian subcontinent but it does not agree as homogeneous model estimates a low-stress value (~180 MPa) in highly seismically active regions like Indo-Burmese region, the Himalayan region and the Andaman arc region. While, heterogeneous model shows high stress of the order of 60 MPa–10^5 MPa at the Himalayan plate boundary, Indo-Burmese region, Andaman arc, Indian Mid-Oceanic, and some parts of the Saurashtra and Southern Granulite regions and is able to reasonable capture the regional stress distribution of the Indian plate. It is concluded that the average stress difference caused by neglecting the heterogeneity is ~ 10–20 MPa, which is 100 times larger than the triggering stress (0.1 MPa). Which will be useful to assess the seismic hazard to identifying seismically active zones by interpreting the strain rate and stress distribution affecting the location and size of earthquake due to lithospheric and regional lateral heterogeneity.

A large number of studies aimed at seismic hazard assessment and earthquake forecasting relies on the assumption that background seismicity is a realization of a homogeneous Poisson process over time, though not necessarily in space. In this study a statistical analysis is performed to assess whether the background seismicity, as identified by different declustering methods, holds the spatio-temporal features typical of such a Poisson process. Various spatiotemporal measures are applied to quantify the residual space and time clustering in the background seismicity, which can be used to assess the performances of the declustering methods in removing the spatiotemporal clustering patterns from the full catalogue. Specifically, the Allan Factor (AF) and the Markov Modulated Poisson Process (MMPP) are used for the analysis of time patterns, while the Morisita Index (MI) is used for space clustering analysis.

To exemplify the proposed procedure, two declustering methods, namely the Nearest Neighbour algorithm (Zaliapin and Ben-Zion, GJI 2016) and the Stochastic Declustering algorithm (Zhuang et al., JGR 2004), are applied to identify the background seismicity of Northeastern Italy. Our results show that the time correlation and the space clustering are reduced, but not totally eliminated, in declustered catalogues. Moreover, we found that the MMPP with multiple states is a more suitable background seismicity model than the traditional homogenous Poisson process. These results are well consistent with those obtained for Northern Algeria (Benali et al., Axioms, 2023), showing that none of the adopted declustering methods totally eliminated the spatiotemporal clustering from the full earthquake catalogue.

This study identifies structure pairs with the potential for simultaneous rupture in a coseismic period and quantifies their rupture recurrence intervals. To assess the potential for a multiple-structure rupture, we calculated the probability of Coulomb stress triggering between seismogenic structures. We assumed that a multiple-structure rupture would occur if two structures could trigger each other by enhancing the plane with thresholds of a Coulomb stress increase and the distance between the structures. We discussed the uncertainties of multiple-structure rupture pair identification from various thresholds of stress change and structure distances, effective friction coefficient, and rotation of rake angles. Note that since our approach is based on static Coulomb stress change, the possibility of a multiple-structure rupture in a coseismic period might be overestimated. To estimate the recurrence intervals for multiple-structure ruptures, we implemented a scaling law and the Gutenberg-Richter law. Considering that a single structure may be involved in multiple cases of multiple-structure ruptures, we developed new formulas for slip partitioning in a complex fault system. We discussed the uncertainty of recurrence interval from epistemic uncertainties from deviations of slip rate and rupture area, various empirical formula of rupture parameters. Due to a larger characteristic magnitude and a larger displacement of the multiple-structure rupture, the rupture's recurrence interval could be longer. Therefore, considering the multiple-structure rupture leads to an increase in seismic hazard in a long return period, crucial for the safety evaluation of infrastructures.

Experimental studies suggest that large, locked faults accumulate stresses both on themselves and in their surroundings, producing changes in low-magnitude seismicity patterns on regional scales. Still, the complex spatiotemporal distribution of low-magnitude seismicity, in conjunction with the incompleteness of previous earthquake catalogs, hinders determining whether large seismic events are unequivocally preceded by some kind of seismic or tectonic unrest. This can be alleviated in the near future thanks to the advent of new machine learning-based methodologies, which offer alternative ways to recognize subtle and non-linear hidden patterns from previous experience. Here, we explore with a new multivariate, supervised, machine learning-based algorithm whether low-magnitude seismicity hides robust, non-linear, precursory patterns that may unequivocally alert of impending large magnitude earthquakes. Our algorithm, which integrates a random forest machine learning approach and statistical features built from openly-available earthquake catalog data, reveals that the M6.4-M7.1 2019 Ridgecrest (California) sequence and the M7.1 2018 Anchorage (Alaska) earthquake were preceded by up to ~3 months of tectonic unrest on regional scales, as evidenced by abnormal low-magnitude seismicity that spread over ~15-25% of the total area of Southern California and Southcentral Alaska. Our analysis is further supported by finite element solid mechanics models which show that the existence of large, locked faults can increase the average shear stress in surrounding areas by up to ~80% upon constant compressional loading. These findings may open up new perspectives for surveillance agencies to detect when a region approaches an earthquake of great magnitude weeks to months before it occurs.

Recent multifault ruptures, such as the 2010 El Mayor-Cucapah and 2016 Kaikōura earthquakes, have demonstrated the potentially complex interactions of faults in single earthquakes, contrasting with the typical assumption of characteristic fault ruptures in seismic hazard assessment. Physics-based earthquake simulators, such as RSQsim (Dieterich & Richards-Dinger, 2010; Richards-Dinger & Dieterich, 2012), offer one approach to understanding potential multifault earthquakes, and their effects on the time-dependence of earthquake recurrence. Here we investigate the effects of known uncertainties in fault-network geometry on the outputs of such simulators. We use the Canterbury and North Marlborough regions of the South Island of Aotearoa New Zealand – the epicentral region of the 2016 Kaikōura earthquake – as a case study. Using recently developed fault modelling tools, we create 3D fault networks corresponding to a range of possible fault-network geometries in the region, including the potential for missing faults and variable geometries at fault intersections. The different networks we develop are motivated by key observations from the Kaikōura earthquake, such as the high proportion of previously unmapped faults in the rupture (Litchfield et al., 2018), and by explicit uncertainties in the New Zealand Community Fault Model (Seebeck et al., 2022). We generate synthetic earthquake catalogues on these different fault networks and investigate their similarities and differences, both statistically and in terms of the generated multifault ruptures. By doing so, we are able to better understand how the "known unknowns" of fault-network geometry impact earthquake simulator outputs.

The study of tsunami hazard is frequently approached from numerical modelling in a deterministic or probabilistic way. When probabilistic assessments are developed, epistemic and aleatory uncertainties are taken into account and incorporated into logic-tree and Monte Carlo approaches. Our approach is based on the use of physics-based earthquake simulators, developed in recent decades to overcome the temporal limitation of the instrumental seismic catalogue in probabilistic seismic hazard assessment (PSHA). Recent development of numerical codes based on the rate-and-state constitutive law for fault slip and frictional behaviour (RSQSim) allows also the modelling of the short-term rupture process based on a quasi-dynamic physical approximation. We have applied this model to the Eastern Betic Shear Zone, where one of the major faults of the western Mediterranean is present, the Carboneras Fault. This fault is a left-lateral transpressive structure oriented with a length of ∼150 km, most of them offshore, and a slip rate of 1.3 mm/yr. This fault has been proposed as source of the 1522 Almeria earthquake (Int. VIII-IX) possibly related to a local tsunami. We present tsunami simulations from seismic ruptures of a 1 Myr synthetic seismic catalogue generated with RSQSim, consistent on 773,893 events with magnitudes Mw 3.3 - 7.6. The Carboneras Fault has the capacity to generate locally damaging tsunamis. The frequency - magnitude distribution of the seismic catalogue departs from the classical Gutenberg-Richter potential relation showing a bell-shaped distribution for the bigger events. The inter-event times for the maximum earthquake magnitudes are between 2000 and 6000 years.

The observed variability of seismic dynamics in the Pacific Northwest

DOI: 10.57757/IUGG23-0382 - LINK

Anastasia Nekrasova[1], *Vladimir Kossobokov*[1,2]
[1]*Institute of Earthquake Prediction Theory and Mathematical Geophysics- Russian Academy of Sciences, IEPT RaS, Moscow, Russian Federation*
[2]*International Seismic Safety Organisation, ISsO, Arsita, Italy*

To gain new insight into patterns of earthquake activity in the Pacific Northwest we study regional seismic dynamics in terms of several moving averages. In particular, the variability of the Unified Scaling Law for Earthquakes (USLE) coefficients in 3D have been evaluated at the three separate seismic focal zones – Southern Kamchatka, Northern Kamchatka, and Commander segment of Aleutian arc.

USLE states that the logarithm of expected annual number of earthquakes of magnitude M or larger in an area of linear dimension L follows within the magnitude range [M–,M+] the relationship $\log N(M,L)=A+B\times(5-M)+C\times\log L$, where A, B, C are empirical constants. Naturally, USLE compliments to a- and b-values of the Gutenberg-Richter relationship with C, an estimate of fractal dimension of epicentres at a given site. USLE allows for realistic rescaling seismic hazard to the size of exposure at risk and its scaling parameter η controls regional distribution of inter-event times.

We considered shallow and intermediate depth earthquakes with magnitude $M \geq 4.0$ in 1996–2020 reported in the open access database of the Kamchatka Branch of GS RAS.

The results show up distinct statistically significant differences in the southern and the northern segments of the Kamchatka slab as well as in the western segment of the Aleutian arc. The plots of the three USLE coefficients in 3D display their complex correlation patterns of different type in the preselected volumes of seismic genesis.

The study is carried on in the framework of the Russian State Task of Scientific Research Works of IEPT RAS (0143-2019-0006).

Development of seismic process before the M 8.3 Illapel, Chile, 2015 Earthquake observed in an equivalent dimension space

DOI: 10.57757/IUGG23-0923 - LINK

Yaseen Mahmood[1]*, Stanisław Lasocki*[1]
[1]*Institute of Geophysics PAS, Seismology, Warsaw, Poland*

The dynamics of seismic processes is expressed by non-random, stochastic characteristics of seismic series. Investigating these characteristics may assist in solving earthquake prediction problems. We approach the seismic process development employing the probabilistic transformation to equivalent dimension (ED) space of earthquake parameters. The present research concerns the seismic process preceding the magnitude 8.3 Illapel, Chile, 2015. The seismic catalog is reparametrized. The new parameters of seismic events are interevent time, orthodromic epicentral distance, and magnitude. Then these parameters are transformed to ED space by adopting a non-parametric kernel estimation method. The transformed parameters are now comparable, and the distance between the earthquakes in ED space is Euclidean. We trace the changes in time of the average distance between earthquakes in the ED space, calculating this distance in sliding data windows of the same number of earthquakes. The results exhibit distinct and statistically significant changes in the two years preceding the Illapel mainshock. The average distance between earthquakes increased from 2013 to the midst of 2015. Then the distance decreased until the mainshock in September 2015. A similar pattern was obtained in the previous study of seismicity clustering before the magnitude 8.2 Tehuantepec, Mexico, 2017 earthquake, though in the Tehuantepec earthquake's case, the systematic changes of the average distance between earthquakes before the mainshock lasted longer, some eleven years.

The results exhibit distinct and statistically significant changes in the two years preceding the Illapel mainshock. The average distance between earthquakes increased from 2013 to the midst of 2015. Then the distance decreased until the mainshock in September 2015. A similar pattern was obtained in the previous study of seismicity clustering before the magnitude 8.2 Tehuantepec, Mexico, 2017 earthquake, though in the Tehuantepec earthquake's case, the systematic changes of the average distance between earthquakes before the mainshock lasted longer, some eleven years.

New clues for seismic hazard from statistical properties of seismicity, rheology and tectonics

Probabilistic seismic hazard models are usually grounded on a basilar statistical analysis of recent and historical seismicity, and only a small number of them also considers the local geodetic strain and the discrete seismogenic sources. Nevertheless, a large amount of information is buried in spatial and temporal time series as well as in the geophysical properties of the different tectonic settings. Here, we show some preliminary results about the connection between advanced statistical properties of seismicity, rock physics, tectonics and the mid-/long-term seismogenic potential. The role of local and global, spatial, and temporal clustering of seismic events is deeply analysed also with reference to local geodynamics and other routinely investigated features of seismicity, e.g., the b-value of the Gutenberg-Richter law.

The 2016 Mw 6.5 earthquake struck a large region of the Apennines in central Italy and produced impressive and complex surface ruptures. These ruptures were investigated and mapped by field geologists for years after the earthquake thanks also the use of remote sensing data.
Here we present detailed maps of the ground deformation pattern produced by the Vettore normal fault activated during the Mw 6.5 mainshock, using Differential Synthetic Aperture Radar Interferometry. The DInSAR analysis has been retrieved from ALOS-2 SAR data, via the Parallel Small BAseline Subsets (P-SBAS) algorithm. At the local scale, we automatically identify many surface ruptures, most of which already observed in the field. At the large scale, we trace a set of five geological cross-sections to inspect a possible link between the coseismic vertical displacement, the lithology distribution and the tectonic structures of the area (i.e., thrusts, normal faults). On these sections, we also project the seismicity distribution recorded during October 2016.
The integration of such datasets allows the recognition of an important geological control in the overall distribution of the deformation, which shows maximum values in correspondence of the carbonatic multilayer and minimum values within the clastic succession. The distribution of seismicity allows also us to distinguish seismogenic by aseismic slip associated with fault ruptures.
The results of this work demonstrate that the integration of surface geology, remote sensing data and seismicity, can lead to a better understanding of the influence of geological structures on the distribution of the ground deformation associated with earthquakes.

Estimating the background stress fields in the source region of the 2016 Kumamoto earthquake based on shear strain energy

DOI: 10.57757/IUGG23-0404 - LINK

We aimed to estimate the background stress field prior to the 2016 Kumamoto earthquake sequence, examining temporal changes in elastic strain energies from various aspects. Firstly, we modeled the six components of the background stress fields by examining the fault orientations relative to the stress orientation, and by assuming the Coulomb failure criterion with three apparent friction coefficients of m' = 0.4, 0.2, and 0.1. We also calculated coseismic stress change fields due to the largest preshock and the mainshock of the sequence, using the slip distributions of the events and slip response function. We obtained three (absolute) stress fields immediately after the mainshock, superposing the coseismic stress changes fields on the background stress fields. In the case of m' = 0.4, the larger slip contributed to release shear strain energies more. We found similar tendency in the case of m' = 0.2 except for the shallow part with large slip on the Hinagu fault. In the case of m' = 0.1, on the other hand, large slip in most shallow parts contributed to increase shear strain energies. The results with m' = 0.1 are inconsistent with that earthquakes are physical process to release shear strain energies. This perspective is supported by further analyses on the relation between temporal changes in slip and shear strain energies and temporal changes in stress orientation. We concluded that the background stress fields with m' = 0.4 can be the most rational, and that the source region is in the Anderson-Byerlee stress condition.

The characterisation of faults within intraplate regions, especially those with longer seismic cycles, is beneficial to the improvement of seismic hazard assessment. In southern Africa, the link between the instrumental, historical, and paleo-seismic activity with active faults is often difficult due to low seismic strain rate (< 1 mm/yr) and sparse distribution of seismic stations. The relatively low level of seismic activity and low deformation rate require an understanding of the long-term active tectonics and recurrence interval of large and damaging earthquakes. Here, we perform detailed reanalysis of the 1932 St Lucia earthquake, as well as investigations in seismotectonics and tectonic geomorphology in the Kwazulu-Natal region, with the objective of characterising physical parameters of active faults necessary for seismic hazard assessment. First, we delineate the seismic and tectonic characteristics of the E-W and ENE-WSW trending Tugela and Greytown fault scarps, respectively, as a structural background of past earthquakes. We proceed with the description of geomorphic markers of fault scarps using tectonic geomorphology. Airborne magnetics added with electrical resistivity tomography and seismic reflection profiles are used as ground geophysical methods to further investigate physical fault geometries. The integration of these studies shows evidence of active faulting with right lateral offsets along the Tugela and Greytown fault scarps. The late Quaternary tectonic activity and characteristics of the Tugela fault suggest a possible correlation with the 1932 earthquake. Field investigations along fault scarps combined with geophysical and seismotectonic studies will likely lead to a realistic seismic hazard assessment in the KZN region.

Numerous active shear systems can easily be detected in the Eastern and Western Deserts (ED & WD) of Egypt. The Nubia Shear System (NSS) is an eye-catching structural feature in the extreme southern part of the WD. The NSS is typified by two main trends; E-W and N-S. Propagation of shearing along both trends resulted in the formation of different styles of shear zone-related folding reflecting transtensional and transpressional regimes. The present work is an integrated field/structural and seismological approach aiming to decipher the recent activity and seismic hazard potentiality of the NSS. Several lines of evidence indicate recent activity including topographic expression and intensive degree of shearing, and severe fragmentation and pulverization. Such activity led to low to moderate earthquakes with magnitude up to 5.6 ML. The full moment tensor inversion, which was decomposed it into three parts Isotropic (ISO), Double Couple (DC) and Compensated Linear Vector Dipole (CLVD), offers further information about the NSS. The obtained complete focal mechanism for the whole district is characterized by non-DC components which have been represented by ISO and CLVD with average value 22.2 % and 34.4 % respectively, and DC components with average value of 39.1 %. The focal mechanism solutions (FMS) for earthquakes in the concerned area demonstrate two nodal E- to ENE- trending planes, with subordinate right-lateral strike-slip component, and N- to NNW- trending planes, with left-lateral strike-slip component. The directions of tectonic extension (T) and compression (P) are NNE-SSW and NNW-SSE, respectively.

Resolving dynamic and chemical features of the lowermost mantle from global seismic tomography

DOI: 10.57757/IUGG23-2495 - LINK

Laura Cobden[1]
[1]*Utrecht University, Department of Earth Sciences, Utrecht, Netherlands*

We apply a variety of statistical and machine learning techniques to elucidate the key 1-D and 3-D features of Earth's lowermost mantle as imaged by seismic tomography. Multiple observables are required to break the trade-off between temperature, composition and mineral phase changes. Using bulk and shear wave speeds we can distinguish lateral and vertical variations in silica content and place a broad constraint on the temperature. Including density allows us to further resolve variations in iron content and place a tighter constraint on the temperature. Globally, the base of the mantle appears to be enriched in SiO2 compared to the overlying mantle. We demonstrate that the large low shear velocity provinces (LLSVPs) are more likely to be enriched in post-perovskite than their surroundings, and that dense piles at the base of the LLSVPs are likely enriched in both iron and silica.

In the last 10 years, global seismic tomographic models have shown that some subducting slabs pond in the extended upper mantle transition zone (ETZ, between 660 and 1000 km depth), as do most "fat" plumes that originate at the core-mantle boundary. These plumes extend quasi-vertically across the lower mantle, but have more complicated pathways in the upper mantle, where they are more difficult to resolve, since these plumes become thinner, likely due to a lower ambient viscosity. Recent results from full waveform tomography in the Atlantic and Indian Oceans show a variety of behaviors in the ETZ, with plumes meandering towards hotspot volcanoes at the earth's surface, and in the process, ponding at different depths in the upper mantle. Rarely does a plume extend vertically into the deep mantle directly beneath a hotspot. This is also the case beneath some well resolved continental plumes such as Yellowstone.

I will review these results and their geodynamic significance. In particular, I will discuss evidence for secondary scale convection across the ETZ in ocean basins, with cells aligned with absolute plate motion and a periodicity of ~2000 km. Combining evidence from seismic tomography and the analysis of meso-scale geodetic signals in the Pacific Ocean suggests the presence of lenses of partial melt atop the 410 km discontinuity, in the upwelling limbs of the secondary scale convection, likely due to dehydration melting.

Examination of double seismic discontinuities at the base of the mantle transition zone beneath the northern Japan

DOI: 10.57757/IUGG23-3987 - [LINK]

Keiko Kuge[1]
[1]*Kyoto University, Department of Geophysics, Kyoto, Japan*

While the 660 km discontinuity at the base of the mantle transition zone is believed to be caused by a phase transition of the olivine system, multiple seismic discontinuities around 660 km have been found by using reflected and converted seismic waves, for example, beneath Mariana (Tibi et al., 2007) and Tonga (Zang et al., 2006). Since the multiple discontinuities can be associated with phase transitions of the non-olivine system in the mantle, the appearance and spatial extent of the multiple discontinuities are important for understanding the nature of the mantle.

Near the northeastern edge of China, double or multiple seismic discontinuities at the base of the mantle transition zone were indicated by the receiver function studies (Niu and Kawakatsu, 1996; Sun et al., 2020). However, the spatial extent to the east is not known. This study examines P waves triplicated by discontinuities around 660 km beneath the northern Japan where is located in the east of the previously indicated double discontinuities. The Japanese seismic stations recorded the P waves from deep-focus earthquakes in the northern Japan Sea and southwestern Sea of Okhotsk. A clear triplication of P wave from an earthquake appears in a similar manner to iasp91. In addition, the following signals are observed in vertical components, which might be the manifestation of another triplication. The series of P wave are considered to transverse the bottom of the mantle transition zone that is significantly below and away from the descending Pacific slab.

Detection of sharp upper mantle discontinuities across North America: Silencing sediment reverberation and crustal multiples

DOI: 10.57757/IUGG23-0163 - LINK

Ziqi Zhang[1], Steve Carr[1], Tolulope Olugboji[1]
[1]University of Rochester, Department of Earth and Environmental Sciences, Rochester, USA

P-to-S receiver function (Ps-RF) is an effective approach to imaging sharp velocity discontinuities. However, when applied to continental-scale lithospheric imaging, it faces two fundamental challenges that cause significant signal distortion: (1) high-amplitude sediment reverberation that could completely mask conversion phases, and (2) crustal multiples that arrive at similar time window as mantle discontinuities, and thus complicate the interpretation of imaging results. Overcoming these difficulties and obtaining an improved mantle image of the continental United States is the goal of this study. We first apply a recently developed data-driven approach, using autocorrelation and homomorphic analysis, to teleseismic data recorded by Earthscope USArray Transportable Array (TA) to identify potential contamination from sediment reverberations. This technique does not require a-priori knowledge of the elastic structure of the reverberant layers. A frequency domain resonance removal filter, whose parameters are appropriately tuned by the seismic data, is then applied to stations with strong reverberation signatures. We then apply a selective sparse non-linear Radon filter to eliminate crustal multiples from the Ps-RF. The key idea emphasizes stable decomposition of noisy data-domain RF images into their underlying wavefield contributions in the radon domain by imposing sparsity-promoting constraints. The proposed methods are currently being applied to ~680,000 events, where we anticipate providing improved constraints on the composition, hydration, or change in the anisotropic signature that best characterizes seismic discontinuities beneath the contiguous US.

The region atop the core-mantle boundary (CMB) contains numerous heterogeneities that have been imaged using seismology. Ultra-low velocity zones (ULVZs) are extremely slow seismic anomalies that are tens of kilometres thick. Their origins are not known, but possibilities include iron-enrichment, the presence of partial melt, or both. It is also possible that ULVZs are part of an extensive layer of low seismic velocities that, being too thin to be robustly detected, has thus far eluded detection.

We test the visibility of such a layer to seismic data at different wavelengths, utilising both high-frequency core diffracted waves and normal mode centre frequencies. Using forward modelling we test the effect of a thin slow layer atop the CMB, finding that PKKPdiff, which diffracts three times at the CMB, is incredibly sensitive to such a structure, as are the centre frequencies of some normal modes. We compile datasets of PKKPdiff observations and normal mode centre frequencies and find that not only is a thin seismically anomalous layer compatible with observations, but that both data types are better fitted by the inclusion of an approximately single kilometre thick global layer with ULVZ-like velocity reductions. Nevertheless substantial trade-offs, both between different seismic parameters and the thickness, do remain.

Our results cannot uniquely constrain the origin or composition of such a layer, however the possible presence of this structure atop the CMB could have profound consequences for core-mantle chemical interaction, core-mantle coupling, CMB heat flow and convection in both the mantle and outer core.

The 660-km discontinuity (660) plays an important role in deep slab dynamics and mantle convection. Increasing numbers of seismic observations suggest controversial morphologies of the Pacific slab beneath the Kuril-Kamchatka located in the northwest rim of the Pacific Ocean, highlighting the poorly understood interaction of the slab and mantle discontinuities. Here we collect near-source SdP converted waves from a large dataset with several dense seismic networks and systematically image the new 660 topographic map around the Pacific slab beneath the Kuril-Kamchatka. We conduct detailed comparisons of the 660 depths and seismicity along some vertical cross sections. In comparison with the discontinuity depth in the IASP91 model, the 660 exhibits broad depressions up to 32–63 km with apparent downward deflections beneath the Kamchatka Peninsula and northern Kuril (region I), supporting slab penetration into the lower mantle; in contrast, the 660 depressions beneath southern Kuril (region II) are less than 21–28 km with a relatively flat configuration, implying a stagnating slab with possible hot entrained mantle materials and/or partial melts below it. We interpret these regional variations in the 660 topography as reflecting local low-temperature anomalies due to different slab morphologies associated with contrasting subduction modes. We suggest compound effects of pressure-driven mantle flow and trench retreat for inducing the inferred subduction mode change of the Pacific slab from region I to region II. Our results can provide direct seismic evidence for the 660 with slab-induced depressions and shed new light on the morphology and subduction dynamics of the northwestern Pacific slab.

The 660-km discontinuity (660) plays an important role in deep slab dynamics and mantle convection. Increasing numbers of seismic observations suggest controversial morphologies of the Pacific slab beneath the Kuril-Kamchatka located in the northwest rim of the Pacific Ocean, highlighting the poorly understood interaction of the slab and mantle discontinuities. Here we collect near-source SdP converted waves from a large dataset with several dense seismic networks and systematically image the new 660 topographic map around the Pacific slab beneath the Kuril-Kamchatka. We conduct detailed comparisons of the 660 depths and seismicity along some vertical cross sections. In comparison with the discontinuity depth in the IASP91 model, the 660 exhibits broad depressions up to 32–63 km with apparent downward deflections beneath the Kamchatka Peninsula and northern Kuril (region I), supporting slab penetration into the lower mantle; in contrast, the 660 depressions beneath southern Kuril (region II) are less than 21–28 km with a relatively flat configuration, implying a stagnating slab with possible hot entrained mantle materials and/or partial melts below it. We interpret these regional variations in the 660 topography as reflecting local low-temperature anomalies

due to different slab morphologies associated with contrasting subduction modes. We suggest compound effects of pressure-driven mantle flow and trench retreat for inducing the inferred subduction mode change of the Pacific slab from region I to region II. Our results can provide direct seismic evidence for the 660 with slab-induced depressions and shed new light on the morphology and subduction dynamics of the northwestern Pacific slab.

S15b - Boundary Layers in Earth's Mantle: Origin, Structure, and Influence on Convection

The upper mantle and the transition zone under Peru and Chile

We analyse 22,504 receiver functions obtained from 1162 seismic stations from 10 permanent and 32 temporary networks in South America. This region has been affected by the interaction of the subduction of the Nazca slab, which has changed its geometry through geologic time, breaking up and leaving fossil remnants or bucking it up above the 660. The receiver functions complexity and the topography of the upper mantle discontinuities correlate with the interaction of the Nazca plate with the upper mantle and mantle transition zone, the presence of a remnant slab segment and the hydration due to the slab.

Earth's upper mantle is characterised by abundant seismic discontinuities, which influence global mantle convection. Their physical properties (depth, and reflectivity) provide insights into the spatial variation of temperature and composition. Here, we perform global seismic interrogations of regional-scale discontinuities at 300 km, 520 km, and 660 km depth, to identifying regions of compositional layering associated with impeded flow of material or efficient flux.

The global 660-km discontinuity marking the base of the mantle transition zone (MTZ) comprises two mineral phase changes of ringwoodite and garnet, and is typically invisible to PP-precursors. Its visibility is associated with high temperatures and a dominant garnet transition, which promotes upward transport of high temperature material. Better constraints on the 660 will therefore contribute to models of global circulation patterns.

Observations of the 300 km deep "X" discontinuity are sporadic, typically beneath continental regions and subduction zones. Its presence is attributed to mineral transformations within basalt-enriched material, thereby aiding the detection of stagnant slabs. Conversely, the 520, caused by the transition of wadsleyite to ringwoodite, is observed in a larger portion of the globe, displaying complex variability in its visibility, depth, and splitting.

Mineral physics modelling predicts that the seismic characteristics of these features are highly dependent on local thermochemistry. We combine seismic measurements from large global datasets to generate high resolution maps of the discontinuities. We interpret our results in the context of recent thermochemical maps for the MTZ, to obtain new insight into chemical segregation and stagnation of convecting material in the upper mantle.

Subduction zone forearcs deform transiently and permanently due to the frictional coupling with the converging lower plate. Transient stresses are mostly the elastic response to the seismic cycle. Permanent deformation is evidenced by forearc topography, upper plate faulting, and earthquakes; its relation to the megathrust seismic cycle is debated. Here we study upper plate seismicity in the northern Chile subduction zone as a proxy for forearc brittle deformation. We find that seismicity is distributed unevenly and a dramatic increase correlates with the onset of a change in subduction obliqueness. Earthquakes in the South American crust show a remarkably homogenous trench-parallel, compressional stress field. Earthquake fault mechanisms are dominated by trench-perpendicular thrusts. Further inland, where the lower plate becomes uncoupled, the stress field is more varied with a compression direction approx. convergence parallel. The stress regime above the plate-coupling-zone, almost perpendicular to the plate convergence direction, may be explained by a change in subduction obliqueness due to the concave shape of the plate margin, which we demonstrate by investigating inter-plate earthquake slip vectors. From these, we derive a strain rate and compare it to one derived from upper plate earthquakes and geological time-scale shortening. Based on the distribution of the type of faulting we investigate the trench-perpendicular stress field with a force balance model taking into account gravitational stresses and the traction along the megathrust. The observed deep strike-slip earthquakes, expression of trench-perpendicular tension, require the deepest extent of the megathrust to be very weak.

The Hindukush- Pamir Himalaya region is one of the most active orogenic regions of the world having complex and peculiar tectonics, experienced several large to great earthquakes in the past. The area 25^0-40^0N and 65^0-85^0E, have been considered for b-value mapping. A homogeneous and complete seismicity database with cut-off magnitude Ms$\geq$ 4.0 has been prepared for the period 1853 to Oct. 10, 2005 from different existing sources. The a and b-values for the study region G-R relationship (Log N = a – b M) has been estimated. In order to map a and b-values the most complete seismicity database for Ms $\geq$ 4.0 during the period 1963 to Oct. 10, 2005 has been used. The a and b-value has been estimated by maximum likelihood method using spaced grids of 0.50 X 0.50 with 50 to 200 nearest earthquakes and considering spatial variation of Mc. The spatial variation of ‘a’ value ranges from a low of 5.20 to as high as 8.51 and b-value ranges from a low of 0.7 to as high as 1.5. The Low b- value regions infer as the growing stress regime releasing larger magnitude earthquakes while high b value indicates increased crustal heterogeneity and low stress buildup with continued stress release through numerous smaller magnitude earthquakes. The b value varies as a function of depth suggest a random distribution of low to high b-value showing the heterogamous crustal structure beneath it. However, in subduction zones which may indicates a phase transformation of material in subducting slab.

The uncertainties on the calculation of routine seismic event localization at the convergence zone between the Caribbean Plate and Norandean Block are mainly caused by general procedures adopted by seismic agencies such as Red Sismológica Nacional de Colombia (RSNC) and United States Geological Service (USGS). Here we improve the characterization of seismogenic sources of the Colombian Caribbean by estimating and using local velocity models, performing robust regional moment tensor inversion and embodiment of additional geophysical inputs. The sources are spatially constrained as superficial (0-30 km), intermediate (30-70 km) and deep (>70 km). Most significant seismicity in the South American Plate is given by the North Romeral fault (especially along the eastern part of this system), Sierra Nevada de Santa Marta (SNSM), northern Bucaramanga Nest and the Panama-Choco Arc. Furthermore, a seismic cluster indicating the interaction between the fault systems of Santa Marta-Bucaramanga (SMB) and Oca-El Pilar (OP) is proposed at its offshore intersection point. The effect of complex seismogenic geometry controlled by the convergence and interaction of three tectonic plates is investigated by means of the analysis of Wadati-Benioff zones through seismic profiles across the study area. For the northernmost part, the Moho's expression changes due east, and it is described here as a shallowly dipping, ductile and incipient subduction not related to the Paleo-Caribbean Plate that is found southward and striking E-W. In the western part, the "Nazca - Norandean Block - Caribbean Plate" triple point interaction undergoes strong compressional movements as well as tectonic uplifting.

The Gulf of Gökova is located in one of the most substantial horst-graben systems in Western Turkey, generating significant seismic activity owing to the development of several complex features alongside The Gökova Fault Zone (GFZ) due to plate motions along the Aegean subduction zone. The region has experienced significant seismic activity both in historical and instrumental periods. With an estimated size of M6.8 and an intensity of IX, the oldest documented event took place in 412 BC near Kos Island. Notably, following the 2017 Mw6.6 Bodrum earthquake, the complicated tectonic structure of the area was studied extensively and highly debated indicating the necessity of a detailed study of the active tectonics of the region.

In this study, source parameters of 140 earthquakes (M>3.0) that occurred between 2006-2022, in and around the Gulf of Gökova (located between 36.5°-37.5°N and 26.8°-29°E), are calculated to be further implemented in stress tensor inversion. The region is split into six sub-regions concerning depth, focal mechanism variations, and active tectonic features and analyzed individually. In the northern part of the gulf, including the Gökova and Muğla faults, the maximum principal stress indicates normal faulting, with a counter-clockwise motion from NE-SW to NW-SE. The southern part of the gulf exhibits scattered seismicity and diverse tectonic elements, including Datca, Bozburun, Selimiye, and Taşlıca faults. Hence, the observed principal stresses indicate a transformational structure that concurrently induces normal and strike-slip faulting.

The corner frequency of the seismic source spectrum and the stress drop are crucial to predict accurate strong ground motion. These parameters depend on other parameters, such as the focal mechanism, depth, and focal region. A high occurrence probability is estimated for a megathrust earthquake along the Kuril trench from off Tokachi to off Nemuro, Hokkaido, Japan. We tried to determine the corner frequency and stress drop using M>5 earthquakes to improve the accuracy of the strong motion prediction of megathrust earthquakes in this area. Using spectral inversion analysis, we separated the seismic source characteristics, propagation path, and site amplification from the strong ground motion records of middle to large earthquakes in the southern Kuril trench. The site amplification factor of HKDH05, a rock site, is a constraint condition. We obtained the source characteristics of 159 earthquakes and the site amplification characteristics of the 190 sites. The Qs value for the attenuation characteristics in the fore-arc region of the volcanic front is consistent with previous studies, and the site amplification characteristics are also comparable to existing values from previous studies. Regarding the seismic source spectra, we fit the omega-squared model and obtained the corner frequency for each earthquake. The short-period levels extracted from the fitted source spectra of intraslab earthquakes are approximately twice as high as those of interplate earthquakes. The stress drops have a weak correlation with the focal depth and vary depending on the focal region, with values off Nemuro being larger than those off Tokachi.

1. Council for Geoscience, South Africa, smyendeki@geoscience.org.za
2. The University of the Western Cape, South Africa, jvanbeverdonker@uwc.ac.za

Earthquakes are not always directly linked to visible structures; some structures are deep and blind. This study will demonstrate an interdisciplinary techniques approach; using ArcGIS to map seismic events, high-resolution Airborne Magnetic data to map deep-seated lineaments, and LiDAR (a high-resolution airborne topographic mapping tool) to identify elusive surface expressions of active faults.

The seismicity clusters being investigated are situated in the West Rand within the Witwatersrand Basin. The West Rand region in South Africa is known for deep-level mining operations. The seismicity activity dates back to the early 1900s and has continued intermittently to the present day. The thousands of events found to be present in the region are generally suggested to be mining related. However, some investigations have indicated that seismicity is a mixture of natural, triggered, and mine-related events.

The bigger events (i.e. M $\geq$ 3.0) often occur on geological structures and result in extensive damage underground and on the surface. Geological structures that are under high stress or are susceptible to destabilization due to mining may be more susceptible to larger seismic events.

The identification of seismogenic structures, especially ahead of mining activity can contribute much towards creating a safe mining environment as well as more realistic seismic hazard assessment studies. Thus, this study aims to identify seismogenic structures associated with earthquake locations.

Located in the northern part of the Netherlands, the Groningen gas field is one of the largest gas fields in Europe and is known as an earthquake-prone area for induced seismicity. The prolonged gas extraction in the area have been pointed out as the main cause of the earthquakes. While many studies have indicated that the earthquakes mainly originated from the reservoir layer, several latest studies show the possibility that the majority of the earthquakes nucleated just above the reservoir layers. In this study, we investigate the possibility of the latter hypothesis as well as the main mechanisms of the Groningen earthquakes. To do that, we applied an efficient probabilistic algorithm, the Hamiltonian Monte Carlo algorithm. The aim is to estimate ten earthquake source parameters. Those are the moment tensor (six components), hypocenter (three coordinate components), and origin time. Having the probabilistic estimates of the parameters, we then compare them with the reservoir map of Groningen to asses the pre-described hypothesis. We also used the fault map of the Groningen subsurface to see the match between the mechanisms we obtained and the orientation of the mapped subsurface faults. Additionally, we also compare our results with several related research from the area. In the end, we found that there is indeed a high probability of earthquakes nucleated just above the reservoir level, with the mechanisms mainly triggered by the movement of the mapped subsurface faults.

The characterization of a seismic source is crucial to understand seismogenic processes. Simplified source models, e.g., a moment tensor, may not be suited for certain physical processes, such as landslides or complex earthquake ruptures. We propose here a double source model to reproduce landslide processes, with two opposite oriented forces representing the detachment and impact of a sliding mass. A double source model is also suited to characterize complex earthquake ruptures, as it allows modeling the failure of two patches along a single or on two different faults. The inversion for a double source is implemented in a Bayesian bootstrap-based probabilistic inversion scheme with uncertainty estimation for all parameters. In the case of landslides, the source is described by two independent single forces and earthquakes are described by two dependent double-couples. The double single-force model includes 16 free parameters and the double double-couple model includes 18. Here we show the results obtained in the analysis of three different landslides (Val Bondasca-Switzerland 2017, Anak Krakatoa-Indonesia 2018 and Uttarakhand-India 2021) and two complex earthquake ruptures (Alaska 2018, South Sandwich islands 2021). Our findings show that our approach can resolve the landslide geometry and slope orientation. For the case of earthquakes, we were able to resolve the focal mechanism along two faults, which were active during the Alaska 2018 earthquake, as well as the time delay and orientation of the South Sandwich doublet in 2021.

The characterization of a seismic source is crucial to understand seismogenic processes. Simplified source models, e.g., a moment tensor, may not be suited for certain physical processes, such as landslides or complex earthquake ruptures. We propose here a double source model to reproduce landslide processes, with two opposite oriented forces representing the detachment and impact of a sliding mass. A double source model is also suited to characterize complex earthquake ruptures, as it allows modeling the failure of two patches along a single or on two different faults. The inversion for a double source is implemented in a Bayesian bootstrap-based probabilistic inversion scheme with uncertainty estimation for all parameters. In the case of landslides, the source is described by two independent single forces and earthquakes are described by two dependent double-couples. The double single-force model includes 16 free parameters and the double double-couple model includes 18. Here we show the results obtained in the analysis of three different landslides (Val Bondasca-Switzerland 2017, Anak Krakatoa-Indonesia 2018 and Uttarakhand-India 2021) and two complex earthquake ruptures (Alaska 2018, South Sandwich islands 2021). Our findings show that our approach can resolve the landslide geometry and slope orientation. For the case of earthquakes, we were able to resolve the focal mechanism along two faults, which were active during the Alaska 2018 earthquake, as well as the time delay and orientation of the South Sandwich doublet in 2021.

ISC-PPSM: Assessing moment tensor resolution, and addressing shallow earthquake depth resolution

DOI: 10.57757/IUGG23-2916 - LINK

Thomas Garth[1], *Karin Sigloch*[2], *Dmitry Storchak*[1]

[2]*Université Côte d'Azur, CNRS Geoazur, Nice, France*

We present a new technique to assess the moment tensor, source time function (STF) and depth of an earthquake, along with a full estimate of the uncertainties in each of these parameters. This methodology is being applied at the ISC (International Seismological Centre) to construct a new catalogue of earthquake point source models, referred to as ISC-PPSM (International Seismological Centre – Probabilistic Point Source Models).

We employ a Bayesian inversion strategy to produce an ensemble of earthquake point source models that satisfactorily describe the P- and SH-waves observed tele-seismically at global broadband seismic stations. The methodology builds on the techniques proposed by Stähler & Sigloch (2014, 2016). Here we explore several ways of parameterising the earthquake STF, including describing the STF as a set of weighted harmonic functions, and describing the STF as the sum of multiple Gaussian spikes.

ISC-PPSM is applied to moderate magnitude (5.5 – 7.2 Mw) earthquakes across the globe. As we jointly solve for the earthquake depth and STF, we can add new depth resolution to shallow (< 40 km depth) moderate magnitude earthquakes, where the depth phases become subsumed within the STF. Additionally, the Bayesian inversion strategy allows us to assess the range of earthquake moment tensors that can describe the observed waveforms for a given event. This allows is to go some way towards constraining the variability in moment tensors reported to the ISC for many events.

The source parameter, stress drop, is a key parameter estimating strong ground motion, as it controls the level of peak ground acceleration. Several studies have investigated source parameters for many regions by various methods and assumptions (e.g., Japan, Southern California, and central Italy). In this study, we apply a non-parametric spectral decomposition to isolate the source, site, and path contributions on the Fourier amplitude spectra (FAS) in Europe. We propose the two-domain regionalized attenuation models in the spectral decomposition to take into account the varying attenuation of two spatial domains along the Alps. We download all available data from 1990 to 2020 in Europe through the European Integrated Data Archive (EIDA) within the *stream2segment* software. The analyzed FAS are selected from 35.6 million recordings which contain 6,135 earthquakes recorded by about 1,600 stations. The final data includes the induced events in Groningen and Poland and some significant events in Italy which provide the opportunity to discuss the variation between induced and natural earthquakes. To derive comparable source parameters in such a large study area, we set one station, LLS (Linth-Limmern), in the Swiss network as a reference site to obtain the corrected source spectra. Finally, we fit the source spectra with a standard ω^2-model. The resulting stress drop shows a positive correlation with earthquake magnitude in the magnitude range of 2 to 4.5 and a constant value for larger magnitudes (M>4.5).

Systematic exploration and characterization of moderate magnitude seismicity in scarcely instrumented places

DOI: 10.57757/IUGG23-4630 - LINK

Martin Vallée[1]
[1]*Université Paris Cité- Institut de Physique du Globe de Paris, Seismology, Paris, France*

As a result of the uneven geographical coverage by seismic stations, the seismicity of a number of seismogenic areas (including oceanic ridges, but not only) is only known for large magnitude events exhibiting high-frequency arrivals. Besides affecting the completeness of the earthquake catalogues, this undetected seismicity may also have some specific source properties, in particular in terms of frequency content. The analyses of the global seismic wavefield (e.g. Ekström, 2006) reveal that large magnitude (above magnitude Mw5) exotic tectonic sources are very likely rare; at lower magnitudes, the detection of very-low-frequency earthquakes (VLFE) shows that such sources exist, but with a global abundance which remains today unclear.

Isolated places where a few regional broadband seismometers, usually from the global broadband networks (GSN, Geoscope, Geofon), are in operation since the 1990’s or 2000’s can be selected to exhaustively detect the seismicity of the last decades, at a threshold of Mw3.5-4. To do so, the present work proposes to match-filter the continuous records with the waveforms of all the known earthquakes, in order to search for events that are similar at long periods (e.g. 20-50s) but may differ at short periods. This study will present results from a few areas of the world where such a method has been implemented.

In this study, we analyze the 2020 earthquake swarm on the Reykjanes Peninsula by moment tensor inversion in order to improve our understanding of the seismogenic processes and their relation with magmatic and tectonic activities. The densified seismic monitoring operational during the study period provides a unique dataset for the seismic sequence preceding the 2021 Fagradalsfjall eruption. We perform full moment tensor (MT) inversion for 85 earthquakes with magnitudes Mw > 2.5 using a probabilistic approach. For the first time, we attempted to integrate DAS data into the MT inversion. Focal mechanisms exhibit predominantly strike-slip faulting with a few normal faulting events and are overall compatible with the regional tectonic regime. Earthquake foci are shallow with an average depth of 3 km. We estimate robust, significant, positive isotropic components contributing up to 15% to the moment release. We hypothesize that the origin of such significant non-double-couple (non-DC) components may be attributed to volume changes accompanying the surface uplift and rifting processes in the region. Our study demonstrates that non-DC earthquake source components can be monitored prior to eruption and potentially, their identification may be used as indicator for magma intrusion in the shallow crust.

Two seismic sequences occurred between March and April 2021 near Neunkirchen and Gloggnitz, about 50 km from Vienna, Austria. The mainshocks epicenters of both series are located around 15 km apart from each other.

According to the Austrian Seismological Service at GeoSphere Austria, the Neunkirchen sequence, which includes the two largest earthquakes of both series (Mw 4.0), started on March 11th, 2021 and finished on May 12th, 2021. Over two months, 245 earthquakes, with local magnitudes ranging from -0.5 to 4.6, were recorded.

The Gloggnitz sequence started on April 1st, 2021, and continued until May 8th, 2021. Here, a total of 65 earthquakes were detected and located. The local magnitudes of this seismic sequence ranged from -0.3 to 3.8 and depths varied between 4 and 7 km.

Taking advantage from the high density of seismic stations (Geosphere Austria, AlpArray, and neighboring networks), we relocated the seismicity and performed centroid moment tensor inversions for the largest earthquakes of the series. Results highlight some peculiarities of these two seismic sequences, which only affected small seismogenic volumes along or next to known fault structures. The heterogeneity of focal mechanisms of events in close proximity suggests the activation of different faults at slightly different depths. To include smaller events in the analysis of activated faults, we further investigate waveform-similarity based event clusters.

The detailed analysis of volcanic seismicity can allow the identification of the processes occurring in a volcanic system and obtain information about its state and evolution. In the last decades, the seismicity of Mt. Vesuvius has consisted mainly of volcano-tectonic (VT) seismic events, with an average rate of some hundreds of earthquakes per year with magnitudes between −1.0 and 2.5, located up to 6-7 km below sea level (b.s.l.). Unusual low-frequency (LF) seismicity has also been observed, localized at a depth of 5-7 km. Previous seismic source analyses applied conventional methodologies based on first pulse characteristics, which are difficult due to high background noise, low magnitude and emergent first arrivals. To overcome these challenges, we analyze here the Mt. Vesuvius seismicity over the past 20 years by using a robust probabilistic seismic source inversion tool. This methodology provides the results in terms of moment tensor solutions estimated by using seismic waveforms and waveform attributes. In agreement with previous studies, two clusters of seismicity are clearly evidenced, both in terms of depth (0-4 km and 5-7 km b.sl. for VT and LF events, respectively) and frequency content (5-15 Hz and 2-6 Hz, respectively). Our preliminary results show that: a) the probabilistic approach for the whole waveform inversion provides acceptable results even for small magnitude earthquakes, and b) both seismicity clusters show strongly heterogeneous focal mechanisms, confirming past literature studies. We attribute the latter result to a highly heterogeneous stress field beneath Mt. Vesuvius.

Fault plane identification of the September 2021 Mw 5.9 Woods Point earthquake

DOI: 10.57757/IUGG23-1383 - LINK

Fifty broadband, research-grade seismic stations housed in schools are operated by the Australian Seismometers in Schools (AuSIS) network across Australia. Using only data from the AuSIS network we present the feasibility of identifying the fault plane of moderate earthquakes on the Australian continent. We examine the fault plane of the September 2021, MW 5.9 Woods Point earthquake which happened roughly 130 km northeast of the Melbourne metropolitan area. We estimate the hypocentre and the centroid-moment-tensor to differentiate the fault plane from the auxiliary plane in the focal mechanism. In order to simulate seismic arrivals and full waveform data, we test a variety of 1D models and a 3D Earth model. The centroid-moment-tensor is obtained from full waveform modelling by grid search across a set of trial sites around the hypocentre. The hypocentre is resolved using P and S-wave arrivals in a probabilistic framework. Our model indicates that the main shock ruptured the depth of 15±4 km, with a strike-slip mechanism striking 348º North on a nearly vertical plane. The high double-couple (DC) percentage of this event suggest a simple rupture that propagated from the south (hypocentre) toward the north (centroid) while remaining underground. This indicates that the causative fault ruptured deeper parts of the crust which might be different to the previously identified shallow, NW-SE striking faults of the region. The P- and T-axis inferred from our fault model are clearly aligned with the maximum horizontal crustal stress in the region.

The submarine Main Marmara Fault is overdue for an M>7 earthquake in the direct vicinity of the Istanbul megacity and is the only segment of the right-lateral North Anatolian Fault Zone that has not been activated since 1766. On 26 September 2019, an Mw5.7 earthquake occurred offshore Silivri (west of Istanbul), stimulating discussions on a future major earthquake. The predominant faulting style for this pending earthquake remains enigmatic. In this study, we investigate the coseismic rupture evolution of the 2019 Silivri earthquake and decipher the multi-type-faulting aspects by a nonstandard approach. The event was dominated by a large compensated-linear-vector-dipole component, of about -50% that we interpret as a consecutive strike-slip and thrust double-couple episode, closely collocated in space and time. Due to local variations of the fault geometry at the eastern boundary of the Central Basin, crustal shortening and related thrust-faulting are expected. A striking observation is the almost synchronous occurrence of both faulting types during a single earthquake. The earthquake complexity here is reported for the first time in the Sea of Marmara region and has to be considered in future rupture scenarios of an expected M>7 event, with subsequent consequences for tsunami hazard and risk.

The 2022 MW 6.0 Gölyaka-Düzce earthquake: a medium size earthquake in a fault zone early in its seismic cycle

DOI: 10.57757/IUGG23-1710 - LINK

Patricia Martínez-Garzón[1], *Dirk Becker*[1], *Jorge Jara*[1], *Xiang Chen*[1], *Grzegorz Kwiatek*[1], *Marco Bohnhoff*[1]
[1]*Helmholtz Centre Potsdam GFZ German Research Centre for Geosciences, Department 4, Potsdam, Germany*

On November 23rd 2022, a M_W 6.0 earthquake occurred in direct vicinity of the M_W 7.1 Düzce earthquake that ruptured a portion of the North Anatolian Fault in 1999. The M_w 6.0 event was attributed to a small fault portion of the Karadere segment that did not rupture during the 1999 sequence. We analyze the spatio-temporal evolution of the M_W 6.0 Gölyaka-Düzce seismic sequence at various scales and resolve the source properties of the mainshock. Modelling the decade-long evolution of background seismicity of the Karadere Fault employing an Epistemic Type Aftershock Sequence model shows that this fault was almost seismically inactive before 1999, while a progressive increase in seismic activity is observed from 2000 onwards. A newly generated high-resolution seismicity catalog from 1 month before the mainshock until six days after created using Artificial Intelligence-aided techniques shows only few events occurring within the rupture area within the previous month, no spatio-temporal localization process and a lack of immediate foreshocks preceding the rupture. The aftershock hypocenter distribution suggests the activation of both the Karadere fault which ruptured in this earthquake as well as the Düzce fault that ruptured in 1999. First results on source parameters and the duration of the first P-wave pulse from the mainshock suggest that the mainshock propagated eastwards in agreement with predictions from a bimaterial interface model. The M_W 6.0 Gölyaka-Düzce represents a good example of an earthquake rupture with damaging potential within a fault zone that is in a relatively early stage of the seismic cycle.

A large seismic swarm affected the North Mid-Atlantic ridge between September and November 2022, with an outstanding seismicity rate and a cumulative moment equivalent to a magnitude Mw 6.3. We performed a detailed seismological analysis using regional, teleseismic and array data to reconstruct the spatiotemporal evolution of the seismicity. Combining template matching, relative location and full moment tensor inversion, we identify that most seismicity was located in a narrow band along the ridge, with typical normal faulting mechanisms. However, some of the latest and strongest events occurred up tp 25 km off the ridge axis, with thrust mechanisms that are atypical at mid-ocean ridges and inconsistent with the extensional tectonics. Seismicity also present a clear migration pattern, propagating over ~60 km from North to South, with the thrust mechanisms only occurring in the late phase of the swarm and only in the central-southern section. We hypothesize a magmatic intrusion as driver of the seismicity, with a vertical dyke first propagating southward, accompanied by normal faulting earthquakes, and then thickening, to produce a stress perturbation able to trigger thrust earthquakes on pre-existing structures on the side of the dike. The 2022 unrest provides evidence for sporadic spreading accompanied by large swarm episodes driven by magma intrusions at the mid-ocean ridge.

Seismicity also present a clear migration pattern, propagating over ~60 km from North to South, with the thrust mechanisms only occurring in the late phase of the swarm and only in the central-southern section. We hypothesize a magmatic intrusion as driver of the seismicity, with a vertical dyke first propagating southward, accompanied by normal faulting earthquakes, and then thickening, to produce a stress perturbation able to trigger thrust earthquakes on pre-existing structures on the side of the dike. The 2022 unrest provides evidence for sporadic spreading accompanied by large swarm episodes driven by magma intrusions at the mid-ocean ridge.

Since 2015, when a cabled observatory was first set up on Axial Seamount, >150,000 earthquakes have been located within a 25 km^3 block of crust. The volcanic system has also experienced the passage of seismic waves from >120 large remote earthquakes and periodic tidal loading. Therefore, it represents a unique laboratory for us to probe how earthquakes respond to static and dynamic stress changes. We find that the seismicity rate increases while the b-value decreases (larger proportion of large events) systematically with increasing tidal stress. The stress dependence of seismicity rate conforms to triggering theory over the whole tidal stress range, demonstrating that there is no triggering stress threshold and stress shadowing is simply a continuous function of stress decrease. We also observe statistically significant episodes of dynamic triggering for ~11% of large remote earthquakes. However, while some coincide with changes in permeability estimated from changes in the tidal phase lag of hydrothermal vent temperature, others are not. Therefore, permeability change is likely not the only mechanism underlying dynamic triggering of earthquakes.

Although the physical mechanism of earthquake nucleation processes is under debate and it is still challenging to distinguish foreshocks during an ongoing seismic sequence, foreshocks may still provide unique and valuable information for earthquake nucleation process. Investigating the temporal and spatial evolution of foreshock sequences with high resolution and monitoring *b*-values in real time may shed light on these key issues. Here we investigate a series of earthquake sequences in western Yunnan, China, where a number of moderate to strong earthquakes were well recorded by the newly established seismic network. To find missing earthquakes and build more comprehensive earthquake catalogs, we first carry out earthquake detection using the matched-filter detector. We use events in the standard catalog of China Earthquake Networks Center as templates to scan through continuous waveforms 3-6 months before and after the mainshock. We then estimate the *b*-value and its temporal changes based on the newly developed catalogs. An obvious reduction in *b*-values before the major earthquake was observed in both the 2016 Ms5.1 Yunlong and 2021 Ms6.4 Yangbi sequences. However, we didn't observe such a feature before the 2017 Ms5.1 Yangbi mainshock, showing spatial variations in the region. After the relocation of the detected earthquakes and deriving their source parameters including focal mechanisms and stress drops, we found that the foreshocks in western Yunnan exhibit mostly a cascading rupture manner, rather than indicating slow-slip driving nucleation of mainshocks.

Evidence of the ambiguous critical state transition from aseismic to seismic slip

DOI: 10.57757/IUGG23-2989 - LINK

Rebecca O. Salvage[1], *Carolyn Furlong*[1], *Jesus Rojas Parra*[1], *David Eaton*[1]
[1]*University of Calgary, Dept. of Geoscience, Calgary, Canada*

The idea that earthquake processes occur on a continuum from aseismic (stable sliding) to seismic slip (event nucleation) is not new, however the mechanisms causing any evolution between the two end-members is not fully understood. Possible mechanisms may relate to dynamic fault weakening, static stress transfer, the concentration of shear stress at the boundary of an aseismic region, some combination of these, or a mechanism we have yet to detect. Moreover, the detection of aseismic processes is inherently difficult, adding to the challenges in detecting and understanding this evolution. Here, we investigate evidence for a critical state transition within the subsurface using data from several recent seismic sequences in western Canada. The first case investigates a potential change in seismic event rate following prolonged fluid injection at a water disposal well, suggesting that initial deformation in the subsurface related to the injection was aseismic. Twelve months into the injection program, a large change in the seismic event rate was observed, along with a change in the source characteristics of the events, suggesting a transition from dominantly aseismic to seismic slip. Another case investigates seismicity in a historically quiescent area where there is ongoing fluid injection. A M5.3 mainshock was followed by an unusual aftershock sequence, which showed limited evidence of Omori-like decay, and instead, remained persistent. We investigate these sequences using an array of techniques including ambient seismic noise, repeating seismicity and the identification of tremor-like signals to determine whether there is evidence of a critical state transition at depth.

In this study, we aim to develop a deep-learning method to monitor spatio-temporal evolutions of short-term SSEs based on a dense GNSS network. We theoretically create two types of noiseless three-dimensional (3D) deformation data assuming 272 subfaults in western Shikoku, southwest Japan; 16 subfaults along the strike multiplied by 17 subfaults along the dip. One is deformations at 95 GNSS stations, and the second is those at 900 virtual stations which are regularly located over the target area. We tailor two supervised-learning models to estimate the slip area and the slip amount of SSE by learning those deformation images as input data. Nakagawa et al. (2021, Fall Meeting in Geodetic Society of Japan) showed that the model trained with GNSS stations estimated SSEs with 91.8% variance reduction (VR) while the other model achieved 98.3% VR. We concluded that this difference in estimation accuracy is contributed to the dissimilarity between input deformation images. Therefore, we newly implement Model-supervised Interpolation (MSI) approach to overcome this problem. MSI successfully reproduces the deformations at 900 virtual stations only from the deformations at 95 GNSS stations with 97.4% VR although nearly half of the target area is located on the offshore region. Additionally, a model trained with deformation images predicted by MSI improves the VR of the slip estimation by 0.5%.

Recent estimates of the rupture scenarios of moderate-to-large earthquakes highlights the need of incorporating segmented fault surfaces into seismic hazard models rather than individual, planar ones. The 2014 Northern Nagano earthquake sequence provides an opportunity to rethink the fault system geometrical complexities of the Itoigawa-Shizuoka tectonic line, one of the most inland active faults in Japan, and their impact on the fault rupture nucleation and development. For this study we used continuous records of 37 seismic stations to detect and locate 2500 events that occurred from 1st October 2014 to 31 December 2014. By refining the automatic arrival time picks, based on the cross-correlation and the hierarchical clustering, we relocated the earthquake hypocenters with the double-difference location and a three-dimensional (3D) velocity model. We obtained a high-quality earthquake location catalog and the composite focal mechanisms which served for constraining the 3D geometry of the segmented fault system. We found that the early aftershocks are distributed along two sub-parallel, NNE-SSW striking, en-echelon, left-stepping fault segments and analyses on the spatio-temporal evolution of fault activation suggest that the rupture propagates in a clockwise direction, involving first the shallow northern portion of the segmented fault system, then the deeper northern portion of it, and finally the deeper and the shallower parts of the southern portion. Results suggest that a relationship exists between the rupture mechanism and the 3D segmented fault geometry. This relationship between initial structure of the segmented fault controls the earthquake rupture becomes crucial to assess reliable scenarios in seismic hazard.

Earthquake simulations, geodetic and seismological data analyses, and field surveys of fault outcrops indicate that the slip distribution on the coseismic fault is self-similarity. This characteristic can be used for fault slip estimation as prior information for the regularization of an ill-posed problem. In this study, we introduced the characteristic using the von Karman autocorrelation function and developed the method to simultaneously estimate the fault slip and its correlation length, which has been treated as a hyperparameter from the ground displacement. The method was constructed based on Bayesian inversion using Hamiltonian Monte Carlo to evaluate parameters' uncertainty quantitively. We conducted numerical experiments using a random slip distribution whose correlation length is assigned to validate our method. Under the assumption of a dense observation network, the input slip and the correlation length were retrieved correctly. Furthermore, the experiment assumed that the observations are distributed at only the fault's down-dip side. As a result, although, the longer correlation length has been explored than the result under the dense observations, its posterior distribution peaked near the assumed value. This presentation will also show the results of an application to the 2016 Kumamoto earthquake (Mw 7.0). In addition, we will discuss an application for a numerical test of a megathrust in the Nankai trough subduction zone, which has a more realistic, 3D-distributed fault system.

Reconstruction of slip distributions on multiple faults with applications to the 2016 kumamoto MW7.0 earthquake

DOI: 10.57757/IUGG23-0461 - LINK

Peiliang Xu[1]
[1]*Kyoto University, Disaster Prevention Research Institute, Uji, Japan*

Slip inversion is essential to understand source mechanics of earthquakes. Problems of inverting for static/kinematic rupture from surface measurements have been almost always stated to be inherently non-unique in the seismological literature. Given the geometry of a fault and the displacement functions on the surface of the semi-infinite elastic medium, the slip function on the fault is defined by Fredholm integral equation of the first kind. We prove that Fredholm integral equation of the first kind for slip inversion is mathematically of a unique solution, theoretically implying that earthquake slip/rupture can be properly reconstructed. The inherent non-uniqueness issue of slip inversion in the seismological literature is not mathematically true but is practically caused due to lack of measurements. We propose a new inequality-constrained regularized inversion of slip distributions on multiple faults, which implements physically more general inequality constraints to accept more complex dislocation models and/or a combination of complex dislocation models and can be applied to a large earthquake involving multiple faults with different rake angles. It is a natural extension of positivity and the 45 degrees constraints by Olson/Apsel and Hartzell/Heaton. We apply the proposed method to the 2016 Kumamoto Mw7.0 earthquake with GEONET GNSS measurements. The inversion results of slips show that the 2016 Kumamoto earthquake is only of magnitude Mw6.6-6.7 and severe rupture takes place very shallowly on Hinagu and Futagawa faults, with the maximum slips of 4.81m on Hinagu fault and 7.89m on Futagawa fault, respectively, which may well explain the largest damage in Mashiki town.

Observational evidence of cascading earthquake rupture with hierarchical structure in the Tohoku-Oki region, Japan

DOI: 10.57757/IUGG23-0615 - LINK

Satoshi Ide[1]
[1]*The University of Tokyo, Department of Earth and Planetary Science, Tokyo, Japan*

Over the past ~20 years, high-quality data have revealed the detailed behavior of repeating earthquakes in the Tohoku-Oki region, Japan, as a cascading rupture process within a hierarchical structure. This presentation reviews our recent studies that provide observational evidence for such hierarchical cascading ruptures. The centroid of repeating earthquakes can be precisely relocated using waveform correlation, while accurate relocation for the hypocenter is also possible using the P-wave first motions. Chang and Ide (2021) developed a method for the simultaneous relocation of hypocenters and centroids and applied it to three repeating earthquake sequences in the Tohoku-Oki region. They found that, although the hypocenter locations and the final slip distributions for large, medium, and small repeating earthquakes were largely determined, the combination of the hypocenter and centroid may be different, especially in the case of the Naka-Oki sequence, suggesting the limited predictability of the rupture process. The slip inversion of Okuda and Ide (2019a) also found that the slip of M~5 earthquakes in this group has an anisotropic spatial distribution in the subduction direction. The limited predictability suggests that two ruptures starting at different times from the same point may share a rupture on a small structure but subsequently exhibit different cascading behaviors. Okuda and Ide (2019b) first identified such a pair in the Naka-Oki sequence, and Ide (2019) confirmed the existence of many such pairs in the Tohoku-Oki region. We suggest that a hierarchical structure with limited predictability is ubiquitous on the plate interface in the Tohoku-Oki region.

The contribution of fluid in the rock to the response of the Earth to external/internal forces is more and more attractive. Poroelastic rebound is one of the mechanisms of the post-seismic deformation. However, the conventional source functions, i.e. discontinuities in displacements and stresses across the source level, are still being used in investigating the poroelastic rebound. The forward and inverse problems are of great importance in evaluating earthquake hazard and investigating source mechanisms, as well as interpreting the observed deformation of the Earth, where the key link is the Green's functions which are computed in terms of the dislocation Love numbers (DLNs). The DLNs are obtained by solving the boundary value problem, in which the source functions are crucial. According to the body force equivalence and the theory of poroelasticity, we derived the source functions of a point dislocation in a porous medium. We found that, except the well-known solid dislocation, there are an independent fluid dislocation (explosion source) and a solid-liquid coupling term in dislocation type of horizontally tensile fracture. We first modeled the displacements caused by a given porous fault and then invert the slip parameters of this fault, respectively, by pure and porous elasticity to show the impact of the differences in source functions in the two theories. The results show that the impact is significant. Therefore, we recommend that a new unknown of fluid displacement normal to the fault be included in the inverse problem to get a forward fault model for geodetic applications.

Numerical Modelling of Earthquake Cycles and Surface Topography Based on Navier-stokes Equations with Viscoelastic-plasticity Rheology

DOI: 10.57757/IUGG23-3767 - LINK

Louis Moresi[1], Haibin Yang[1], Huihui Weng[2], Julian Giordani[3]
[1]Australian National University, Research School of Earth Sciences, Canberra, Australia
[2]Nanjing University, School of Earth Sciences and Engineering, Nanjing, China
[3]University of Sydney, School of Geosciences, Sydney, Australia

Visco-elastic-plastic modelling approaches for long-term tectonic deformation assume that co-seismic fault displacement can be integrated over 1,000s-10,000s years (tens of earthquake cycles) with the appropriate failure law, and that short-timescale fluctuations in the stress field due to individual earthquakes have no effect on long-term behavior. Models of the earthquake rupture process generally assume that the tectonic (long-range) stress field or kinematic boundary conditions are steady over the course of multiple earthquake cycles. In this study, we develop a numerical framework that embeds earthquake rupture dynamics into a long-term tectonic deformation model by adding inertial terms and using highly adaptive time-stepping that can capture deformation at plate-motion rates as well as individual earthquakes. We reproduce benchmarks at the earthquake timescale to demonstrate the effectiveness of our approach. We then discuss how these high-resolution models degrade if the time-step cannot capture the rupture process accurately and, from this, infer when it is important to consider coupling of the two timescales and the level of accuracy required. To build upon these benchmarks, we undertake a generic study of a thrust fault in the crust with a prescribed geometry. We find that lower crustal rheology affects the periodic time of characteristic earthquake cycles and the inter-seismic, free-surface deformation rate. In particular, the relaxation of the surface of a cratonic region (with a relatively strong lower crust) has a characteristic double-peaked uplift profile that persists for thousands of years after a major slip event. This pattern might be diagnostic of active faults in cratonic regions.

Systematic understanding of slow and fast earthquakes in terms of the porosity evolution law

DOI: 10.57757/IUGG23-0621 - LINK

Takehito Suzuki[1], Hiroshi Matsukawa[1]
[1]Aoyama Gakuin University, Department of Physical Sciences, Kanagawa, Japan

We have constructed the systematic formulation treating both the slow and fast earthquakes using the 1D Burridge-Knopoff model and the interaction among the heat, fluid pressure, and porosity (Suzuki and Matsukawa, in prep.). By employing the assumption that the dependence of the model parameters such as bulk moduli on the porosity can be neglected (constant-parameter assumption) and a single block, we show that the thermal (pore-generation) effect is dominant for the fluid pressure change, the fast (slow) earthquake occurs. We extend the framework to that without these assumptions. When the porosity increases monotonically to the upper limit with increasing the slip, changing the upper limit for the porosity is important step to remove the constant-parameter assumption. We also consider multiple block model.

We first assume the large upper limit. We found that the slow-to-fast transition occurs, and several blocks slowly slip after the fast earthquake. This behavior is interpreted as a tremor, which is considered to consist of sequential slow earthquakes like low frequency earthquakes. When the upper limit of the porosity is reduced, the tremors are harder to occur because the pore generation effect on fluid-pressure change becomes smaller than that of the thermal effect. In this case, both fast and slow earthquakes occur several times, but their prediction is impossible. When the upper limit of the porosity is negligibly small, the pore generation effect is almost negligible, and only the fast earthquakes repeat.

We have constructed the systematic formulation treating both the slow and fast earthquakes using the 1D Burridge-Knopoff model and the interaction among the heat, fluid pressure, and porosity (Suzuki and Matsukawa, in prep.). By employing the assumption that the dependence of the model parameters such as bulk moduli on the porosity can be neglected (constant-parameter assumption) and a single block, we show that the thermal (pore-generation) effect is dominant for the fluid pressure change, the fast (slow) earthquake occurs. We extend the framework to that without these assumptions. When the porosity increases monotonically to the upper limit with increasing the slip, changing the upper limit for the porosity is important step to remove the constant-parameter assumption. We also consider multiple block model.

On the frictional growth of fractures in the preparation phase of earthquakes

DOI: 10.57757/IUGG23-2078 - LINK

Torsten Dahm[1], *Sebastian Hainzl*[1], *Eleonora Rivalta*[1]
[1]*GFZ German Research Centre For Geosciences, Geophysics, Potsdam, Germany*

We develop a simple fracture mechanics model for the stable growth of a penny-shaped shear crack under friction. We assume equilibrium between released strain energy and frictional energy and suggest a stability criterion that combines the tip stress intensity in fracture mechanics with the threshold criterion of frictional strength in a Coulomb failure approach. Fracture growth causes a slow but steady buildup of stress. On a larger fault, patches of increased shear stress may develop with the time to failure and the size of the patch depending on the background stress and the constitutive relations. The model predicts a self-regulating feedback loop that keeps stress intensity low until a strength threshold is exceeded at the point of high stress. At this point, instability occurs and a rupture nucleation phase may start culminating in a co-seismic rupture. The available fracture energy scales with the third power of the fracture length, while the slip on the fracture is a linear function of the fracture length.

The new model may explain how a slow preparatory phase transitions into rupture nucleation. It suggests that large earthquakes tend to develop on faults with intermediate stress levels. Faults with very low stress may not produce stress asperities and remain stable, while faults with very high stress tend to produce smaller earthquakes after a short preparation period.

Complex fault geometry can strongly affect earthquake rupture processes and slip sequences. I will first present our recent work on modeling earthquake and slow slip sequences on 3D fault surfaces, with applications to the Yingxiu-Beichuan fault (YBF) which hosted the 2008 Mw 7.9 Wenchuan earthquake in China and the Cascadia subduction zone. In the rate-and-state friction computational framework, earthquake and aseismic slip nucleate and propagate spontaneously under the influence of long-term tectonic loading and heterogeneous frictional properties. In particular, fault dip angle has a primary control on the along-strike segmentation of simulated earthquake and slow slip, in general agreement with observations from YBF and Cascadia. Fault local strike angle on the other hand strongly affects small-scale along-strike variations in the rupture speed and slip rate. Next, I will introduce a newly developed mixed-flux-based discontinuous Galerkin method and its application to simulate fully dynamic ruptures on complex fault geometries. The new method greatly reduces numerical dependence on mesh quality, and can accommodate complex fault properties including geometry, material heterogeneities and multi-physics mechanisms such as off-fault plasticity and thermal pressurization.

Physical interpretation of slow earthquake migration process based on a friction law

DOI: 10.57757/IUGG23-0024 - LINK

Keisuke Ariyoshi[1]
[1]*Japan Agency for Marine-Earth Science and Technology JAMSTEC, R&D Center for Earthquake and Tsunami Forecasting, Yokohama, Japan*

I derive a quantitative relationship between various types of migrating slow earthquake phenomena and frictional properties of a rate and state dependent friction law. By assuming that local pore water in front of the migration drives rapid tremor reversal and is so local as to hold a constant stress drop, the application of the analytical solution to observational results suggests that(i) the temporal changes of observed migration speeds for the rapid tremor reversal could be explained by about 70% reduction of the effective normal stress; (ii) effective normal stress for the deeper extension of seismogenic segment in the western part of Shikoku is about 1.5 times greater than that in the central part. Applying rupture time delay between slow earthquake asperities for the duration longer than regular earthquake, I also conclude that (iii) the characteristic slip distance of rate-and-state friction for low-frequency earthquakes is roughly between 30 μm and 30 mm; (iv) the stress and strength drops of very low-frequency earthquakes is much smaller than 1 MPa.

The fascinating tectonic evolution of the Mediterranean region comprises subduction at numerous subduction zones, extension and seafloor spreading in back-arc areas, and convergence of major continents and smaller continental blocks between them. The active subduction of the Greater Adria block is a dominant feature of the central Mediterranean dynamics. AdriaArray, the ongoing major international experiment, has produced unprecedentedly dense seismic data sampling of the area. It brings into focus both its structure and dynamics and the methodologies for how to best use the abundant seismic and other data to determine the physical structure and dynamics of the lithosphere and underlying mantle.

The Mediterranean lithosphere is highly heterogeneous in its thickness, temperature and mechanical strength. This heterogeneity evolves with time and exerts controls on the intraplate magmatism and seismicity. Combined evidence from seismic anisotropy and the geological record sheds light on the 3D patterns of lithospheric deformation. Physical structure of the lithosphere can be determined with seismic surface waves. Using computational petrology and thermodynamic databases, we can invert surface-wave and other data for temperature and composition at depth, equilibrium lithospheric geotherms and lithospheric thickness. It is essential to use accurate surface-wave measurements and fit them closely, to impose constraints on the models from other available data and physical relationships, and to tune the inversions so as to resolve parameter trade-offs. With these developments, thermodynamic inversions yield increasingly accurate models of the lithospheric temperature, thickness and internal structure, with important inferences on its dynamics, evolution and controls on deformation and volcanism.

We perform a comprehensive P-to-S and S-to-P receiver function analyses to determine the depth of lithospheric discontinuities in the Eastern Alps, Pannonian Basin, Carpathians, and the Dinarides. The Pannonian Basin of Central Europe hosts thick sedimentary deposits of up to 7 km thickness in extensional half-graben geometries overlying the crystalline orogenic basement. Prior to this study, the mapping of the seismic discontinuities in the lithosphere beneath the investigated area was not uniform and the estimated depth values bore non-negligible uncertainties.

Owing to the combined, dense station coverage of more than 380 seismological stations we can achieve hitherto unprecedented spatial resolution. Our study is based on two decades (2002–2022) of broadband waveforms with uniform automatic waveform processing and quality control procedures. This detailed procedure provides new geological and geophysical information about the lithosphere of the region.

The obtained results allow us to infer a 3D lithospheric structural model of the region. We have developed a new interpolation and visualization algorithm. We mapped the thickness of the main crustal layers and the lithosphere, together with an estimate of their uncertainties.

We present the sedimentary thickness map, the first Conrad depth map and an improved, detailed Moho map, the first upper and lower crustal thickness maps, as well as the lithospheric (Lithosphere-Asthenosphere-Boundary and Mid-Lithospheric-Discontinuity) thickness map obtained from receiver function analysis. We show migrated Common Conversion Point cross-sections beneath the Pannonian Basin and Carpathians, and the Eastern Alps–Pannonian Basin transition zone.

Finally, we compare and jointly interpret the results of the receiver functions with previous geophysical investigations and seismic tomography models.

Identifying Seismic Anisotropy Patterns and Improving Tomographic Images in the Alps and Apennines Subduction Environments with Splitting Intensity

DOI: 10.57757/IUGG23-3537 - LINK

Judith Confal[1], *Paola Baccheschi*[2], *Silvia Pondrelli*[1]

Active and past subduction systems influence the interpretation and understanding of current tectonics and velocity structures of the upper mantle of the Alps and Apennines. Computational advances over the years made it possible to identify remnant and active slabs up to great depths. 824 stations were used in this study to calculate splitting intensities in an automated process. Compared to SKS measurements, more stable fast polarisation directions were recovered with a pattern paralleling the strike of the mountain belts and a clockwise rotation in the Alps. While strong anisotropy has been recovered over the bulge of the Alps and Apennines chain, weaker anisotropy has been found beneath the Po plain, the eastern sector of the Apennines, in the western sector of Sicily and the external European domain. On the other hand it is still difficult to get reliable depth-dependent anisotropy, therefore we adopted the tomographic method relying on the inversion of splitting intensity (SI). Since it is linearly related to the elastic perturbations of the medium through the 3-D sensitivity kernels, SI can be easily inverted, providing the basis for a better interpretation of shear wave splitting measurements. The anisotropic tomography models obtained so far allowed us to recover the most prominent splitting patterns and see some changes with depth, especially for the strength of anisotropy. Directional changes often seem to be related to the slab domain or dimension (e.g. Central Italy or Sicily).

The complex geophysical structures in the Italian region make it even more difficult to invert gravimetric data for determining the depths of the Moho. However, a revised computation approach based on windowed Least Square Collocation has been set up to deal with local features like Ivrea Body, important sedimental basins, tectonics and orogenic activities. The Italian ground-based gravity dataset has been used to determine the Moho depths over land and sea areas and the gravimetric model have been compared with the Moho depth values obtained by different techniques as the seismic reflection and refraction profiles, receiver functions and seismic surface waves. Nowadays different solutions are available for some areas, as the Alpine Region, however the Moho depths can differ for several km, so the gravimetric Moho validation represents also a validation of the seismic models, because the gravimetric inversion represent an independent estimate with respect to the seismic solutions.

The tectonic structure of the Eastern Alps is heavily debated with successive geophysical studies that are unable to resolve areas of ambiguity (e.g., the presence of a switch in subduction polarity and differing crustal models). In order to better understand this area, we produce a high resolution Moho map of the Eastern Alps based on a dense seismic broadband array deployment. Moho depths were derived from joint analysis of receiver function images of direct conversions and multiple reflections for both the SV (radial) and SH (transverse) components, which enables us to map overlapping and inclined discontinuities. We observe the European Moho to be underlying the Adriatic Moho from the west up to the eastern edge of the Tauern Window. East of the Tauern Window, a sharp transition from underthrusting European to a flat and thinned crust associated with Pannonian extension tectonics occurs, which is underthrust by both European crust in the north and by Adriatic crust in the south. The Adriatic lithosphere underthrusts northward below the Southern Alps and becomes steeper and deeper towards the Dinarides where it dips towards the north-east. Our results suggest that the steep high velocity region in the mantle below the Eastern Alps, observed in tomographic studies, is likely to be of European origin.

On transient creep in Earth's upper mantle: How to link geophysical observations on short-term deformation to long-term geological deformation?

DOI: 10.57757/IUGG23-0352 - [LINK]

Shun-Ichiro Karato[1]*, Girard Jennifer*[1]
[1]*Yale University, Earth and Planetary Sciences, New Haven, USA*

Rheological properties of Earth can be inferred from several types of time-dependent deformation including the post-glacial isostatic adjustment (GIA) and post-seismic deformation (PSD). The time scale of deformation is ~10^3-10^4 y for GIA, and 1-10 y for PSD, as compared to 10^7-10^8 y for geological deformation. The stress magnitude associated with GIA and PSD is not much different from that with geological deformation, but the strain is vastly different: ~ elastic strain (or less) for GIA and PSD, while it is much larger than elastic strain for geological deformation.

In order to link rheological properties inferred from small strain phenomena to rheological behavior associated with large strain, we need to understand the physical mechanisms of transient creep. Currently two models are proposed: (i) intra-granular and (ii) inter-granular transient creep. In the former, transient creep behavior is attributed to dislocation dynamics within a grain (with a given slip system), while in the latter, it is attributed to grain-grain interaction involving multiple slip systems. We have conducted deformation experiments of olivine aggregates and single crystals together using a synchrotron facility to test these models. Strain is measured by X-ray imaging while stress is measured by radial X-ray diffraction form a polycrystalline olivine as well as a pyrope stress sensor. The results show that in a polycrystal, the average stress is near the lower end of stress levels inferred from various diffraction planes (hkl) at small strains, but it becomes close to the upper end at large strains (with a transition strain close to the elastic strain). This suggests a transition in the rate controlling slip systems with strain. In comparison, the transition strain for a single crystal (for the [001] slip) is substantially smaller than elastic strain. We conclude that in a deforming polycrystal olivine, single crystals attain steady-state quickly and the transient behavior is largely controlled by the evolution of controlling slip systems caused by grain-grain interactions. Because sensitivity of deformation on some parameters such as water content differs among different slip systems, applications of rheological properties inferred from short-term geophysical with long-term deformation needs to be made with a great care.

Rheological properties of Earth can be inferred from several types of time-dependent deformation including the post-glacial isostatic adjustment (GIA) and post-seismic deformation (PSD). Olivine radiative heat transport can cause premature dehydration of subducting slabs

DOI: 10.57757/IUGG23-0918 - LINK

Enrico Marzotto[1], Sergey Lobanov[1], Sergio Speziale[1]
[1]Deutsches GeoForschungsZentrum GFZ- Potsdam,
Section 3.6: Chemistry and Physics of Geomaterials, Potsdam, Germany

Temperature is a key parameter that governs the physical behavior of subducting slabs: their buoyancy, rheology, phase transitions, and dehydration reactions. Upon their descent into the mantle, subducting slabs are heated by diffusion, which is controlled by the total thermal conductivity. In mantle minerals, two microscopic mechanisms contribute to total conductivity: lattice and radiative heat transport. The crystal structure of a mineral determines its lattice conductivity, whereas the optical absorption coefficient determines the radiative component. Both depend on P, T, composition, and phase polymorphs. Nevertheless, in thermal evolution models of slabs, lattice component is often assumed constant while radiative is usually ignored, because its variation with P, T, phase, and composition is generally unconstrained. Here, we measured the optical absorption coefficient of olivine at T up to 1000 K and P up to 10 GPa to infer its radiative thermal conductivity. We found that radiative contribution is as important as lattice contribution for diffusing heat transport, representing 40-50% of olivine´s total conductivity. We further modelled slab thermal evolution with 2D finite-difference method. Accounting for radiative heat transport produces slabs that are ~200 K warmer than the models with only the lattice contribution. Our models show extensive dehydration of the upper 10 km of the slab at depths of ~140-280 km. The released water fails to reach the MTZ, and it might be responsible for the intermediate-deep seismicity. Water delivery into the MTZ is therefore only possible within the cold slab core (~30 km) or inside fast sinking slabs (>10 cm/year).

Temperature is a key parameter that governs the physical behavior of subducting slabs: their buoyancy, rheology, phase transitions, and dehydration reactions. Upon their descent into the mantle, subducting slabs are heated by diffusion, which is controlled by the total thermal conductivity. In mantle minerals, two microscopic mechanisms contribute to total conductivity: lattice and radiative heat transport. The crystal structure of a mineral determines its lattice conductivity, whereas the optical absorption coefficient determines the radiative component. Both depend on P, T, composition, and phase polymorphs. Nevertheless, in thermal evolution models of slabs, lattice component is often assumed constant while radiative is usually ignored, because its variation with P, T, phase, and composition is generally unconstrained. Here, we measured the optical absorption coefficient of olivine at T up to 1000 K and P up to 10 GPa to infer its radiative thermal conductivity. We found that radiative contribution is as important as lattice contribution for diffusing heat transport, representing 40-50% of olivine´s total conductivity. We further modelled slab thermal evolution with 2D finite-difference method. Accounting for radiative heat transport produces slabs that are ~200 K warmer than the models with only the lattice contribution. Our models show extensive dehydration of the upper 10 km of the slab at depths of ~140-280 km. The released water fails to reach the MTZ, and it might be responsible for the intermediate-deep seismicity. Water delivery into the MTZ is therefore only possible within the cold slab core (~30 km) or inside fast sinking slabs (>10 cm/year).

Squirt-flow in the crust and seismic intrinsic Q: Some micro-physics for naturally fractured formations

DOI: 10.57757/IUGG23-4544 - LINK

Pierre-Michel Rouleau[1]
[1]*Memorial University of Newfoundland, School of Science & the Environment / Physics, Corner Brook, Canada*

Dissipation of elastic energy by way of the "squirt-flow" mechanism is considered as a predominant cause of the frequency dependence of the quality factor Q observed in vibrated fluid-saturated rock samples. Models of the process (e.g. BISQ) have long been useful to infer key properties of fluid-saturated granular rocks but extension of such modelling to crustal-scale formations has yet to be thoroughly investigated. Central to the modelling is a micro-scale locus of dissipation represented by a dual pore system, with one part more compliant than the other – a system that is required to have characteristic dimensions. Rock formations in the brittle crust are highly fractured, with fracture-wall topography known to be fractal; thus, ab initio, the rough, porous interstitial space within natural fractures appears to have no "characteristic dimensions". However, as argued here, a closer look at such inter-space does reveal a characteristic dimension, one that is quantifiable by hydraulic properties of rock formations measured at the crustal scale. The structure of the permeable space in between two fractal fracture walls suggests that a locus of dissipation therein can be modelled as a fluid-saturated dual pore system, with a compliant narrow cylindrical gap centre, surrounded by a less compliant permeable ring. The complex stiffness of such a system under oscillatory forcing is solved for, subjected to boundary conditions imposed by the inter-space structure, and subsequently scaled-up to field-scale measurements. Results are presented in term of seismic Q versus frequency of forcing, under realistic thermodynamic conditions of a brittle crust.

Evidence for amorphous calcium carbonate originated mid-lithospheric discontinuities

DOI: 10.57757/IUGG23-0798 - LINK

Mingqiang Hou[1]
[1]*Innovation Academy for Precision Measurement Science and Technology, State Key Laboratory of Geodesy and Earth's Dynamics, Wuhan, China*

Cratonic lithosphere is a vast host for deep recycled carbon, trapping up to several weight percent CO_2 among its compositions at depths overlapping the seismic mid-lithospheric discontinuities (MLDs). However, the role of carbonates, especially for the latest discovered amorphous calcium carbonate ($CaCO_3$), is underestimated in forming MLDs. Using the pulse-echo-overlap method in a Paris-Edinburgh press coupled with X-ray diffraction, we explored the acoustic velocities of $CaCO_3$ under high pressure-temperature (*P*-*T*) conditions relevant to the cratonic lithosphere. Two anomalous velocity drops were observed associated with the phase transition from aragonite to amorphous phase as well as with pressure-induced velocity drop in amorphous phase around 3 GPa, respectively. Both drops are comparable with approximately 35% and 52% reductions for compressional (V_P) and shear (V_S) wave velocities, respectively. The V_P and V_S values of the amorphous $CaCO_3$ above 3 GPa are about 1/2 and 1/3 of those of the major upper-mantle minerals, respectively, and they are the same with aragonite below 3 GPa. These velocity reductions by the presence of $CaCO_3$ would readily cause MLDs at depths of 70–120 km dependent on the geotherm even if only 1-2 vol.% $CaCO_3$ presents in the cratonic lithosphere. The $CaCO_3$-originated MLDs is weak so as to be expected to influence the stability, rifting, and delamination of the craton.

Identifying available and minable critical minerals worldwide is crucial to stabilizing the supply chains and the markets for these minerals. Because of the low concentrations of critical minerals throughout the world, we focus on identifying geophysical signatures from geological structures associated with the origin and geochemical character of these minerals. In this work, we identify geophysical signatures generated by critical minerals in west Texas using publicly available geophysical datasets, including aero-radiometric, topographic, aero-magnetic, and gravity datasets, on both local and regional scales. We also compile geological information along with the geophysical datasets in caldera systems at various evolution stages, specifically studying the subsurface structures of felsic igneous provinces along a tectonic rift shoulder in west Texas, including what we believe are undeveloped calderas in a well-studied area consisting of laccoliths. We are creating a geological geochemical and geophysical signature database of potential critical mineral sites in west Texas because rift shoulders have an unusual concentration of critical minerals. These databases are cross referenced with other regions that show similar characteristics. For example , Round Mountain is a site currently under development for HRREs and other critical minerals. However, some sites may be economically feasible for exploration of critical minerals, but may never be exploited because they lie in protected regions.

Seismic tomography maps seismic-velocity distributions within the Earth. Lateral variations of seismic velocities in the mantle depend primarily on variations in temperature. Thus, tomography gives us a proxy for the thermal heterogeneity in the Earth, of great interest because it determines the thickness and mechanical strength of the lithosphere and the density variations and convection patterns in the sub-lithospheric mantle. Obtaining accurate, quantitative mapping of temperature, however, is not straightforward. Tomographic models are non-unique solutions of inverse problems, regularized to yield solutions with properties such as smoothness or small model norm, not physical plausibility. For example, lithospheric geotherms computed from tomographic models typically display unrealistic temperature oscillations, with implausible temperature decreases with depth. If a tomographic model is all we have, a reasonable approach is to look for a physically plausible geotherm that fits seismic velocities in the entire lithospheric depth range best, in some sense. A generally more accurate approach is to invert seismic data, from the start, directly for what we want to know. Using computational petrology and thermodynamic databases, we can invert seismic-surface-wave and other data for temperature and composition at depth, equilibrium lithospheric geotherms and the lithospheric thickness. We must use accurate surface-wave measurements and fit them closely; impose constraints on the models from other available data and physical relationships; and tune the inversions so as to resolve essential parameter trade-offs. With these developments, thermodynamic inversions yield increasingly accurate models of the lithosphere's temperature, thickness and internal structure, with important inferences on its dynamics and evolution.

Despite 160 years of probing the world crust, due to lack of seismic and ground gravity observations, there are still white spots in the worlds' crustal thickness map. The crustal structure in those regions is among the least understood of the Earth's continental areas, and variations in basic but fundamental parameters - such as crustal thickness - are still poorly constrained over large areas. Recent research has shown that satellite gravity-based crustal modeling in regions with limited seismological coverage can provide unique insights in crustal thickness and underlying geodynamical processes.

In almost all of these cases the gravity signal related to crustal structure is isolated by applying 3 different corrections: topography, sediments, and upper mantle structure.

Of these three, the upper mantle correction is least well addressed. It doesn’t account for any lateral inhomogeneity upper mantle composition close to the crust-mantle boundary. As a result, satellite gravity data reductions for upper mantle structure are a source of uncertainty.

Our new model includes a new state-of-the-art upper mantle correction. By combining satellite gravity and seismic tomography, we have formulated a new methodology to integrate potential field data inversions, tomographic modelling, and petrolophysics into a single inversion scheme. Our crustal thickness model ECM22 has therefore more accurate crustal thickness values, is seismically fitting better than previous models, and is now also consistent with gravity observations: up to a factor 85 times more accurate than e.g. CRUST1.0 and 4 times better than the GEMMA crustal model.

Earlier studies revealed the effect of different degrees of depletion on lateral/vertical velocity and density variations in the upper mantle of the Precambrian cratons. The South Africa cratonic region includes the Kaapvaal and Zimbabwe craton, whose deep and fast lithospheric roots are likely depleted in heavy constituents. In contrast, there exist regions, such as the Limpopo belt and Bushveld Complex, which are characterized by negative velocity anomalies in the upper mantle, likely indicating a more fertile composition. To unravel the origin of these anomalies and link them to the tectonic history of the area, we apply an integrative technique based on a joint interpretation of the seismic tomography and gravity data, which can discern temperature and compositional variations. For this purpose, we combine the global surface seismic tomography model [1] with the embedded regional model [2], derived from teleseismic tomographic inversion of the S-body wave dataset recorded by the Southern African Seismic Experiment. The combined seismic model is inverted for temperature, assuming an initial fertile composition based on the xenolith data [3], using a mineral physics approach [4]. The composition and temperature of the upper mantle are iteratively changed to fit the residual density, obtained from the joint inversion of the residual gravity and residual topography. The key results show different structures and properties of the upper mantle, improving our understanding of the South African cratonic lithosphere.

The influence of Moho depth on the seismic / density structure of the Antarctic upper mantle

DOI: 10.57757/IUGG23-1697 - LINK

Rosaria Tondi[1], Alessandra Borghi[1], Andrea Morelli[1]
[1]Istituto Nazionale di Geofisica e Vulcanologia INGV, Sezione di Bologna, Bologna, Italy

With its hostile and remote environment, information on Antarctica's geologic history and its internal geophysical structure remains today the most incomplete on Earth. In particular, Moho depth estimate studies are in disagreement by more than 10 km in several regions and, the Antarctic upper mantle remains among the most poorly imaged regions in the Earth.

In this study, we explore the impact of using different Moho surfaces on the reconstruction of the 3D density and velocity parameters beneath the Antarctic continent.

To achieve this goal we selected as input for the used optimization algorithm (Sequential Integrated Inversion, Tondi et al., 2012) four Moho depth estimates, which we believe to be the most representative of the last studies on the continent: (a) a pure gravimetric Moho (Borghi, 2022); (b) a depth to Moho (Baranov et al., 2018) recovered using the BEDMAP2 subglacial relief (Fretwell et al., 2013) together with results from the analysis of recent seismic data (Baranov and Morelli, 2013; Chaput et al., 2014) and gravity constraints; (c) a seismological Moho (An et al., 2015); (d) a Moho depth estimate constrained by both satellite gravity and seismological information (Pappa et al., 2019).

To complete the starting information, we exploited: (1) the surface wave tomography of the Antarctic upper mantle (Danesi and Morelli, 2001) and (2) the gravity database synthetized by the global satellite gravity model GO_CONS_GCF_2_TIM_R6e (Zingerle et al., 2019).

Results show the crucial implications of the Moho topography on the recovered geophysical parameters, especially in little explored areas.

The presence of fluids in closely aligned fractures is important for a range of processes within the Earth. In the near-surface, understanding systems of fluid-filled fractures is important in various applications such as geothermal energy production, monitoring CO_2 storage sites and exploring for metalliferous sub-volcanic brines (e.g., Blundy et al., 2021). In the mantle, melting is an important geodynamic process, exerting control over mantle composition and dynamic processes. Upper mantle melting weakens the lithosphere, facilitating rifting (Kendall et al., 2005) and other surface expressions of tectonic processes.

Models of aligned fluid-filled fractures, or inclusions with small aspect ratios, predict both velocity and attenuation anisotropy for shear-waves (e.g., Hudson, 1982; Chapman 2003). Forward modelling shows that attenuation anisotropy is highly sensitive to important fracture properties, such as fracture length and orientation, and can be frequency dependent. Attenuation anisotropy can be observed by measuring shear-wave splitting as the two separated shear-waves experience a different seismic quality factor as they propagate through the anisotropic medium.

Measurements of attenuation anisotropy therefore offer a new approach to seismically detect fluids in the subsurface. Here we present a method for measuring attenuation anisotropy using an adaptation of the instantaneous frequency method of Mathenay and Nowack (1995). We explore the potential of this technique using synthetics and make measurements of attenuation anisotropy in SKS data collected at the Yellowknife array, Canada, and at stations across the Main Ethiopia Rift. These results highlight the potential for attenuation anisotropy as a tool to detect geofluids in the subsurface.

Ambient noise tomography reveals the affinity of the Tan-Lu Fault to regional deformation in Eastern China

DOI: 10.57757/IUGG23-0368 - LINK

Terhemba Shadrach Bem[1], Huajian Yao[1], Junlun Li[1]
[1]University of Science and Technology of China,
Laboratory of Seismology and Physics of Earth's Interior- School of Earth and Space Science s, 96 Jinzhai Road- Hefei 230026 Anhui, China

In Eastern China, complex tectonic structures of high geological/geophysical relevance suggest multiple subductions in the region making the region an ideal physical laboratory for investigating the feedback effect of subduction on the continent. In particular, subduction could have resulted in the formation of the Tan-Lu Fault Zone (TLFZ); a tectonic structure believed to have significantly aided the instability of the lithosphere and as well, played an essential role in the further modification of the lithosphere. To provide additional observational constraints on the fault activities such as its affinity to regional deformation, we took advantage of the ambient noise dataset to produce joint tomography models of Vsv (isotropic and azimuthal anisotropy) across the TLFZ. First, the models reveal structural segmentation, with structures that trend in the direction of the strike of the TLFZ. The isotropic Vsv shows a widespread low velocity in the lower crust, which could serve as a stress accumulator for the reactivation of faults. The polarization of azimuthal anisotropy in the TLFZ and the Zhangbaling uplift are NNE-SSW to N-S; sub-parallel to the strike of the fault in the crust and uppermost mantle. The trend of the anisotropy mimics the shape of the TLFZ in the crust and the uppermost mantle, which confirms that the Tan-Lu fault is a deep-seated lithospheric structure. This may also suggest that the fault controls the anisotropy and hence, the deformation in the region. These models highlight the dominant control of the fault on the regional deformation and geodynamic processes in eastern China.

Shear-velocity anisotropy in the lower crust of the Bohemian Massif from ambient noise tomography

DOI: 10.57757/IUGG23-1686 - LINK

Jiri Kvapil[1], *Plomerova Jaroslava*[1], *AlpArray Working Group*[2]
[1]*Institute of Geophysics of the Czech Academy of Science, Department of Seismology, Prague, Czech Republic*
[2]*http://www.alparray.ethz.ch/en/home/, Eth, Zurich, Switzerland*

Previous research of the Bohemian Massif (BM) crust using ambient noise tomography (ANT) indicates a transversely isotropic layer in the lower crust (Kvapil et al., 2021). In this study, we have developed a new method for extracting seismic anisotropy from dispersion curve measurements in the regional scale using synthetic ray-path modelling over reference isotropic 3D v_{SV} model. We examine how the derived seismic anisotropy correlates with the major tectonic units of the BM.

Seismic anisotropy records the stress/strain conditions of each originally independent tectonic microplate during the formation of the BM crust. We use ambient noise cross-correlation data from the seismic stations included in the AlpArray passive seismic experiment with its complementary PACASE experiment and data from PASSEQ experiment which complement the sparse coverage in the northern part of the BM. Our anisotropic inversion procedure is proving to be an efficient tool for measuring seismic anisotropy in the lower crust on a dense grid directly from Rayleigh and Love wave dispersion curves.

We calculate synthetic Love velocities (v_{SH}) from the 3D isotropic v_{SV} model and compare the synthetic v_{SH}/v_{SV} with measured v_{SH}/v_{SV}. The higher ratio of measured v_{SH}/v_{SV} to synthetic v_{SH}/v_{SV} proves the existence of velocity anisotropy in the lower crust of the BM in the reference ANT model (Kvapil et al., 2021). We show that variations in azimuthal anisotropy are period dependent, with zonation of fast velocity directions on a regional scale; this can provide constraints for the reconstruction of geodynamic processes during the formation of the BM.

Previous research of the Bohemian Massif (BM) crust using ambient noise tomography (ANT) indicates a transversely isotropic layer in the lower crust (Kvapil et al., 2021). In this study, we have developed a new method for extracting seismic anisotropy from dispersion curve measurements in the regional scale using synthetic ray-path modelling over reference isotropic 3D v_{SV} model. We examine how the derived seismic anisotropy correlates with the major tectonic units of the BM.

While the presence of anisotropy in the uppermost mantle is well established, its detailed patterns are still debated. We present SPacific-rani, a new upper mantle radially anisotropic model of the Pacific which builds on the global whole mantle radially anisotropic model SGLOBE-rani by including additional data along with improved waveform modelling based on the spectral element method. SPacific-rani shows an asymmetry at the East Pacific Rise, requiring stronger radial anisotropy to the West of the East Pacific Rise than to the East, which is possibly due to lattice preferred orientation produced by shear-driven asthenospheric flow beneath the South Pacific superswell. Moreover, SPacific-rani shows a reduction in radial anisotropy with lithospheric age, possibly due to a deviation from horizontal flow as the mantle is entrained with slabs. In order to interpret existing models of upper mantle anisotropy beneath the oceans we develop 2D ridge flow models combined with mantle fabric calculations. We find that faster plates generate higher tectonics stresses and strain rates which lower the dislocation creep viscosity and lead to deeper anisotropy than beneath slower plates. By applying a tomographic filter to the geodynamical models, we retrieve a flat depth-age trend and stronger anisotropy beneath faster plates, which correlates well with existing 3D global anisotropic mantle models. Our predictions and observations suggest that as plate speed increases from 2 to 8 cm/yr, radial anisotropy increases by ~0.01–0.025 in the upper 100–200 km of the mantle between 10 and 60 Ma.

Seismic anisotropy and upper mantle flow in southeastern Mexico inferred from teleseismic and local intraslab earthquakes

DOI: 10.57757/IUGG23-2122 - LINK

Samuel Celis[1], Raul W. Valenzuela[1], Xyoli Pérez-Campos[1]
[1]Universidad Nacional Autónoma de México, Instituto de Geofísica, Ciudad de México, Mexico

Silver and Chan (1991) covariance method was used to measure shear-wave splitting for both teleseismic and local intraslab earthquakes. Teleseismic measurements are consistent with subslab entrained flow below the subducted Cocos slab and with corner flow in the mantle wedge except in Chiapas where the fast polarization directions show greater variability and short delay times. Local measurements can be divided into three regions: The first region is located southeast of the Tehuantepec ridge extension. The measured fast polarization directions show a trench-parallel orientation that can be interpreted to result from the presence of a serpentinized mantle wedge beneath the forearc and a trench-parallel flow through the mantle wedge core. The second region is located northwest of the Tehuantepec ridge extension. Northeast of the 100 km isodepth contour of the Cocos slab the fast axes are trench perpendicular. This could be explained assuming the development of A-type olivine fabric and the existence of corner flow driven by the downdip motion of the Cocos slab. Between the 60 and 100 km isodepth contours, measurements are consistent with the presence of a serpentinized mantle wedge. Right above the Tehuantepec ridge extension, a change in the fast polarization directions from trench-normal to trench-parallel could suggest a change in the mantle flow pattern and could be evidence of a vertical tear in the Cocos slab coincident with the Tehuantepec ridge extension. Lastly, the third region is located above the subhorizontal Cocos slab where crustal faults seem to be the dominant factor producing the observed anisotropy.

Canada presents an excellent opportunity to study lithospheric and sublithospheric processes due to its preservation of ~4 billion years of geological history. Deformation from past tectonic processes is preserved in the thick lithosphere of the Canadian Shield, in contrast to the active tectonics and thin lithosphere in the Canadian Cordillera. Such large variations in lithospheric thickness, whether on a sharp or gradual lateral scale, likely perturb mantle convective flow beneath the continent, adding complexity to sublithospheric fabric.

We use dispersion data from teleseismic Rayleigh waves to investigate upper-mantle structure beneath Canada and the central-northern USA. For periods of 20 to 220 seconds, azimuthal coverage of inter-station paths is sufficient to resolve isotropic heterogeneities and azimuthal anisotropy across the study area. Significant lateral variation in azimuthal anisotropic parameters and changes as a function of period suggest complex lithospheric and sublithospheric fabric. However, the stratification of the anisotropy is difficult to interpret directly from the phase velocity maps due to the wide depth range sampled by each period.

To investigate the depth-dependence of azimuthal anisotropy, we extract the 1D dispersion parameters at selected points in the phase velocity maps. An anisotropic depth inversion is carried out to investigate the relative roles of 'frozen' lithospheric fabric and lattice-preferred orientation related to active mantle convective flow. We also search for stratification in azimuthal anisotropy with depth within the thick lithosphere of the Canadian Shield and speculate on the tectonic processes that contribute to such layering.

Variation of seismic anisotropy with depth in deformational regimes of continental plates

DOI: 10.57757/IUGG23-3661 - LINK

The correlation between mantle flow and seismic anisotropy emphasizes its key role in understanding tectonic processes. While global geodynamic modelling of asthenospheric mantle flow results in a good correlation, the large spatial variation of seismic anisotropy beneath continents indicates a considerable complex contribution of the shallow lithosphere, which is not yet well understood. A detailed imaging of anisotropy with depth is therefore an important challenge for seismic investigation.

Here, we present our current advances in improving the depth resolution based on receiver function and SKS-splitting techniques applied at the continental margins of the European Alps and Central Appalachians.

Classical shear-wave splitting techniques are mostly used to infer a single anisotropic layer. This becomes misleading for continental margins with complex deformation. An azimuthal variation of splitting parameters is an indication for vertical layering of anisotropy and can be analyzed systematically providing insight into these complexities. However, this approach allows no direct constraint on the depth distribution. Recent developments involve the calculation of sensitivity kernels for Splitting Intensity observations, which allows us to consider the laterally broadened sensitivity for the anisotropic structure with depth. A requirement of this tomographic technique is a dense station spacing, which is satisfied by a growing number of seismic deployments.

The increased lateral stress in deformational regimes at shallow levels results in a possible contamination of shear-wave splitting by crustal anisotropy. We suggest a stepwise approach in which receiver functions are examined for their harmonic variation with backazimuth to determine and correct for significant anisotropic crustal effects.

Body-wave recordings from passive seismic experiments AlpArray-EASI (2014-2015) and AlpArray Seismic Network (2016-2019) are evaluated to image the upper mantle large-scale anisotropy and to model the lithosphere-asthenosphere boundary (LAB) beneath the western part of the Bohemian Massif and the Eastern Alps. We analyze P-wave traveltime deviations and interpret them along with results of splitting parameters from core-mantle refracted shear waves at 240 broad-band stations in about 200 km broad and 540 km long band along 13.3° E longitude. The body-wave anisotropic parameters are inverted jointly for 3D self-consistent anisotropic-velocity models of individual mantle lithosphere domains, assuming hexagonal symmetry with inclined ‘slow’ or ‘fast’ axes. To control the depth extent of the fabric, we apply coupled 3D anisotropic-isotropic P-wave tomography (Munzarova et al., 2018). Anisotropic signals in body waves are consistent within sub-regions and often sharply change at tectonic boundaries. The coincidence of boundaries of the anisotropic models of the mantle lithosphere domains with main tectonic features, correlation of the anisotropy depth extent with the LAB models as well as a decrease of anisotropy strength in the sub-lithospheric mantle support fossil origin of the directionally varying component of detected anisotropic fabrics of the continental mantle lithosphere.

Lithospheric architecture and deformational patterns below the Eastern Ghats Mobile Belt: an integrated seismological perspective

DOI: 10.57757/IUGG23-2598 - LINK

Niptika Jana[1], Arun Singh[2], Chandrani Singh[2]

Understanding of the evolutionary geodynamics of the Eastern Ghats Mobile Belt (EGMB), is crucial to reconstruction of the Rodinia and Gondwana supercontinents. However limited aspects of its structure and evolutional origin are known. Based on lithological assemblage and geochronological data, EGMB is divided into multiple heterogeneously deformed terranes. Recent seismological studies across the EGMB-Archaean craton boundary adds new perspective regarding the deformation of the region and its correlation with East-Antarctica. Integrated studies reveal heterogeneous structure across the craton and mobile-belt characterised by 32-37km, ~42km and 110-160km, 80-120km thick crust and lithosphere respectively, suggesting collisional thrusting of EGMB against the Archean Cratons that explains the abrupt changes in crustal thickness across the craton-mobile belt. The influence of mantle-plumes, owing to the trajectory of the Indian subcontinent across the Kerguelen/Crozet hotspots, results in thinner cratonic-lithosphere than its erstwhile neighbours in the Gondwanan configuration. Observations indicate crustal amalgamation of different blocks in the evolution of the present EGMB, akin to observations from East-Antarctica also touted to be composed of different Proterozoic crustal terranes. Parity in crustal thickness is also noted. Strained minerals along the upper-mantle fabrics influence the variation of anisotropic parameters across different domains, indicating large-scale pervasive deformation related to various collisional-rifting episodes. The most notable being the disparity in anisotropic trends and lithospheric architecture across the eastern and western Phulbani Domain establishing them as separate blocks. Thereby, deeper understanding into the complex geodynamics of EGMB and its correlation with East-Antarctica can be achieved through unified geophysical studies across both the regions.

Seismic anisotropy beneath a transect of Kumaon Himalaya using shear wave splitting analysis

DOI: 10.57757/IUGG23-2017 - LINK

Sivaram Krishnavajjhala[1], *Sandeep Gupta*[1], *Sudesh Kumar*[1], *Prasad Bnv*[1], *Dixith M Sai*[1], *Saneesh Ali*[1], *Vishal Rawat*[1]
[1]*CSIR- National Geophysical Research Institute, Seismological Imaging Group, Hyderabad, India*

We explore the pattern of seismic anisotropy beneath a ~300 km transect in the Kumaon Himalaya, an active, orogenic region formed by the collision between the India-Eurasian plates, and carrying world-wide attention for its mysterious geometry and seismic potential. Applying the shear wave splitting analysis of the teleseismic core-refracted phases (SKS, SKKS, PKS and PKKS) on a linear profile of 32 broadband seismograph stations, we uncover the signatures of enigmatic strain histories and mantle dynamics. The measured shear wave splitting parameters i.e. Φ (Fast Polarisation Direction, FPD) and δt (Delay Time, DT) carry extraordinary information of the anisotropy formed through the complex mantle-deformation. We observe a strong dependence of the splitting data on the back-azimuth directions, which fits fairly well with a two-layer anisotropy model, with the lower layer having a low dipping angle at most of the stations. We present a geodynamic model depicting the preserved and the current situation of the compression-forces at the India-Asia collision zone. Incidentally, the mean Φ are primarily sub-parallel to the North East (NE)-oriented absolute plate motions (APM), and nearly orthogonal to the major geological boundaries in the Higher Himalaya. In the Lesser Himalaya, the mean Φ are nearly orthogonal to the APM and are sub-parallel to the surface expressions of major geological features. Similarly, we observe a wide variation in the mean δt. Our detailed analysis indicates a predominantly asthenospheric source of anisotropy, and a possible slab-tearing for this segment of the Kumaun Himalaya.

Outreach and engagement to ensure the success of an Earthquake Early Warning System for Canada

DOI: 10.57757/IUGG23-5027 - LINK

Alison L. Bird[1], Henry C.J. Seyward[1], Stephen Crane[1], Nicholas Ackerley[1]
[1]Canadian Hazards Information Service, Natural Resources Canada, Ottawa, Canada

Natural Resources Canada (NRCan) is developing a national Earthquake Early Warning (EEW) system for Canada. The network will focus on regions with a) an expectation of strong earthquakes, and b) concentrations of population and/or critical infrastructure (CI). These regions include parts of British Columbia, Ontario and Quebec.

The system will facilitate mitigation of earthquake impacts, allowing for timely and appropriate response actions by the public, emergency measures organizations, CI operators, and other industrial facilities. However, for the system to be effective, a culture of awareness is necessary to ensure appropriate protective actions are taken when alerts are received.

A coordinated public education campaign is underway to help achieve this. NRCan is hosting workshops and other outreach activities with CI operators to ensure they are aware of the benefits of installing systems that automatically translate EEW alerts into protective actions. Simultaneously, NRCan is encouraging equipment providers in Canada to develop such automated systems. In these efforts, NRCan is collaborating with federal and provincial public safety organizations, private and international partners, and Non-Governmental Organizations. This will ensure that EEW messaging is authoritative, consistent and accessible. Social science research by collaborators is underway and will guide the education of vulnerable populations including First Nations peoples, new immigrants, people with low income, and the elderly.

By making it possible to take safe actions before the arrival of potentially harmful shaking, the national EEW system will contribute to the reduction of earthquake risk in Canada.

A historical case study teaching about earthquake intensity and magnitude: Research to help Canadians better understand earthquake early warning alerts

DOI: 10.57757/IUGG23-4695 - LINK

Esther Muturi[1], *Glenn Dolphin*[1]
[1]*University of Calgary, Department of Geoscience, Calgary, Canada*

Canada is developing an earthquake early warning system (EEWS) for implementation in 2024. To help prepare the Canadian public to take appropriate protective action when getting an EEW alert, educating them about the phenomenon of earthquakes is essential. To this end, we are developing a historical case study focusing on the conceptual development of earthquake intensity and magnitude. Historical case studies in science education have usually focused on helping learners understand the nature of science better, but they have also been effective in teaching scientific content.

The case study begins with the human experiences of earthquakes and how they used myths to explain the observations. The story then picks up in the 18th century and documents many different earthquakes (Lisbon, Portugal, 1755; Naples, Italy, 1857; Mino-Owari, Japan, 1891; Assam, India, 1897; San Francisco, USA, 1906; and Alaska, USA, 1964) and the development of understandings of what earthquakes are, how they happen, and how the concepts of intensity and magnitude played a role in those understandings.

The case study reveals the switch from mythic explanations to reasoned ones; that earthquakes are natural occurrences and therefore steps can be taken to mitigate death and destruction. The narrative distinguishes between an observational era and one of the instruments. After the development of the seismometer, there was a much more quantitative approach to seismology. A stark contrast between earthquake intensity (very concrete, yet subjective) and magnitude (abstract, yet calculated) became quite apparent. By focusing on this contrast, readers will develop a robust understanding of both conceptions.

A three-pronged approach for understanding earthquake intensity and magnitude for increasing the efficacy of earthquake early warning alerts

DOI: 10.57757/IUGG23-4628 - LINK

Glenn Dolphin[1]
[1]*University of Calgary, Department of Geoscience, Calgary, Canada*

Geologic hazards put the lives and property of humans at risk. To mitigate such risks, countries have developed and implemented alerting systems that can warn people to take timely protective actions. Canada's geological context creates a risk of large earthquakes along its western provinces due to Cascadia subduction, and along the northern and eastern territories and provinces, mainly due to glacial rebound. In response to this risk, Canada is developing an earthquake early warning system (EEWS). Using the same foundation as the USGS's ShakeAlert. Canada's EEWS calculates the magnitude (energy released) and intensity (amount of shaking) of each event recorded. An alert gets sent once pre-determined thresholds for magnitude and intensity are met. Having the public take protective actions (such as drop, cover, and hold on) once they receive an alert is imperative to the success of the system.

The heart of our research is how the public understands earthquake intensity and magnitude. We investigate this focus from three directions:

- Historical–Documenting the conceptual development of earthquake intensity and magnitude, then creating a historical narrative to teach these concepts.
- Linguistics–The language used when talking about earthquakes, earthquake intensity, and magnitude, by the public on news and social media platforms.
- Socio-cultural–The state of seismicity education in Canada, how that education has developed through time, and how it compares to the contexts of other seismically active regions around the world.

This presentation builds an argument for the three approaches and delineates the products they will yield.

Using Did You Feel It? data to trace people's understandings of earthquake magnitude and intensity

DOI: 10.57757/IUGG23-4546 - LINK

Jason Curtis Droboth[1]
[1]*University of Calgary, Department of Geoscience, Calgary, Canada*

The effective initial public adoption and proper sustained use of Earthquake Early Warning (EEW) systems depend, in part, upon effective education, outreach, and communication (EOC) campaigns. The success of such campaigns are themselves dependent upon strategic plans designed around audience needs, interests, codes, and understandings. From this, clear, concise, and easily comprehensible messaging and interactions should be implemented and repeatedly distributed through multiple trusted channels and sources.

While much work has been done on public perceptions of earthquake risks, little seems to have been done to explore how the general public understands and describes earthquakes, including their lived experiences with them, especially in terms of earthquake magnitude and intensity. Developing effective EOC strategies and messaging requires accurate knowledge of audiences' understandings of earthquake magnitude and intensity and the linguistic codes they use to describe them.

This presentation will share some preliminary results of a study looking at people's linguistic descriptions of their first-hand experiences of earthquakes by conducting qualitative analyses of thousands of public submissions to the USGS's *Did You Feel It?* survey concerning the 2019 California Ridgecrest earthquakes.

[1]*National research and Innovation agency,*
Research Centre for Behavioural Economics and Circular, JAKARTA TIMUR, Indonesia

Indonesia is a country that crosses the Ring of Fire or active mountain paths. The region is 40,000 km in size and shaped like a horseshoe. Moreover, the plate-meeting path contributes to Indonesia's high earthquake risk. According to the Meteorological Climatology and Geophysics Agency (BMKG), Indonesia is a meeting point for three tectonic plates: the Indo-Australian plate, the Eurasian plate, and the Pacific plate. This causes many earthquakes, tsunamis, and volcanic eruptions that often occur in Indonesia. A natural catastrophe is an extreme occurrence that causes casualties, environmental damage, property loss, and psychological effects. With the availability of a Geographical Information System (GIS), information such as tsunami or earthquake evacuation routes and disaster education may be transmitted visually. The government has created several android applications. The application contains information about earthquakes, climate maps, flash floods, volcanic eruptions, landslides, and tsunami waves. Info BMKG, inaRISK Personal, My Earthquake Alert, Newest Earthquake Info, BMKG Real-time Earthquakes, WRS-BMKG, and MAGMA Indonesia are some of the applications available. Because the public may be alerted of the probability of a disaster in advance, this application can assist in reducing casualties in the case of a disaster. Once this application is operational, it is intended to assist relevant organizations in disseminating community-required information more promptly, precisely, and properly.

Tsunami mitigation strategy through tsunami community preparedness training course

DOI: 10.57757/IUGG23-1335 - LINK

Madona Madona[1], *Nelly Florida Riama*[1]

The Education and Training Center, Jakarta, Indonesia

An advanced tsunami early warning system will not be sufficient for safe life if communities, especially in high-hazard risk areas, do not have adequate knowledge and capacity to respond to the early warning as well as to react and take action without official warning or guidance. The IOC Assembly declared the IOC Ocean Decade Tsunami Programme (2021-2030). This programme is dedicated to a safe ocean where life and livelihood are protected from tsunamis hazards. It is expected to establish 100% of communities at risk of tsunami prepared for and resilient to tsunamis by 2030 through the implementation of the UNESCO/IOC Tsunami Ready Recognition Programme and other initiatives. This could be achieved through a collaborative effort to meet a standard level of tsunami preparedness through the fulfillment of a set of established indicators. Therefore, BMKG in collaboration with Ocean Teacher Global Academy (OTGA) conducted Tsunami Community Preparedness Training in 2022. Tsunami Community Preparedness Training Course is a continuation of the previous training, namely the Tsunami Ready Training Course. Conducting this training is an effort of tsunami mitigation strategy from a capacity-building perspective. That training was addressed for local/national disaster management institution officers, government/ non-government organizations working in the disaster management field, and researchers of tsunami science. Moreover, we invite volunteers as an activator of an independent tsunami-ready community. Training is an effective attempt to enhance knowledge regarding how to build a resilient community, so we comprehensively evaluate its implementation until several months after the training has been completed.

Investigation of crust and lithosphere transition between the Alborz and the South Caspian basin in NW Iran

DOI: 10.57757/IUGG23-1598 - LINK

Shiva Arvin[1], *Farhad Sobouti*[1]
[1]*Institute for Advanced Studies in Basic Sciences IASBS, Earth Sciences, Zanjan, Iran Islamic Republic of*

We analyzed P and S receiver functions to investigate the structure of the crust and uppermost mantle beneath 37 temporary and 7 permanent broadband seismic stations located in the western Alborz region and coastline of the South Caspian Basin. We identified the geometry and depth of the Moho and the lithosphere-asthenosphere boundary under two different seismic profiles in the area. There is no evidence of underthrusting the South Caspian Basin beneath Alborz in our results. We believe that the oceanic or oceanic-like nature of the crust of the South Caspian Basin is unacceptable because of its 25-30 km crustal thickness, so we introduced the nature of the south Caspian basin as a continental crust with a sediment thickness of 20 km. We found evidence of underthrusting the Central Iran crust beneath the Alborz, and also the depth of Central Iranian moho in the northern flank of western Alborz goes to 68 km, which could be a sign of the presence of Paleottech sutures in this region. We also detect some evidence to identify the lateral displacements caused by the Lahijan fault zone. The presence of a discontinuity at depths of 120 to 140 km in S receiver functions results was considered evidence for the confirmation of the existence of lithosphere delamination under the western Alborz. Given the geometry seen from this discontinuity along the two different profiles, which are approximately perpendicular, we assume that the possible delamination is in its early stages

Seismicity and Tectonics of the Caucasus Region Revisited

DOI: 10.57757/IUGG23-1649 - LINK

István Bondár[1], *Tea Godoladze*[2], *Eric Cowgill*[3], *Gurban Yetirmishli*[4], *Stephen Myers*[5], *Tuna Onur*[6], *Irakli Gunia*[2], *Albert Buzaladze*[2], *Rengin Gök*[7], *Andrea Chiang*[5]

Despite its role in Arabia-Eurasia convergence between the Black and Caspian Seas, the Caucasus region lacks a comprehensive catalog. To address the issue, the Lawrence Livermore National Laboratory and the Institute of Earth Sciences (IES) at Ilia State University generated a new, comprehensive seismic catalog for the Caucasus region by combining data in the IES bulletin with bulletins of the Republic Seismic Survey Center of Azerbaijan, monitoring centers in Turkey and Armenia, and the ISC covering the period 1951 to 2019.

We present the bulletin that contains some 20,000 relocated events. We first relocated each event using the single-event location algorithm iLoc and RSTT predictions and identified GT events. Then we relocated the entire seismicity of the Caucasus region with the multiple-event location algorithm Bayesloc, using the iLoc results as initial locations and the GT events as constraints.

We show that each relocation step leads to significant improvements, as indicated by tightening of event clusters. The improved view of the seismicity reveals a narrow band of crustal events along the southern flank of the Greater Caucasus we interpret as a megathrust, and confirms both a region of deep seismicity beneath the northeastern Caucasus and a possible area of slab detachment in the central part of the range.

[2]Technical University of Munich, Institute for Astronomical und Physical Geodesy, Munich, Germany

The large ring laser array ROMY (ROtational Motions in seismologY) consists of four Sagnac inferferometers, each representing an individual, high-sensitive rotation rate sensor, joined as a tetrahedral, heterolithic structure, due to its triangular rings of 12 meter side length. This size and the heterolithic construction introduces new challenges in the operation and monitoring of a large ring laser. Currently high performing ring lasers, such as G-ring, are individual, monolithic large ring lasers, that are less affected by mechanical instability, however, suffer from orientation changes that contribute to the variation in Sagnac frequency. Exploiting the full potential of a large ring laser such as ROMY would enable to observe rotational ground motions close to the rotational low noise model. We discuss required steps towards a stable and enhanced performance of the hetherolicitc ring laser array ROMY, especially for seismology and present implemented tilt and environmental monitoring as well as the influence of the signal processing chain on the obtained signals.

Foreshock characteristics of the 2020 M6.4 Jiashi earthquake

DOI: 10.57757/IUGG23-1454 - LINK

Shiguang Deng[1], *Yanyan Han*[1], *Haikun Jiang*[1]
[1]*China Earthquake Networks Center, Earthquake Prediction Department, Beijing, China*

Foreshocks could provide valuable information for seismogenic process. Similar to aftershocks and swarms, foreshocks are usually clustered in time and space, which could result in low magnitude earthquakes being overwhelmed by the coda waves of other earthquakes. In addition, the limited observation condition could result in the loss of small earthquakes in local catalog. The waveform correlation technique has been proved to be an effective method to detect missing small earthquakes and widely used in foreshock and aftershock sequence detection. On January 19, 2020, the M_S6.4 earthquake occurred in Jiashi, Xinjiang. About 45 hours before the earthquake, the M_S5.4 earthquake occurred in the focal area, which formed a typical foreshock sequence. In this study, we collected the continuous waveforms between December 1, 2019 and January 31, 2020 from 6 stations located within 100 km of the mainshock. With 791 relocated earthquakes (including 33 foreshocks) as templates, 4664 earthquakes (including 261 foreshocks) were detected and located by the Match & Locate method. The complete magnitude of the catalog was reduced from M_L1.6 to M_L1.0. With the enhanced catalog, we observe that the foreshock sequence has lower *b*-value than aftershocks and lacks small-magnitude (M_L<0.3) events, which are generally consistent with other studies. According to the spatial and temporal evolution of the earthquake sequence, seismicity becomes relative quiet within 26 days before the Jiashi M_S5.4 earthquake and 2 days before the mainshock. In addition, the earthquakes during the two days before the mainshock migrated to the mainshock epicenter.

Updates on the ISC-GEM Global Instrumental Earthquake Catalogue (1904-2019)

DOI: 10.57757/IUGG23-0476 - LINK

Domenico Di Giacomo[1], *Dmitry A. Storchak*[2]
[1]*International Seismological Centre, ISC, Thatcham, United Kingdom*
[2]*International Seismological Centre, International Seismological Centre, Thatcham, United Kingdom*

The first version of the ISC-GEM Global Instrumental Earthquake Catalogue (www.isc.ac.uk/iscgem/index.php) was released in January 2013 (Storchak *et al*., 2013). The goal of the catalogue is to improve the homogeneity (to the largest extent possible, in time and space) of earthquake parameters (e.g., location and magnitude) and list them along with formal uncertainties to facilitate, among others, seismic hazard and Earth's seismicity studies.

Ten years on from the first release, we report on the latest developments of the catalogue following the completion of the Extension (Di Giacomo *et al*., 2018) and Advancement projects (Di Giacomo and Storchak, 2022). We expanded the catalogue with several thousands moderate earthquakes down to ~M5.5 between 1904 and 1959 and earthquakes down to ~M5.0 from 1976. Furthermore, we added over a thousand source mechanisms from the literature for earthquakes that occurred before GCMT began in 1976. Finally, we provide an overview of ongoing activities to further improve the catalogue. These include the use of station data recently digitized from the BCIS bulletins for 1950-1963 (Di Giacomo and Storchak, 2023), the reassessment of MS for hundreds of earthquakes for 1964-1970, and the digitization of the Chinese network bulletins for 1971-1979.

Evidence for the presence of metastable olivine within subducted oceanic lithosphere in the uppermost lower mantle beneath eastern United States

DOI: 10.57757/IUGG23-4721 - LINK

Fansheng Kong[1], Stephen S Gao[2], Kelly Liu[2], Yinxia Fang[1], Hejun Zhu[3], Robert J. Stern[3], Jiabiao Li[1]
[1]Second Institute of Oceanography, Key Laboratory of Submarine Geosciences- MNR, Hangzhou, China
[2]Missouri University of Science and Technology, Geology & Geophysics, Rolla- Missouri, USA
[3]University of Texas at Dallas, Department of Geosciences, Richardson- Texas, USA

Approximately two-thirds of Earth's outermost shell is composed of oceanic plates that form at spreading ridges and recycle back to Earth's interior in subduction zones. A series of physical and chemical changes occur in the subducting lithospheric slab as the temperature and pressure increase with depth. In particular, olivine, the most abundant mineral in the upper mantle, progressively transforms to its high-pressure polymorphs near the mantle transition zone, which is bounded by the 410 km and 660 km discontinuities. However, whether olivine still exists in the core of slabs once they penetrate the 660 km discontinuity remains debated. Based on SKS and SKKS shear-wave differential splitting times, we report new evidence that reveals the presence of metastable olivine in the uppermost lower mantle within the ancient Farallon plate beneath the eastern United States. Such differential splitting times were attributed to anisotropy in the D” layer. Spatial coherency analysis and consistency between the area with differential splitting times and that with higher than normal seismic velocities favor an uppermost lower mantle origin of the differential times. We estimate that the low-density olivine layer in the subducted Farallon slab may compensate the high density of the rest of the slab associated with the low temperature, leading to neutral buoyancy and preventing further sinking of the slab into the deeper part of the lower mantle.

Similarity analysis for event characterisation in the context of the Comprehensive Nuclear-Test-Ban Treaty (CTBT)

DOI: 10.57757/IUGG23-4151 - LINK

Nicolai Gestermann[1], *Jens Ole Ross*[1]
[1]*Federal Institute for Geosciences and Natural Resources,*
Federal Seismological Survey- Nuclear-Test Ban, Hannover, Germany

Monitoring compliance with the Comprehensive Nuclear-Test-Ban Treaty (CTBT) requires reliable seismological methods for event characterisation to identify possible candidate events within a sequence of seismic events, which are possible treaty violations.
National Data Centre (NDC) are the national scientific organizations to advise their governments concerning CTBT monitoring and analysing suspicious events. The German NDC (BGR) regularly organises international NDC Preparedness Exercises (NPE), dealing with fictitious treaty violations to practice the combined analysis of CTBT verification technologies. These exercises help to evaluate the effectiveness of analysis procedures applied at NDCs and the quality, completeness and usefulness of IDC products.
The last exercise - NPE2019 - was a combined waveform-radionuclide scenario. The source region and time domain of a possible treaty violation activity was determined from atmospheric transport modelling (ATM) in backtracking mode with input data from fictitious particulate radionuclide and radioxenon measurements at stations of the International Monitoring System. An earthquake sequence could be identified within the specified source region and time period from ATM analysis. Due to the untypical shallow focal depth of about 3 km and no mining activities, the earthquake sequence in combination with synthetic data is well suited to assess discrimination methods.
Synthetic waveform data, which were modified from real recordings to simulate more explosive like characteristics, are added to the earthquake sequence. A similarity analysis was applied to the combination of fictitious and real waveform data with the objective to identify the fictitious recordings as conspicuous. Various score values were defined to achieve an automatic procedure.

Seismotectonics of the Shahrud Valley in western Alborz

DOI: 10.57757/IUGG23-0217 - LINK

Mir Ali Hassanzadeh[1], *Esmail Shabanian*[1], *Abdolreza Ghods*[1]
[1]*Institute for Advanced Studies in Basic Sciences IASBS, Earth Sciences, Zanjan, Iran Islamic Republic of*

The Shahrud fault lies in the western Alborz and in the southeast of the sinistral strike-slip Rudbar fault (1990 7.3 Mw Rudbar-Manjil). The surface trace of the Shahrud fault is depicted on the active faults map of Iran as a continuous twisted curve of 65 km in length. Shahrud fault lies in the north of Qazvin and is accounted for a potential source of future destructive earthquakes. 698 local earthquakes have carefully relocated and focal mechanisms were determined for two events. According to the focal mechanisms of earthquakes that occurred in the area between the Rudbar and Shahrud faults, sinistral kinematics is suggested for the western part of the Shahrud fault. The remote sensing analysis of satellite imageries complemented by field measurements allows for revising the fault map of the area. Also, earthquake-related features such as thermal and travertine springs as well as landslides are aligned along the main fault traces of the area indicating the tectonic activity of these deep-seated structures. The kinematics investigation based on seismological and geological data indicates that the Shahrud Valley is affected by a complex fault network comprising a variety of faults with different orientations. The seismicity extended over the area and fault kinematics measured along the fault zones indicate that the Shahrud fault zone is not a simple S-dipping ”thrust fault”, but, is a simplified geological interpretation of an intersection zone produced by kinematic and structural interactions of distinct E-W, NNE- and NW-striking fault trends at the southern flank of the Shahrud Valley.

Vertical component tilt property of Japanese BBOBS and its implication

DOI: 10.57757/IUGG23-0532 - [LINK]

<u>Takehi Isse</u>[1], Hajime Shiobara[1], Yuki Kawano[1]
[1]the University of Tokyo, Earthquake Research Institute, Tokyo, Japan

Broadband ocean bottom seismometer (BBOBS) is essential instrument to reveal the deep Earth structure so that many seafloor observations by BBOBS have been deployed. It is difficult for BBOBS to make the sensor's level accurate, and this makes a high noise level of vertical component of BBOBS. To reveal the leveling accuracy and its contribution to noise of BBOBS is important to improve the BBOBS design.

We estimated the tilt angle and direction of the vertical component of sensor by applying noise reduction method (Kawano et al., 2023) to more than 80 Japanese BBOBS. The Japanese BBOBS contains all components in the titanium alloy sphere housing, and the sensor (CMG-3T) is installed on the leveling unit.

Estimated tilt angles are 0.02–2.4 degrees (0.9±0.4 degree in average). The direction of tilt is around the NS output of the sensor. The tilt angle and direction are stable during its one-year seafloor observation, and those of the same sensor and leveling unit in different observations are similar , suggesting that estimated tilt is considered to be unique to each sensor unit.

The estimated directions of the tilt are around NS output which is consistent that the vertical component of the CMG-3T is designed to oscillate along NS direction.

The leveling unit to keep it in level within ±0.3º during the observation, however, the estimated tilt are larger than that. One possible explanation of the difference between measured and estimated tilt is that the seafloor current is slightly tilted along with seafloor topography.

Shear-wave splitting patterns in the Habanero Geothermal Field, Cooper Basin, Australia

DOI: 10.57757/IUGG23-4392 - LINK

[2]Hellenic Mediterranean University Research Center,
Institute of Physics of Earth's Interior and Geohazards - UNESCO Chair on Solid Earth Phys ics and Geohazards Risk Reduction, Chania, Greece

Upon entering a medium with a strongly anisotropic feature, shear-waves refract and produce two orthogonally polarized waves, travelling with different velocities (the S_{fast} and S_{slow}). The polarization direction of the S_{fast} and the time-delay between the arrivals of the two waves are common metrics to quantify splitting. In the upper crust, anisotropy has been often attributed to stress-sensitive fluid-filled microcracks, whose characteristics may change over time. The Habanero Geothermal Field in Cooper Basin (Australia) is a site of multiple hydraulic stimulation tests, closely monitored by a dense network of 24 surficial and borehole sensors. In the current study, we use a fully automatic analysis scheme to identify shear-wave splitting in waveforms of approximately local 30,000 earthquakes, which occurred in a shallow ~500 m thick sub-horizontal layer. Results indicate a complex state of anisotropy, with both azimuths of faulting and the local maximum horizontal compressive stress component being represented in the measured polarization directions. Time-delay changes present a potential association with the activation of the structure due to the stimulation.

Precise earthquake locations are a prerequisite for determining real fault structures. To improve the precision of the event location, a few relative locations methods are commonly used to refine event locations. Relative relocation methods reduce effects of an imperfect velocity model and errors due to arrival time measurement. We performed comparative tests of three different relocation methods: HypoDD (HD), GrowClust (GC) and Master event (ME). We tested the efficiency and differences in the event locations using these three methods on dataset from REYKJANET seismic network operating in Iceland on Reykjanes Peninsula. All these methods provide substantially focused shapes of clusters compared to the absolute event locations but the locations of individual events differ evidently depending on the method used. We also aimed at an effect of the control parameters of HD, GC and ME on final location results and their optimization as well as computational and memory demands.

[1]China University of Petroleum East China, College of Geosciences, Qingdao, China
[2]Missouri University of Science and Technology, Geology & Geophysics, Rolla, USA

The spatial distribution of seismic azimuthal anisotropy beneath Australia is investigated using splitting of the teleseismic PKS, SKKS, and SKS phases to delineate asthenospheric flow and lithospheric deformation beneath one of the oldest and fast-moving continents on Earth. In total 511 pairs of high-quality splitting parameters were observed at 116 seismic stations. Unlike other stable continental areas in Africa, East Asia, and North America, where spatially consistent splitting parameters dominate, the fast orientations and splitting times observed in Australia show a complex pattern, with a slightly smaller than normal average splitting time of 0.85 ± 0.33 s. On the North Australian Craton, the fast orientations are mostly N-S, which is parallel to the absolute plate motion (APM) direction in the hotspot frame. Those observed in the South Australian Craton are mostly NE-SW and E-W, which are perpendicular to the maximum lithospheric horizontal shortening direction. In east Australia, the observed anisotropy can be attributed to either APM induced simple shear or lithospheric fabric parallel to the strike of the orogenic belts. The observed spatial variations of the azimuthal anisotropy, when combined with results from depth estimation utilizing the spatial coherency of the splitting parameters and seismic tomography studies, suggest that the azimuthal anisotropy in Australia can mostly be related to simple shear in the rheologically transition layer between the lithosphere and asthenosphere. Non-APM parallel anisotropy is attributable to modulations of the mantle flow system by undulations of the bottom of lithosphere, with a spatially variable degree of contribution from lithospheric fabric.

On the stress dependence of the elastic tensor

DOI: 10.57757/IUGG23-0579 - LINK

The dependence of the elastic tensor on the equilibrium stress is investigated theoretically. Using ideas from finite elasticity, it is first shown that both the equilibrium stress and elastic tensor are given uniquely in terms of the equilibrium deformation gradient relative to a fixed choice of reference body. Inversion of the relation between the deformation gradient and stress might, therefore, be expected to lead neatly to the desired expression for the elastic tensor. Unfortunately, the deformation gradient can only be recovered from the stress up to a choice of rotation matrix. Hence it is not possible in general to express the elastic tensor as a unique function of the equilibrium stress. By considering material symmetries, though, it is shown that the degree of non-uniqueness can sometimes be reduced, and in some cases even removed entirely. These results are illustrated through a range numerical calculations, and we also obtain linearized relations applicable to small perturbations in equilibrium stress. Finally, we make a comparison with previous studies before considering implications for geophysical forward- and inverse-modelling.

Geometry of the rivera and cocos plates in western Mexico from local seismicity studies

DOI: 10.57757/IUGG23-0211 - LINK

Francisco Javier Nunez Cornu[1], *Diana Nuñez*[1], *Carlos Suarez Plascencia*[1]
[1]*Universidad de Guadalajara, CA SisVOc, Puerto Vallarta, Mexico*

A total of 5,220 hypocenters located in the region of Jalisco, Colima and Michoacan states in western Mexico are analysed. We observe that the geometry and seismic characteristics of the subduction at Jalisco Block, Colima Rift Zone and Michoacan Block are different. The contact between the Rivera plate and the Jalisco Block is tectonically complex and can be separated into at least four sections: two located between Bahía Banderas and Purificacion River and the other two between Purificacion River and Colima Rift Zone. South of Bahía Banderas, the slab is observed until 130 km with a dipping angle of 24°. In the Tomatlán River and San Nicolas River areas, the slab is observed until 85 km from the trench dipping 26°, while in the region of Purificacion River, the slab is divided into three segments with different dipping angles, up to 140 km from the trench. In the area of the Marabasco River, the slab can be observed in two segments, with dip angles of 26° and 35°, respectively, and up to 145 km from thrench. There is no evidence of a slab below the Colima Rift Zone due to seismicity being scarce, except in the Colima Volcano area and on the coast, where deep earthquakes (> 70km) are below Colima Volcano that could be associated with the volcano. The crustal thickness in the Michoacán Block is 30 km. To the south, the Cocos Plate dips between 24° and 30° and is slightly bent in the west direction.

Seismic imaging of the crust and upper mantle beneath eastern Dominican Republic and Muertos Trough

DOI: 10.57757/IUGG23-4767 - LINK

Diana Nuñez[1], *Diego Córdoba*[1]
[1]*Universidad Complutense de Madrid, Física de la Tierra y Astrofísica, Madrid, Spain*

The oblique convergence between the Caribbean and North American plates produces a tectonic collage in Hispaniola Island, where Muertos Trough marks the trace of a low-angle thrust fault bounding an accretionary wedge. In this work, we analyzed the seismic data corresponding to Profiles C and D of the CARIBE NORTE project (2009) in the frame of the current KUK ÀHPÁN and MICROSIS-I projects. A seismic array of vertical and three-component land stations registered these profiles along N-S and W-E seismic transects of 350 and 450 km, respectively. The seismic sources in these lines corresponded to land borehole explosions 1 Ton (S1, S2, and S3), three marine shooting lines (LM3N, LM3S for Profile C and LM4, for Profile D), and one earthquake that occurred during the registering period.

We constrained the seismic structure of the Dominican Republic by the inversion of wide-angle seismic travel-time data for the previous 2D P-wave velocity model of both profiles. In the eastern zone, the Moho discontinuity rises to 24 km deep. In comparison, it increases towards the island's interior with a maximum depth value of approximately 30 km deep in the west and central part of the transect. The analysis of Profile C shows the deformation produced by Muertos Trough and Muertos Thrust Belt over San Pedro Basin and eastern Hispaniola Island.

Low seismic velocity anomalies marking the active faults of the lebanese restraining bend and the mount-Lebanon thrust

DOI: 10.57757/IUGG23-0027 - LINK

Mohamed Salah[1]
[1]*American University of Beirut, Geology, Beirut, Lebanon*

The Lebanese Restraining Bend (LRB) comprises the NNE-trending Mount Lebanon and the NE Anti-Lebanon ranges which are separated by the Bekaa Valley. Offshore, an east-dipping thrust fault system (the Mount-Lebanon Thrust, MLT) faces the coastal strip between Saida and Arqa. Historical earthquakes with casualties are documented along these active faults in the Eastern Mediterranean. We apply a seismic tomography method to P- and S-wave arrival times retrieved from the ISC seismological bulletins to determine the 3-D seismic velocity structure of the crust and uppermost mantle beneath this region. The seismic data set was generated by carefully selected events which are recorded by at least five stations and all unreliable arrivals have been excluded before the final tomographic inversion. We adopted an initial P-wave velocity model for the tomographic inversion, while the initial S-wave velocity model was computed using an Vp/Vs ratio of 1.725 derived from a wadati diagram. From the obtained P- and S-wave velocity models, we determined the Vp/Vs ratio for a better interpretation of the velocity anomalies. Lateral heterogeneities in the study area are clearly visible. Low velocity anomalies are revealed along the surface traces of the LRB and offshore along the MLT. Average to high Vp/Vs anomalies are clearly detected at lower crustal levels. Results of the checkerboard resolution test and the ray path coverage indicate that the velocity and Vp/Vs anomalies are reliable features. The present observations are compatible with many seismological and geological features detected beneath the Eastern Mediterranean.

The Geo-INQUIRE (Geosphere INfrastructure for QUestions into Integrated REsearch) project, supported by the Horizon Europe Programme, is aimed at enhancing services to allow data, products and software to be accessible to the Geoscience scientific community.

In the framework of Geo-INQUIRE, Transnational Access (TA, both remote and physical) will be provided at six test beds across Europe:the BedrettoLab, Switzerland; the Ella-Link Geolab, Portugal; the Liguria-Nice-Monaco submarine infrastructure, Italy/France; the Irpinia Near-Fault Observatory, Italy; the Eastern Sicily facility, Italy; and the Corinth Rift Laboratory, Greece. These test beds are state-of-the-art research infrastructures, covering the Earth's surface, subsurface, and marine environments over different spatial scales, from small-scale experiments in laboratories to kilometric submarine fibre cable. TA will be also offered for software and workflows belonging to the EPOS-ERIC and the ChEESE Centre of Excellence for Exascale in Solid Earth. TA are grounded on simulation of seismic waves, tsunamis and landslides. Geo-INQUIRE will grant TA to researchers to develop their own experiments with the aim of advancing scientific knowledge of Earth processes while fostering cross-disciplinary research across Europe. To be granted, researchers submit a proposal to the yearly TA calls that will be issued three times during the project life. Calls will be advertised at the Geo-INQUIRE web page https://www.geo-inquire.eu/ and through the existing community channels. The first call is expected to be issued in Fall 2023.The proposals, for both TA and training, will be evaluated by a panel that reviews the technical and scientific feasibility of the project.

Regional and global characteristics of observable foreshocks

DOI: 10.57757/IUGG23-1195 - LINK

[1]Geological Survey of Israel, Seismology, Jerusalem, Israel
[2]University of California Santa Cruz, Department of Earth and Planetary Sciences, Santa Cruz, USA
[3]Volcanological and Seismological Observatory of Costa Rica at Universidad Nacional, Seismological, Heredia, Costa Rica
[4]University of Memphis, Center for Earthquake Research and Information, Memphis, USA

Regional and global variations of foreshock occurrence are systematically examined using earthquake from eight regional catalogs (Italy, Southern California, Northern California, Costa Rica, Onshore Japan, Alaska, Turkey, and Greece) with $M_C \geq 3.0$, and the one global catalog (NEIC) with $M_C \geq 5.0$.

For most of the catalogs (excluding Italy and Southern California) the measured *b-values* of the foreshocks of all region-specific mainshocks are lower by 0.1 to 0.2 than *b*-values of respective aftershocks. Estimates of foreshock probabilities for each mainshock are method-dependent; however, consistent regional trends exist regardless of method. Variations in foreshocks show relatively high probabilities of having at least one foreshock in Italy (~43-56%), compared with other regional catalogs that decrease to 14-41% for regions such as Turkey, Greece, and Costa Rica. Some regions with relatively high background seismicity have comparatively low probabilities of detectable foreshock activity when using methods that account for variable background, possibly due to depletion of near-failure fault conditions by background activity. At a global scale, foreshock rates are similar to regional values with range of 14% to 43% of large mainshocks having at least one foreshock, but a narrower range of 13% to 25% having at least one foreshock with magnitude within two units of the mainshock magnitude. Global variation demonstrates that the western circum-Pacific is prone to having more foreshock activity than the eastern circum-Pacific. The fact that areas having more frequent foreshock activity also have relatively high aftershock productivity suggests common conditions promoting foreshocks and aftershocks.

For most of the catalogs (excluding Italy and Southern California) the measured *b-values* of the foreshocks of all region-specific mainshocks are lower by 0.1 to 0.2 than *b*-values of respective aftershocks. Estimates of foreshock probabilities for each mainshock are method-dependent; however, consistent regional trends exist regardless of method. Variations in foreshocks show relatively high probabilities of having at least one foreshock in Italy (~43-56%), compared with other regional catalogs that decrease to 14-41% for regions such as Turkey, Greece, and Costa Rica. Some regions with relatively high background seismicity have comparatively low probabilities of detectable foreshock activity when using methods

that account for variable background, possibly due to depletion of near-failure fault conditions by background activity. At a global scale, foreshock rates are similar to regional values with range of 14% to 43% of large mainshocks having at least one foreshock, but a narrower range of 13% to 25% having at least one foreshock with magnitude within two units of the mainshock magnitude. Global variation demonstrates that the western circum-Pacific is prone to having more foreshock activity than the eastern circum-Pacific. The fact that areas having more frequent foreshock activity also have relatively high aftershock productivity suggests common conditions promoting foreshocks and aftershocks.

Adapting an existing seismic network to the earthquake early warning mission – southern California experience

DOI: 10.57757/IUGG23-2977 - LINK

Glenn Biasi[1], *Mark G. Alvarez*[1], *Igor Stubailo*[2], *Douglas Given*[1], *Allen Husker*[2], *Rayomand Bhadha*[2]

Earthquake early warning (EEW) for California was initially conceived as a faster version of normal seismic network operations. For the Southern California Seismic Network (SCSN) this early view has been found to be well short of reality. We review lessons SCSN learned through implementation of the ShakeAlert EEW system on the west coast of the United States.

EEW-based adaptations affect stations, telemetry, and data acquisition, processing and archiving. Station coverage in the SCSN was good at the start of EEW implementation but 5+ years of permitting and station installations have been required to reduce EEW detection times to target levels. SCSN started with an advantage not all ShakeAlert networks enjoyed as installed dataloggers could stream the 1-second data packets needed for low data latency. Telemetry priorities can differ between EEW and normal network operations. EEW can only use low-latency data; network operators want complete data to simplify archiving and can accept some latency. EEW only requires three channels of strong-motion data; networks prefer 6 channels, with velocity data. We found that during strong earthquake shaking some links could not support both and developed severe latency. To meet both requirements, telemetry links are now being re-engineered. Multicasting is needed to allow waveform data to be shared across multiple servers for redundant processing. EEW algorithms require separate waveform processing and trigger detection. Specialized algorithms are also required to estimate magnitudes from limited P-wave amplitude data. While similar in appearance, EEW places unique and unanticipated demands on our regional seismic network.

The Central and Eastern European Infrasound Network (CEEIN) established in 2018 as the collaboration between the Zentralanstalt für Meteorologie and Geodynamik, Vienna, Austria; the Institute of Atmospheric Physics of the Czech Academy of Sciences, Prague, Czech Republic; the Research Centre for Astronomy and Earth Sciences of the Eötvös Loránd Research Network, Budapest, Hungary; the National Institute for Earth Physics, Magurele, Romania and the Main Centre of Special Monitoring National Center for Control and Testing of Space Facilities, State Agency of Ukraine. Waveform data of the CEEIN stations are archived at the NIEP EIDA node, and can be downloaded from www.ceein.eu.

We show that CEEIN improves infrasound event detection capabilities in Southern and Eastern Europe, and demonstrate that adding infrasound observations to seismic data in the location algorithm improves location accuracy. We identify coherent noise sources observed at CEEIN stations. We present the bi-annual CEEIN bulletin of infrasound and seismo-acoustic events, our contribution to the European infrasound catalogue. Many of the events in the CEEIN bulletin are ground truth events that can be used in the validation of atmospheric models and infrasound raytracing algorithms.

ORFEUS (Observatories and Research Facilities for European Seismology, orfeus-eu.org) coordinates and promotes seismology in the Euro-Mediterranean region through harmonized collection, archival and distribution of seismic waveform data & metadata, based on services and products managed at national level by more than 60 participating seismological Institutions. ORFEUS is one of the founding members of EPOS Seismology (www.epos-eu.org/tcs/seismology) and its services are largely integrated in the EPOS Data Access Portal (www.ics-c.epos-eu.org). ORFEUS comprises: (i) the European Integrated waveform Data Archive (EIDA; orfeus-eu.org/data/eida); (ii) the European Strong-Motion databases (orfeus-eu.org/data/strong); and iii) the recently established group representing the community of European mobile pools, including amphibian instrumentation (orfeus-eu.org/data/mobile). Currently, ORFEUS facilitates access to the waveforms acquired by more than 18,000 stations including dense temporary experiments (e.g., AlpArray, AdriaArray), with strong emphasis on open, high-quality data. Access to data and products is ensured through state-of-the-art technologies - with strong emphasis on web services - clear policies and licenses, and acknowledging the crucial role played by data providers. Significant efforts are underway to enhance the existing services to tackle the challenges posed by the Big Data Era and the needs of computational seismology, and to actively encourage interoperability and integration of

multidisciplinary datasets in geoscience workflows. ORFEUS also implements community services that include software and travel grants, webinars, workshops, editorial initiatives and discussion forums. ORFEUS activities are assessed and improved through the interaction with a User Advisory Group, which comprises European Earth scientists with expertise on a broad range of disciplines.

GeoNet Aotearoa New Zealand Station Metadata: Managing multidisciplinary instrument and deployment meta-data using a source code versioning system

DOI: 10.57757/IUGG23-3227 - LINK

Mark Chadwick[1], Elisabetta D'Anastasio[1], Jerome Salichon[1], Conrad Burton[1], Steve Sherburn[1], Sam Taylor-Offord[1], Muriel Naguit[1], Megan Madley[1], Richard Guest[1], Jonathan Hanson[1], GeoNet Programme Team[1]
[1]GNS Science, Data Science & Geohazards Monitoring, Lower Hutt, New Zealand

GNS Science Te Pū Ao, through its GeoNet programme, operates a multidisciplinary sensor network to monitor geological hazards in Aotearoa New Zealand. Data from more than 800 permanent monitoring sites are continuously collected, transformed and delivered to a range of end users.

Managing multidisciplinary instrument metadata is a key task of the GeoNet datacentre. In 2017 GeoNet moved away from using a corporate relational database to using a modern and novel approach to manage metadata. All of this metadata is freely available and treated as a dataset (DOI: 10.21420/0VY2-C144) to give users access to whatever metadata they need and to improve visibility and usability.

This system is at the core of the GeoNet data pipeline and allows the data transformation process, from the field to end users, to be automated. The system uses a software development approach: a code versioning system based on git and hosted at "github.com/GeoNet/delta" which allows instrument metadata and their changes in time to be peer reviewed, version controlled and checked for consistency. Equipment and installation details are stored as a set of CSV files and short XML seismic response file segments. This allows for easy access and maintenance, with no proprietary external software needed to decode or examine the information.

Implementation of SAW method in GIS for determining the suitable position for seismological stations in Zadar County

DOI: 10.57757/IUGG23-1758 - LINK

Vedran Damjanović[1], Valentina Gašo[1], Stijepo Grljević[1], Marko Kapelj[1], Iva Kostanjšek[1], Viktorija Milec[1], Marko Pervan[1], Anamarija Tremljan[1], Antonio Brcković[1], Tomislav Fiket[1]
[1]Faculty of Science- Geophysical Department, Croatian Seismological Survey, Zagreb, Croatia

After the devastating earthquakes in Petrinja in December 2020, the Croatian Seismological Survey started the CROSSNET project, whose goal is to improve and expand the existing network of seismological stations in the Republic of Croatia with 95 new seismic stations.

The area of study is Zadar County, the northern part of the Dalmatia Region. The Mediterranean karst terrain requires a different approach when determining the criteria for setting up seismological stations, unlike the Croatian part of the Pannonian basin.

The simple additive weighting method (SAW), also known as the weighted linear combination or scoring method, was used to derive suitability maps for field surveys to find optimal locations for seismological stations. It uses experts' opinions to derive weights for each criterion relative to one another, as well as values for each criterion raster. The score for each alternative (pixel in raster GIS) regarding every criterion was calculated by multiplying the normalized weight of relative importance for each criterion (which is assigned by the decision maker) and the standardized values for each criterion raster. The suitability index for each alternative which represents the final suitability map is a sum of the scores of every criterion raster for each alternative.

Limiting factors of this method are assumptions of linearity and additivity in solving the spatial problem in question but it offers an uncommon GIS approach for seismological network planning.

This work has been fully supported by Next Generation EU and National Recovery and Resilience Plan under project C6.1. R4-I1.

Earthquake occurrence characteristics in the Kefalonia Transform Fault Zone (KTFZ), Greece

DOI: 10.57757/IUGG23-0268 - LINK

Vasileios Karakostas[1], *Eleftheria Papadimitriou*[1]
[1]*Aristotle University of Thessaloniki, Geophysics Department, Thessaloniki, Greece*

The Kefalonia Transform Fault Zone (KTFZ) extends for more than 150 km offshore the western coastlines of Kefalonia and Lefkada Islands being one of the largest sources of seismic hazard in Greece. Since the occurrence of the 2003 Lefkada M_w6.3 main shock, continuous seismic monitoring was intensified in this area, by firstly installing temporary digital seismological stations, and then by transforming this network into a permanent one and incorporating the stations in the Hellenic Unified Seismological Network (HUSN). The network was improved and currently accounts twelve (12) stations in the two Islands, along with five (5) in the nearby Ionian Islands. Microseismicity is continuously monitored; manual phase picking is performed for earthquake as small as M1.2, and relocated for the compilation of a highly accurate earthquake catalogue. Earthquake focal mechanisms are determined by waveform modelling and first polarities, and are exploited along with the highly accurately relocated seismicity for the identification of the local active structures and in particular the geometry and kinematic of the minor fault segments. From the seismicity and fault plane solutions analysis we integrated the major physical features of the regional seismotectonics and suggested a comprehensive seismotectonic model that improves our understanding and must be considered in any seismic hazard model.

Funded by the European Union. Views and opinions expressed are however those of the author(s) only and do not necessarily reflect those of the European Union or European Commission – Euratom. Neither the European Union nor the granting authority can be held responsible for them.

Building the ERMES web platform for preparing strong-motion event reports from ITACA and ESM data and metadata

DOI: 10.57757/IUGG23-4132 - LINK

Giovanni Lanzano[1], *Francesca Pacor*[1], *Chiara Felicetta*[1], *Emiliano Russo*[1], *Sara Sgobba*[1], *Lucia Luzi*[1]
[1]*Instituto Nazionale di Geofisica e Vulcanologia, Milano Section, Milano, Italy*

The exponential growth of seismic networks, at regional, continental and global levels, and the availability of online transmission of large volumes of data in near-real time, allows us to analyze the ground motion of an earthquake, of low or high magnitude, in very short times with high levels of confidence. This was the case of the recent seismic sequences in Italy (2022-11-09 Mw 5.6 Ancona) and Middle East (2023-02-06 Mw 7.8 Turkey-Syria), when thousands of researchers worldwide contributed to providing rapid analyses of seismic motion to support emergency activities and physical understanding of the observed phenomenon during the sequence.

In this work, we present the new web-tool ERMES (Earthquake Reports of strong Motion EStimation) designed to create an event-report describing the characteristics of the ground motion associated with a seismic event. It is integrated with the Italian (ITACA) and the Engineering Strong Motion (ESM) databases. ERMES is developed as a tool for the analysis of the Intensity Measures soon after an event has occurred, that is reviewed and updated by expert users as new data become available and/or particular aspects of shaking need to be highlighted. In case of past events, ERMES is also useful to study the spatial distribution of the strong motion parameters.

ERMES is the result of the collaborative effort of two INGV institutional tasks, namely the the INGV Seismic Hazard Center and the WP9.3 (Data and reports during the seismic emergency) of the DPC-INGV 2022-2025 Agreement.

The INGV is the operational center for earthquake monitoring in Italy, it operates the Italian National Seismic Network and other networks at different scales and is a primary node of EIDA for archiving and distributing seismic recordings. INGV provides earthquake information to the Department of Civil Protection and to the public.

In the frame of the FOCUS (Fiber Optic Cable Use for seafloor studies of earthquake hazard and deformation) project, we deployed a temporary seismic network, FXLand (1J), for a passive seismological experiment to record regional seismicity and teleseismic events. This experiment aims to improve the detection of seismicity; the accuracy of earthquake locations, and to define the crustal structure of the region. The FXLand network (https://doi.org/10.13127/SD/O5QWM6WJCD) is integrated in real-time into the INGV surveillance system. In the deployment period 23rd December 2021- 2nd February 2023, 1186 regional events were located and 153 6+ teleseismic earthquakes occurred (terremoti.ingv.it). We present the analysis of three seismic sequences: one starting on December 23rd 2021 with a magnitude 4.3 near Catania lasting about ten days, one occurred in the Messina Strait on May31st June 1st 2022, the third one in the Ionian Sea from February to April 2022. We applied a template matching technique which doubled the number of detected events in the first two sequences; for the seismicity in the Ionian Sea, to improve detection and locations we are awaiting the data from the FXOBS (XH), a network of broadband and short period OBSs deployed in the Ionian Sea.

Italian 24/7 real-time earthquakes and tsunamis monitoring system

DOI: 10.57757/IUGG23-4439 - [LINK]

Laura Scognamiglio[1], Fabrizio Bernardi[1], Andrea Bono[1], Sergio Bruni[1], Valentino Lauciani[1], Matteo Quintiliani[1], Paolo Bacchi[1], Giorgio Maria De Santis[1], Andrea Di Benedetto[1], Mariangela Trotta[1], Alessandro Amato[1], Lucia Margheriti[1], Alessio Piatanesi[1], Salvatore Stramondo[1]
[1]Istituto Nazionale di Geofisica e Vulcanologia, Osservatorio Nazionale Terremoti, Roma, Italy

The Istituto Nazionale di Geofisica e Vulcanologia (INGV) has the primary responsibility for the seismic surveillance service of the Italian territory and the tsunami alert in the Mediterranean Sea.

The activities in the monitoring room at the INGV National Earthquake Observatory headquarters in Rome (hereafter INGV-Rome), are carried on by two seismologists, one tsunami specialist and one technician/engineer who work in three shifts a day to provide monitoring service on a 24/7 basis. They calculate, as rapidly and accurately as possible, the location and size of all Italian earthquakes with M2.5+ and swiftly disseminate such information to emergency authorities, to government agencies, to the public and the media by different platforms (email, text message, and via Facebook and Twitter). Starting with hypocentral and magnitude parameters, the moment tensors, the historical seismicity map and the shakemaps are also published in (near) real time.

In addition, the INGV-Rome monitoring room hosts the Italian Tsunami Alert Center (CAT-INGV). CAT-INGV is one of the Tsunami Service Providers acting in the North-eastern Atlantic, the Mediterranean and connected sea (NEAM) region of the Intergovernmental Oceanographic Commission (IOC)/UNESCO and is responsible for monitoring the seismicity of the Mediterranean Sea and disseminating tsunami alert messages to member States and EU agencies subscribing its services. The operation and the performance of the INGV monitoring system is ensured by a dedicated research and IT staff who facilitate real-time waveform acquisition and distribution, develop real-time seismic processing systems and new processing algorithms.

The Istituto Nazionale di Geofisica e Vulcanologia (INGV) has the primary responsibility for the seismic surveillance service of the Italian territory and the tsunami alert in the Mediterranean Sea.

The activities in the monitoring room at the INGV National Earthquake Observatory headquarters in Rome (hereafter INGV-Rome), are carried on by two seismologists, one tsunami specialist and one technician/engineer who work in three shifts a day to provide monitoring service on a 24/7 basis. They calculate, as rapidly and accurately as possible, the location and size of all Italian earthquakes with M2.5+ and swiftly disseminate such information to emergency authorities, to government agencies, to the public and the media by different platforms (email, text message, and via Facebook and Twitter). Starting with hypocentral and

magnitude parameters, the moment tensors, the historical seismicity map and the shakemaps are also published in (near) real time.

In addition, the INGV-Rome monitoring room hosts the Italian Tsunami Alert Center (CAT-INGV). CAT-INGV is one of the Tsunami Service Providers acting in the North-eastern Atlantic, the Mediterranean and connected sea (NEAM) region of the Intergovernmental Oceanographic Commission (IOC)/UNESCO and is responsible for monitoring the seismicity of the Mediterranean Sea and disseminating tsunami alert messages to member States and EU agencies subscribing its services. The operation and the performance of the INGV monitoring system is ensured by a dedicated research and IT staff who facilitate real-time waveform acquisition and distribution, develop real-time seismic processing systems and new processing algorithms.

Spain is a country politically divided in states (communities). In the Comunidad Valenciana (Valencian Community, one of these states), after the enact of Law 2/2020 of the Generalitat Valenciana, the Institut Cartogràfic Valencià acquires responsibility for the creation and maintenance of the Valencian Community Broadband Seismic Network. This network has been created from the already existing Seismic Network of the University of Alicante (RSUA) and cover the entire territory of the Valencian Community. The objective of the Valencian Community Broadband Seismic Network, fully operational since the last quarter of 2022, is to serve as a portal for information and awareness of the seismic phenomenon in the community, as well as to provide useful scientific information for all those research groups interested in seismicity and the active tectonics in the Valencian Community.

The Philippine Sea plate is subducting from the Suruga and Nankai troughs beneath southwest Japan. Great interplate earthquakes occurred repeatedly along the troughs. In the near future, Nankai trough earthquake will occur and be possible to become nationwide disaster. Early detection of seismic waves and tsunamis by instrument observation is important in order to reduce earthquake and tsunami disaster and one of the advantages of the earthquake and tsunami observation on the seafloor contributes to early detection of them compared to inland observation. The sea area from the off the Kochi Prefecture to Hyuga-nada, which is correspond to the western half of the focal region of the anticipated Nankai trough earthquake, is a blank area of the seafloor observation networks. In 2019, the National Research Institute for Earth Science and Disaster Resilience started a project to develop the Nankai Trough Seafloor Observation Network for Earthquakes and Tsunamis (N-net) in this blank area. The N-net has two systems, a coastal system and an offshore system, to ensure redundancy, with 18 observation nodes in each system. In this study, we investigated how fast the direct detection of seismic waves and tsunamis can be achieved when N-net data can be acquired. We conducted the calculation of the travel time for seismic waves and tsunamis by assuming point sources. As a result, we found the detection of seismic wave and tsunami was expected to be earlier approximately 20 seconds and approximately 20 minutes at the maximum considering the N-net data, respectively.

Earthquake emergencies in Italy: SISMIKO operational task force for seismic networks rapid deployments and integration in the monitoring system

DOI: 10.57757/IUGG23-3481 - LINK

Milena Moretti[1], *Ezio D'Alema*[2], *Simone Marzorati*[1], *SISMIKO Team and BSI Working Group*
SISMIKO TEAM and BSI Working Group
[1]*Istituto Nazionale di Geofisica e Vulcanologia, Osservatorio Nazionale Terremoti, Roma, Italy*
[2]*Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Milano, Milano, Italy*

SISMIKO is the operational task force at the Istituto Nazionale di Geofisica e Vulcanologia aiming at the rapid deployment of temporary seismic stations in the area hit by a significant earthquake or a seismic sequence causing concern and interest with impact on people. Decreasing the average distance between the seismic stations improves network detection, accuracy of the earthquake locations, shakemaps and strong motion parameters.

The data acquired by SISMIKO are available, without any constraints, to the entire scientific community through the EIDA portal Italy node, which assures a high level of data quality.

A national diffusion of the preconfigured seismic stations in different headquarters and a ready acquisition system, guarantee rapid response after an earthquake and allow the immediate acquisition of the data as soon as each seismic station is installed. An international FDSN network code is registered in advance and a five char codification for the station names is applied to request the ISC station codes (T<emergency identifier><headquarter identifier>).

The last emergency (no. 17) in 2022 was caused by an earthquake of Mw 5.5 in the Costa Marchigiana region, where we installed eight stations of the Y1 network the same day as the mainshock (DOI: 10.13127/SD/TBLKBA-3U6).

We present the organization and the objectives of the SISMIKO operational group and the analysis of the dataset of the latest seismic sequence carried out by the seismic surveillance service, the Italian Seismic Bulletin (BSI) and SISMIKO.

Improving real-time monitoring in Târgu-Jiu Area, Romania

DOI: 10.57757/IUGG23-4065 - LINK

Cristian Neagoe[1], *Eduard Nastase*[1], *Constantin Ionescu*[1]
[1]*National Institut for Earth Physics, Seismic Network, Magurele, Romania*

In February 2023, a seismic sequence started with two strong earthquakes occurring on 13 February with Ml = 5.2 and on 14 February with Ml = 5.7 followed by over 500 aftershocks. Therefore, complex measurements took place in the epicentral area and the nearby regions shortly after the sequence started. In order to increase the quality of locations and record low-magnitude events, new seismic stations were installed in the area. The stations are equipped with broadband sensors (CMG40T), short-period sensors (Mark L4C) and accelerometers (Episensor). The recorded data is sent to the National Data Center for analysis in real time. The processing software used by the Romanian Seismic Network is Antelope. Before processing, all the stations are evaluated to check the performance and data quality. We can calculate the Power Spectral Densities (PSD) and Probability Density Functions (PDF) by analyzing the waveform data and the instrument response files. In addition to the seismic stations, two GNSS mobile stations were installed. One Leica GR50 receiver that replaced the old one on our reference GNSS station TIMA in order to have real-time data from the Velocity and Displacement Engine (VADASE system) at 10 Hz integrated into it. The second one was a new installation, with the same capabilities, both being capable and recording static High-Frequencies measurements to determine the crustal deformation rate and direction within the area.

PNSN: A regional seismic network and so much more!

DOI: 10.57757/IUGG23-4873 - [LINK]

Mouse Reusch[1], *Renate Hartog*[1]
[1]*Pacific Northwest Seismic Network, UW Dept of Earth and Space Sciences, Seattle, USA*

Regional seismic networks play an extremely important role in both the seismic coverage of a nation, but also in the education, outreach, and science support of that region. The proto-Pacific Northwest Seismic Network (PNSN) started out in the late 1960s to improve seismic-monitoring coverage after several M>6 earthquakes in 30 years in the US state of Washington. Over the decades, the network grew in both number of stations and geographical coverage as well as adding significant items of scope that are harder to quantify such as communicating with the press and proactively educating the public about hazards and seismic safety. Today the PNSN uses data from over 650 seismic stations (~ 560 that we operate and maintain). We share 100% of our data and earthquake catalog with scientists and the public, contribute to the ShakeAlert Earthquake Early Warning program, maintain active social media presences, give presentations at workshops, libraries, and community centers in addition to hosting onsite tours of school children and adults in our Seismology Lab. But the challenges are still great with respect to obtaining funding, fighting misinformation, and attempting to stay relevant when earthquakes happen on geologic timescales, but American minds are growing more accustomed to TikTok-length stories to fill up the daily infotainment void. This presentation will discuss the strategy for success: leveraging the strengths of graduate student work, the creativity of our undergraduate workers, the determination and persistence of the full-time staff, and the knowledge resources of our fellow regional networks across the United States.

New Zealand GeoNet multi-hazards Sensor Network: A walk through data products and services for landslide, tsunami, earthquake and volcano monitoring

DOI: 10.57757/IUGG23-0320 - LINK

Jerome Salichon[1], Jonathan Hanson[1], Mark Chadwick[1], GeoNet Programme Team[1]
[1]GNS Science - Te Pū Ao, Data Science & Geohazards Monitoring, Lower Hutt, New Zealand

Aotearoa-New Zealand islands present some of the world largest seismicity, intense deformation, and volcanic activity. In this environment, GNS Science - Te Pū Ao implements the GeoNet programme since 2001 to satisfy needs and requirements for identification, study, preparedness, and mitigation of frequent geological hazards. With a wide range of air pressure, coastal and deep-sea level sensors, cameras as well as numerous GNSS, seismometers and accelerometers, GeoNet teams not only manage, collect, process, and archive hundreds of instruments but also implement a diversity of services and publicly distribute and maintain open data products. The GeoNet programme aims at enhancing New-Zealand hazard information by continuously developing, integrating, and upgrading its sensor networks and related tools: Instrumentation Database, field instrumentation QC applications, seismic network capability assessment tools, automated updating services etc…The resulting processed information is distributed through high performance and resilient web-services, alerting applications, data streams (real time and archives). In addition, near real-time and curated data products such as strong motion parameters, slow slip observations or eruption detection systems are provided to scientists and public, infrastructure, emergency management and governmental agencies. We present a summarizing assortment of GeoNet data, services and products sourced from more than 20 years of programme implementation. We describe challenges to maintain the current systems, ensure the resiliency, operational status and enable evolving observation methods, products, and services, to integrate new instrumentation types along with strict requirements for 24/7 national geohazard monitoring and for operational science during routine and significant event response.

A global overview on the application of urban seismic networks

DOI: 10.57757/IUGG23-3433 - LINK

Salvatore Scudero[1], Antonio Costanzo[1], Antonino D'Alessandro[1], Giovanni Vitale[1]
[1]Istituto Nazionale di Geofisica e Vulcanologia, Osservatorio Nazionale Terremoti, Rome, Italy

Local-scale seismic networks within urbanized areas have been usually employed for short-living seismological experiments or studies. However the possibility, to install permanent (or long-term) earthquake monitoring networks within urban contexts began in the mid '90s.

If, from one hand, this possibility was certainly boosted by the support coming from technological developments (digital devices for acquisition and transmission), from the other, the necessity was also driven by the recent global expansion of many urban centers into large metropolitan areas. Also the awareness of the seismic risk in urban center resulted in the increasing interest in the monitoring these areas, with particular focus the most exposed or the most vulnerable ones.

Earthquake monitoring networks especially designed may reveal important tools for several tasks related to the seismic phenomena: from earthquake warnings, to emergency operational tasks during emergencies, or scientific studies. In this paper we refer to such earthquake networks as "Urban Seismic Networks" (USN).

Because of the increasing resorting USNs for several applications, we consider useful to provide a comprehensive view of the state-of-the-art of the use of USNs, looking at their global distribution and objectives but, most of all, at their design and at their technical characteristics. We retrieved information about 71 USNs worldwide.

The USN objectives, as well the other characteristics, have been classified into prearranged groups in order to provide to easily synthesize the various features of the USNs. This review will represent a reference and a guideline for future implementation of USNs.

In the last decades each nation, especially those with high seismic risk, has up-graded its seismic network to keep it up with the state-of-the-art criteria. Here we perform the evaluation and a comparison between some the national seismic networks, to evaluate their coverage and their capabilities. We show example from Italy, Greece, Taiwan and New Zealand. For our analysis, we consider the spatial distribution of the nodes of the network together with the ancillary information related to the aims of the network itself (e.g. earthquakes' distribution, seismic hazard, population, distribution on completeness magnitude). Such evaluation is performed with a statistical approach which includes descriptive spatial statistics in combination with point pattern techniques. We are able to highlight the strong points and the drawbacks for each of the considered earthquake monitoring network. Finally this approach helps in addressing future developments for the considered networks.

Seafloor pressure observations mainly use precise quartz resonant sensors at the present due to its high sensibility. Recently, a new silicon resonant sensor using Micro Electro Mechanical Systems (MEMS) technology has emerged with low-power consumption, compact-size, constant quality, and high sensitivity. High stability is expected due to small size of a sensing unit, and individual difference of each sensors is believed to be small because of using the MEMS technology. Influence of movement of the sensor itself is small due to mechanism of pressure transmission. Nankai Trough seafloor network for earthquakes and tsunamis-net (N-net) will be equipped with the new sensors. Before routine observations using this new sensor, we evaluate performance of the new silicon resonant sensor for seafloor pressure observation.

An existing Free-fall pop-up type Ocean Bottom Pressure gauge (OBP) has a quartz resonant sensor. We replaced the sensor to the new silicon sensor, and performed seafloor observations off Boso peninsula near Tokyo. We obtained pressure data from two new sensors. Ambient noise spectra of the new sensor was compared to that of the ordinary sensor which was installed at the same position. The new and ordinary sensors have identical noise level at periods longer than about 50 s. However, the new silicon sensor seems to have higher noise levels at periods between 50 s and 10 s. The new sensor observed sea level fluctuation by volcanic eruption in Tonga and The identical waveforms were obtained from the new and ordinary sensors.

Reduced array detections at Gräfenberg stations caused by wind turbine noise

DOI: 10.57757/IUGG23-3366 - LINK

Klaus Stammler[1], Lars Ceranna[1], Stefanie Donner[1]
[1]Federal Institute for Geosciences and Natural Resources BGR,
Federal Seismological Survey, Hannover, Germany

The Gräfenberg array situated in the Frankonian Jura in Germany is the first digital broadband array on earth delivering continuous waveform data since almost 50 years. Besides its outstanding status in global seismology it is also National Technical Mean in the frame of the Comprehensive Test Ban Treaty since it recorded many nuclear explosions since the 1970ies from all known nuclear test areas. The high sensitivity of the array could be retained for many decades, only recently the detrimental influence of wind turbines (WT) in the area substantiated. Even though the individual stations since 2016 are protected by a WT tabu zone of 5 km radius around each location an increasing wind dependence of the array detections has been found. Comparisons of FK detection statistics of the year spans 2001-2007 (before WT installations) and 2015-2021 (after WT installations) show that about 13% of the detections are lost due to WT generated seismic noise, when averaging over all times. At high wind speeds the loss rate can be as high as 40%. This is caused by a few WTs installed inside the protection zone before 2016 and intensified by the large number of WT installations in distances larger than 5 km from the station locations. Due to the intended increase in wind power installations in Germany a further degradation of the array sensitivity can be expected.

System Design of Nankai Trough Seafloor Observation Network for Earthquakes and Tsunamis (N-net) and its Long-Term Reliability

DOI: 10.57757/IUGG23-2211 - LINK

Tetsuya Takeda[1], Shin Aoi[1], Takashi Kunugi[1], Masanao Shinohara[1,2], Takayuki Miyoshi[1], Kenji Uehira[1], Masashi Mochizuki[1], Narumi Takahashi[1]
[1]National Research Institute for Earth Science and Disaster Resilience, Network Center for Earthquake Tsunami and Volcano, Tsukuba, Japan
[2]Earthquake Research Institute the University of Tokyo, Center for geopysical observation and instrumentation, Tokyo, Japan

N-net is now under construction in western half of the source area of the anticipated Nankai trough earthquake and 36 observatories will be deployed on the deep seafloor. The measurement device at each observatory digitizes the output voltage of seismometers with a sampling rate of 1 kHz by 24-bit A/D converter. The output data is transmitted to two landing stations and finally decimated to data with a sampling rate of 100 Hz and a dynamic range of 130 dB. The measurement device has a frequency counter which counts the number of cycles of square waves generated from the newly developed pressure gauge incorporating silicon resonator. The counted data is also transmitted and decimated to 10 Hz and converted to pressure data. The observed data is time-stamped with a precision of 1 μsec or better at each observatory using the precise time clock synchronized to the GNSS disciplined one and signal transmission delay information. The communication between the observatory and the landing station is peer-to-peer through the submarine optical cable and performs reception of STM-4 data compliant with SDH transmission technology. N-net communication system allows IP communication, implementing IP packets in SDH payload. The whole N-net system is designed for long life because it is not easy to repair troubled devices on the seafloor. To enhance reliability of the system, we adopted a variety of redundancies such as two subsystems of offshore and inshore, two landing stations, duplicated sensors, and so on, which enables to keep running over 20 years.

N-net is now under construction in western half of the source area of the anticipated Nankai trough earthquake and 36 observatories will be deployed on the deep seafloor. The measurement device at each observatory digitizes the output voltage of seismometers with a sampling rate of 1 kHz by 24-bit A/D converter. The output data is transmitted to two landing stations and finally decimated to data with a sampling rate of 100 Hz and a dynamic range of 130 dB. The measurement device has a frequency counter which counts the number of cycles of square waves generated from the newly developed pressure gauge incorporating silicon resonator. The counted data is also transmitted and decimated to 10 Hz and converted to pressure data. The observed data is time-stamped with a precision of 1 μsec or better at each observatory using the precise time clock synchronized to the GNSS disciplined one and signal transmission delay information. The communication between the observatory and the landing station is peer-to-peer through the submarine optical cable and performs reception of STM-4 data compliant with SDH transmission technology. N-net communication system allows IP communication, implementing IP packets in SDH payload. Northern Germany is a weak seismicity region with low level of exposure to seismic hazard. Accordingly, seismic hazard assessment has been pursued with low priority in the past. Rather poor observational conditions in the North German Basin are also a limiting factor for seismic monitoring. In a multi-institutional collaboration, we have been able to increase the number of permanent broadband stations in the North German Federal States of Schleswig-Holstein and Mecklenburg-Vorpommern from previously four in the year 2013 to currently fifteen. All data of the network are freely available through the EIDA node at the Federal Institute for Geosciences and Natural Resources (BGR) in Hannover.

Three complementary seismic arrays, notably on the islands of Heligoland in the North Sea and on Rügen in the Baltic Sea, improve monitoring capabilities of offshore areas. Data from these seismic arrays also provide an opportunity to investigate properties of oceanic microseism in epicontinental seas.

In addition to the development and operation of the seismic network, continuous event detection and analysis routines have been established at Kiel University. Besides low magnitude earthquakes, other natural phenomena like rockslides on cliffs or subrosion events have been repeatedly detected. Known controlled explosions provide an opportunity to quantify detection and location capabilities of the network. The recent destruction of the Nord Stream gas pipelines proved the importance of ongoing network expansion, and the need and reliability of routine seismic monitoring in this region.

Non-linear softening and relaxation in rocks and geomaterials: A laboratory perspective

DOI: 10.57757/IUGG23-4571 - LINK

Manuel Asnar[1], Christoph Sens-Schönfelder[1], Audrey Bonnelye[2], Georg Dresen[3]

In rocks and other consolidated geomaterials, dynamic excitation leads to a fast softening of the material, followed by a slower recovery process where the material recovers part of its initial stiffness as a logarithmic function of time. This requires us to exit the convenient framework of time-independent elastic properties, linear or not, and investigate non-classical, non-linear elastic behavior. These phenomena can be observed during seismic events in affected infrastructure as well as in the subsurface. Since the transient material changes are not restricted to elastic parameters but also affect hydraulic and electric parameters as well as material strength, as documented for instance by long lasting changes in landslide rates, it is of major interest to characterize the softening and recovery phases.

To further characterize this behavior in a controlled environment, we perform experiments on Bentheim sandstone in a Materials Testing System triaxial cell with pore pressure and confining pressure control. Our sample is subjected to various low-strain loading cycles in both dry and water-saturated conditions, while an active acoustic measurement setup allows us to perform Coda Wave Interferometry to continuously monitor the changes in modulus in the rock.

Our transducer array allows us to observe the dynamic softening as well as the recovery processes in the sample during repeated loading phases of various time lengths. Our observations indicate high spatial, frequency content and lapse-time sensitivity of the observed velocity changes, indicating a rich landscape of concurrent effects and physical phenomena affecting our sample during these simple experiments.

We present the surface wave dispersion results from the recorded data of 16 broadband seismic stations in the Higher Himalaya region. The Higher Himalayas is seismically very active due to the convergence of the Indian Plate and the Eurasian Plate along a basal decollement known as the Main Himalayan Thrust (MHT). A portion of the area is located in the Kashmir seismic gap, which lies between the Kangra earthquake of 1905 and the Kashmir earthquake of 2005. A surface wave dispersion analysis has been carried out in order to understand the seismotectonic structure beneath the research area. The fundamental mode Rayleigh wave Green's functions have been estimated for station pairs using cross-correlation of vertical component ambient noise data. The generated group velocity maps from 2 to 15s indicate the substantial variation in crustal structure and exhibit strong relationships with well-known geological and tectonic phenomena in the studied region. We found a low-velocity zone in the middle crust of the higher Himachal Himalayas portion between 12 and 15 km deep, which may be caused by the presence of a crustal ramp structure beneath 12 to 22 km of the Main Central Thrust (MCT). Likewise, a shear wave velocity model has been obtained by inverting surface wave dispersion measurements for the Kishtwar region.

We present a Pn wave velocity and anisotropy model of the central segment of the North-South Seismic Belt in China, where there are numerous stable basins and active faults, making this segment attractive for extensive studies. The model was obtained by a tomographic analysis of 49973 Pn wave phase readings collected by the China Earthquake Networks Center and temporary stations in Yunnan and Sichuan. The tomographic velocity model shows that the average Pn wave velocity is 8.06 km/s; prominent high-velocity (high-V) anomalies are visible under the Sichuan Basin, the Zoige Basin and the Ordos block, which clearly outline their tectonic margins. A pronounced low-velocity (low-V) zone is observed from the Songpan-Ganzi block to the Chuan-Dian and Daliangshan blocks, suggesting the presence of hot material upwelling. The station delay data show a gradual variation from negative to positive values, possibly reflecting a crustal thickness variation from the southwest to the northeast of the study area. A correlation between the Pn wave anisotropy and the distribution of velocity anomalies is observed: anisotropy is relatively weaker in the high-V anomaly zones beneath stable basins, while it is stronger in the low-V anomaly zones and the high-to-low-V anomaly transition zones. The high-resolution velocity and anisotropy tomographic model that we obtained could also provide a better understanding of the study area seismicity, since the occurrence of strong earthquakes seems to be related to the presence and strength of lateral heterogeneities at the uppermost mantle level.

An accurate magnitude estimation is necessary to properly evaluate seismic hazard. Unfortunately, magnitudes of small earthquakes are subject to large uncertainties due to high-frequency propagation effects which are generally not properly considered. To address this issue, we developed a method to separate source, attenuation and site parameters from the elastic radiative transfer modeling of the full energy envelopes of seismograms. The key feature of our approach is the treatment of attenuation -both scattering and absorption- in a simple but realistic velocity model of the Earth's lithosphere, including a velocity discontinuity at the Moho.

Our separation method is based on a 2-steps inversion procedure. First, for each source-station pair, we retrieve optimal frequency-dependent attenuation parameters from the fitting of observed energy envelopes in the 0.375-24Hz band. In a second step, we correct for regional propagation effects to determine site amplification and source displacement spectra. From the latter, we estimate the moment magnitude Mw.

The inversion procedure is applied to the 2019 ML 5.2 Le Teil and 2014 ML 4.5 Lourdes earthquakes, which both occurred in Southern France. The inversion results confirm a significant variability in the attenuation parameters (scattering and intrinsic absorption) at regional scale and a strong frequency dependence. We determine moment magnitudes Mw 5.07±0.17 for the Le Teil earthquake and 4.13±0.13 for the Lourdes earthquake, in good agreement with previous estimates. In the future, we intend to automate our method and apply it routinely to smaller earthquakes for which traditional methods are not readily applicable due to the complexity of waveforms.

Geophysical inverse problems (seismic tomography) are often significantly underdetermined meaning that a large range of parameter values can explain the observed data well within data uncertainties. Markov chain Monte Carlo (McMC) algorithms based on Voronoi cell parameterizations have been used for quantifying uncertainty in seismic tomography for a number of years. Since surface waves constrain absolute shear velocities and receiver functions (RFs) image discontinuities beneath receiver locations, joint inversion of both data types based on McMC become a popular method to reveal the structure near Earth's surface with uncertainty estimates.
A one-step 3-D direct inversion based on the reversible jump McMC and 3-D Voronoi tessellation is proposed by inverting for 3-D spatial structure directly from frequency-dependent traveltime measurements and RFs. We take into account the dipping interfaces according to the Voronoi parameterisation, meaning that back azimuth and incidence angle of individual RFs must be taken into account. We present synthetic tests demonstrating the method. Individual inversion of surface wave measurements and RFs show the limitation of inverting the two data sets separately as expected: surface waves are poor at constraining discontinuities while RFs are poor at constraining absolute velocities. The joint solution gives a better estimate of subsurface properties and associated uncertainties. Compared to conventional two-step inversion which may produce bias propagating between two steps and loses valuable lateral structure variations, the direct 3-D direct inversion not only produces more intuitively reasonable results but also provides more interpretable uncertainties.

Impact of reservoir loadings on seismic ambient noise in the Koyna-Warna region, western India

DOI: 10.57757/IUGG23-1623 - LINK

Mallika Kothamasu[1], Rajesh Rekapalli[1], Shashidhar Dodla[1], Purnachandra Rao Nemalikanti[1]
[1]CSIR-NGRI, Seismolgy, HYDERABAD, India

To understand the power spectral variations of the ambient noise, we computed the power spectral density-probability density functions PSD-PDF of continuous seismic noise recordings from Koyna-Warna seismic zone, a well-known site for reservoir-triggered seismicity. The analysis helps us to know the impact of water level changes of the reservoirs on the amplitudes of ambient noise in the range 0.01 Hz to 5 Hz. Several studies have indicated a strong impact of reservoir loading on crustal stress and subsurface pore pressure. The comparison of annual ambient noise power levels within the band 0.01Hz to 3Hz with the new global noise models suggests significant deviations on an average. We have noticed cyclic changes and modulation of power and probability at primary and secondary microseism bands from the monthly PSD-PDF variations for the year 2015. Our results indicate high noise levels at the secondary micro-seismic level (~5Sec) to the north of the seismicity zone, which is close to the Koyna Dam, compared to all other directions. An increase in the randomness over frequencies 0.01Hz to 3Hz was observed just before the monsoon i.e. during the month of June, evidenced by reduced power spectral probabilities. The results also indicate a reduction in the noise power during the post-monsoon season, which may be associated with increased loading of the Koyna reservoir. The results suggest the modulation of noise levels by the changing reservoir water levels, particularly during pre and post-monsoon seasons in the Koyna-Warna region.

In this study, we derive the travel times and angles of arrival of head-wave correlations from ocean ambient noise in a shallow ocean waveguide with a layered seabed using a vertical line array. The up- and down-going head waves from the same sediment interface are correlated, and their travel time differences give the travel times of head-wave correlations. The angles of arrival of head-wave correlations from different interfaces depend on the sound speeds in the water and seabed layers according to Snell's law. The head-wave correlations from the water-sediment interface are periodic in time, while those from deeper interfaces show a more complicated time arrival structure. Combining the travel times and angles of arrival of head-wave correlations from different interfaces, it is able to invert for all the sound speeds and layer thicknesses in the water and seabed. The simulation with wind noise and a sediment layer over a half-space seabed verifies the inversion performance.

In southwestern Taiwan, several active faults ever induced massive earthquakes are distributed at the Western Foothill. The seismicity is quite high and widespread in this region. A dense short-period seismometer array with ninety-six stations was temporarily set in the fault zone between November 2020 and January 2021 to collect continuous ground motion data for evaluating the seismogenic characteristics and seismic hazard. This study applied the high-frequency receiver function method to estimate one-dimension shear-wave velocity profiles beneath these stations. The earthquake records of the array were collected and analyzed with appropriate parameters and procedures. Furthermore, the site responses of these stations were also evaluated using the horizontal-to-vertical spectral ratio method. The site effect and shear-wave velocity variation of the fault zone were constructed to discuss the near-surface complex structure in the region.

Joint active and passive MASW for landslide site investigation: A case study from Northwest Taiwan

DOI: 10.57757/IUGG23-1169 - LINK

Jia-Wei Liu[1], *Young-Fo Chang*[1]
[1]*National Chung Cheng University, Earth and Environmental Sciences, Chia-yi, Taiwan Province of China*

Multichannel analysis of surface waves (MASW) is a seismic method used for engineering and environmental exploration. Passive MASW is becoming more popular due to its advantages, such as compensating for the lack of low-frequency information in active MASW. Therefore, more information of the subsurface can be obtained by using the two methods jointly.

To test the performance of the passive MASW in landslide investigation, a 131-meter seismic array was deployed along a slope close to a railway. Seismic waves produced by the active source and ambient noise were acquired. Analyzing the ambient noise data showed that a stable dispersion curve can be obtained within a few minutes. The dispersion curves of every common source gather showed the phase velocities of the active and passive methods at the overlap frequency range are similar which shows these two methods are consistent. Thus, all dispersion curves were jointed and collected to inverse the S-wave velocity.

The inversion results showed a 2-D subsurface structure down to 60 meters, which is more than the double depth using only active methods (25m). The weak material (soft clay) was identified at a depth of 11-18 meters, and soft to dense sand was observed at 18-34 meters. The base rock is identified at the depth blow 34 m with an S-wave velocity exceeding 750 m/s. Study result demonstrates the efficiency of using both active and passive surface waves to investigate landslides on a slope and suggests reliable results can be obtained from short-time ambient noise nearby a railway.

Estimation of high-frequency source radiation energy of small earthquakes in Japan using seismogram envelopes considering the heterogeneous seismic structure

DOI: 10.57757/IUGG23-0642 - LINK

Masashi Ogiso[1]
[1]*Meteorological Research Institute- Japan Meteorological Agency, Seismology and Tsunami Research Department, Tsukuba, Japan*

Recent progress in the theory of seismic wave scattering has shown that the excitation of coda waves depends on hypocentral depth, and analyses of coda waves recorded by dense seismic networks have revealed heterogeneous excitation of coda waves. These facts should be considered when we analyze coda waves further. In this study, we estimate source radiation energy from full seismogram envelopes considering heterogeneous seismic structures.

First, we calculate synthetic envelopes using the Monte Carlo simulation based on the radiative transfer theory and the Born scattering coefficients with a 3-D velocity structure. We conduct a grid search to find appropriate parameters of intrinsic and scattering attenuation that reproduce the shape of each observed envelope, then we calculate source and site terms by an envelope fitting method.

We applied the method to small earthquakes that occurred around central Japan. The range of magnitude was 3.0 to 4.5, and the depth was down to 100 km. We estimated source radiation energy at the frequency ranges of 1-2 and 2-4 Hz. The estimated source radiation energy correlated with magnitude in both frequency ranges. In addition, we found that deep earthquakes tended to have larger energy than shallow ones. This result may reflect the depth dependency of the physical properties of the earth.

Acknowledgments

We used the seismic records of the Hi-net (doi: 10.17598/NIED.0003). This work was partly supported by the JSPS KAKENHI Grant Nos. JP18K13622 and JP21K14002.

Recent progress in the theory of seismic wave scattering has shown that the excitation of coda waves depends on hypocentral depth, and analyses of coda waves recorded by dense seismic networks have revealed heterogeneous excitation of coda waves. These facts should be considered when we analyze coda waves further. In this study, we estimate source radiation energy from full seismogram envelopes considering heterogeneous seismic structures.

Seismic tomography and attenuation models for the geophysical characterization of the Krafla volcanic area

DOI: 10.57757/IUGG23-2177 - LINK

Maria Aurora Natale Castillo[1], *Magdala Tesauro*[1]
[1]*University of Trieste, Mathematics and Geosciences, Trieste, Italy*

The characterization of underground structures is crucial for explorative studies in geothermal systems. As recently demonstrated, analysis of the propagation of seismic waves provides information on physical rocks' behavior and alternative assessments of the brittle-ductile transition (BDT) depth [1]. In particular, the decay of the amplitude of the seismic waves (i.e. seismic attenuation), which is usually described by a "quality factor" Q, depending on the seismic scale, could be used as an indicator of the subsurface heterogeneities.

In this study, we investigate the sensitivity of the seismic velocity and attenuation to the crustal heterogeneities, by implementing a Q seismic tomography of the Krafla volcanic system, an area affected by young tectonics and hot thermal conditions. The applied method solves for Qp perturbations, using a combination of a spectral decay technique to retrieve the attenuation operator (t*) and tomographic inversion [2]. The distribution of seismic wave velocities is obtained from a 3D tomographic inversion, using 1453 earthquakes detected from a local seismic network (2009-2012) [2,3].

The obtained Qp variations up to a depth of 4 km are interpreted together with the seismic wave velocity values [3]. The joint interpretation helps discriminate between anomalies related to temperatures and compositional heterogeneities, defining the main structures of the area. We also try to define the BDT depth, based on the strong reduction of the Qp, related to hot temperatures/melt conditions.

Groundwater level measurement using the ambient seismic time series across the Santa Ana Basin

DOI: 10.57757/IUGG23-4860 - LINK

Shuaiying Wu[1], *Guoxiang Liu*[1]

Groundwater withdrawal for domestic, industrial, and agricultural consumption has intensified in Santa Ana Basin, California. It's imperative to monitor the hydraulic head for groundwater management and the sustainability of water resources. Observation wells provide direct information on groundwater level. However, the sparse spatial coverage makes it inappropriate for large-area studies. Satellite-based remote sensing observations, such as the GRACE/FO data, can obtain regional groundwater storage. Nevertheless, it has coarse spatiotemporal resolution and suffers non-uniqueness between water volume and aquifer depths. Recently, the seismic velocity change (dv/v) calculated by the cross-correlation of ambient seismic time series has been adopted to reveal the groundwater level change. The dv/v has the advantage of illustrating the purely elastic response of the aquifer. Here, we measure the dv/v change at eleven seismic stations from 2000 to 2022 to study the spatiotemporal variabilities of groundwater levels in the Santa Ana basin. Our results manifest good consistency with observed groundwater levels with a correlation coefficient reaching up to 0.8, which means dv/v can reveal both long-term and seasonal fluctuations. Furtherly, the dv/v showed great agreement with precipitation data, which means the groundwater levels in the Santa Ana basin are modulated mostly by the rainfall pattern. As an independent measurement, dv/v shows great promise for regional groundwater study.

The knowledge of the crustal stress field is crucial for understanding the seismic activity in an area that, in turn, requires an in-depth knowledge on the dynamics of the crust. To that end, the reconstruction of focal mechanisms of earthquakes as reliable as possible is a preliminary and basic requirement to infer proper source mechanisms. Currently, the fault plane solution method, using P-wave polarities, is still frequently used. Anyway, manually determining the polarities of P-waves is time-consuming and susceptible to human error. These issues can be solved by automated processes thorough the application of machine learning techniques.

In our study, the Convolutional First Motion (CFM) network, a Deep Convolutional Neural Network, is presented. It is utilized to categorize seismic traces based on the polarity of the P-waves' first motions. We used waveforms from two datasets: the Italian seismic catalogue INSTANCE and waveforms from earthquakes that occurred in the Mount Pollino region of Italy between 2010 and 2014.

We developed a method based on Principal Component Analysis and Self-Organising Maps, which enabled a clustering process to identify sets of appropriate traces. The network was trained using 130˙000 time windows centered on P-wave arrival times relative to waveforms in the INSTANCE catalogue

The network achieved accuracies of 95.7% and 98.9% on two test sets that were generated using the datasets for Mt. Pollino and a portion of the INSTANCE catalogue, respectively.

This work has been partially supported by PRIN-2017 MATISSE project, No 20177EPPN2, funded by Italian Ministry of Education and Research.

In a seismically active region like Romania, an accurate and homogeneous determination of the seismic events' magnitude is important for properly characterising events' size and defining seismogenic areas. We present an automatic and reproducible scheme for local magnitude (ML) calculation based on the reviewed bulletins of the updated Romanian earthquakes catalogue (ROMPLUS) and the associated horizontal components of the station recordings. The applicability of the method is evaluated on three different case-studies, considered as typical examples, using earthquakes recorded between 2014 and 2023. Firstly, the magnitude calculation scheme is applied to anthropogenic and natural seismic events recorded in the North Romania regions, known for the quarries' exploitations. Secondly, we analyse earthquakes from the Vrancea seismic region, mainly the events that occurred during the February 2023 Turkey-Syria damaging earthquake sequence, in order to review the magnitudes of the local events whose waveforms overlap with the surface waves generated by this sequence. Finally, the intense earthquake sequence from the Central Southern Carpathians seismic zone, with the main shocks corresponding to doublet earthquakes with magnitudes (ML) 5.2 and 5.7 and over 800 aftershocks, was analysed to evaluate the stability of the scheme.

We show that the proposed approach is able to provide a reliable automatic estimation of ML for seismic events, by minimising the magnitude error and allowing to select recordings with good signal-to-noise ratios. Our results demonstrate the usefulness of this scheme for the homogenisation of the ROMPLUS catalogue and its future extension to other seismically active areas of Romania.

Improving aftershock decision criteria for the 2016 Gyeongju and 2017 Pohang earthquakes in South Korea

DOI: 10.57757/IUGG23-0650 - LINK

Gyeongdon Chai[1], *Kyungmin Min*[1], *Sunchen Park*[1], *Jimin Lee*[1], *Eunyoung Jo*[1], *Mikyoung Choi*[1], *Yeongjae Choi*[1]

During the last six years, South Korea has experienced two of its largest earthquakes since instrumental recording began. A specific set of aftershock criteria is necessary for earthquakes that occur near the mainshock. Despite the discovery of the fault associated with the mainshock, some aftershocks have a low relevance to the fault where the mainshock occurred. Providing detailed information about aftershocks to people living near fault areas is important, and the difficulty in specifying their end time has prompted the need for improved criteria. We propose improved criteria for determining the aftershocks of the ML5.8 Gyeongju and ML5.4 Pohang earthquakes.
The criteria are divided into temporal and spatial components. The earthquake Mw-fault information relationship of Wells & Coppersmith (1994) is used for the spatial criterion to calculate the extent of ruptures that can occur based on magnitude. The rupture range is conservatively applied to the Mw5.6 Gyeongju and Mw5.4 Pohang earthquakes. The spatial aftershock distribution is defined within 4 km of the earthquake fault line associated with the mainshock, and it is based on the empirical relationship of the fault down-dip rupture width and the earthquake moment magnitude of past earthquakes. For the temporal criterion, the endpoint of aftershocks is defined as the time when the number of earthquakes per unit of time after the mainshock is equal to or less than the average seismicity in the five years before the mainshock. Using these criteria, the study concludes that the aftershock sequences of the Gyeongju and Pohang earthquakes are still ongoing.

From analog to digital instrumentation and the importance of expanding the seismic network - Targu-Jiu seismic sequence study case

DOI: 10.57757/IUGG23-4253 - LINK

Camelia Andreea Chircea[1,2], Raluca Dinescu[1,3], Daniela Ghica[1], Mihaela Popa[4], Iulia Stefania Armeanu[1,2], Cristian Neagoe[1], Adina Vanciu-Rau[1,5]

The Targu-Jiu seismic zone of Romania is well known for the crustal events with moderate magnitude (ML <5) that rarely occurred. The largest event, with an estimated local magnitude of 5.2 and depth of 9.9 km, was recorded in 1943. At that time, seismic monitoring was done with analog instruments and macroseismic observations.

At the beginning of 2023, a seismic sequence with main shocks as doublet earthquakes occurred on February 13th and 14th, with local magnitudes of 5.2, respectively 5.7, followed by over 900 aftershocks.

When the sequence started, the Targu-Jiu area was monitored by 45 seismic stations of the Romanian Seismic Network (RSN). Therefore, the earthquake parameters were determined accurately.

Moreover, for lowering the event magnitude threshold and a better seismic coverage, four more seismic stations were installed in the epicenter area, after the 5.7ML event recorded on February 14th.

The main goal of this paper is to highlight the importance of well-distributed seismic stations in the epicenter area and high quality recorded data. To reach the purposes of this study, two different approaches were conducted. Firstly, we used only the stations nearby the epicenter area. Then, we use data recorded by all the RSN stations (over 160 recordings for the 5.7 ML event). The results of this study showed that a better location is obtained when using stations well distributed in the epicentral area.

HEX 2.0: an improved local seismic phase associator

DOI: 10.57757/IUGG23-3984 - LINK

Andreas Rietbrock[1], Jack Woollam[1], Spina Cianetti[2], Carlo Giunchi[2]

The task of association of seismic phases into events is particularly challenging in every workflow dealing with seismically active regions where dense networks are usually deployed. Additionally, recents developments of picking algorithms based on deep learning frameworks provide an increased number of phase onsets with respect to standard approach based on the computation of characteristic functions of the seismic waveforms. Especially the number of S-picks has been increased by orders of magnitude, which now requires the simultaneous association of P- and S-wave arrivals or even detecting events only based on S-wave arrivals. We present an improved version of HEX (Hyperbolic Event eXtractor), a new technique based on the logic of Random Sample Consensus here applied to association of seismic phases. Since this algorithm is particularly effective in dealing with high noise in the input data, we show the benefits of HEX2.0 to analyze picks from deep learning methods. These datasets are characterized by either detections of small amplitude earthquakes that, according to network geometry, may not show at a sufficient number of seismic stations to declare an event or, sometimes, to a high rate of false positives. The application of HEX2.0 on real data from a seismic sequence of Sannio-Matese (Southern Apennines, Italy) occurred in 2013-2014 show that: i) resulting events show a high number of phases compared to previous catalogs; ii) few phases are discarded in the event location. HEX2.0 provides an accurate, easy-to-use and computationally effective solution to the seismic phase association problem.

Automated procedures for seismic arrival-time picking on large and real-time seismological waveform datasets are critical for many seismological tasks. Recent, high-performance, automated arrival-time pickers mainly use deep-neural-networks applied to nearly raw, seismogram waveforms as input data. However, there is a long history in earthquake seismology of rule-based, automated arrival detection and picking algorithms that efficiently exploit variations in amplitude, frequency and polarization of seismogram waveforms.

Here we use this classical, seismological domain-knowledge to transform raw seismogram waveforms into input features for a deep-learning picker. We preprocess 3-component, broadband seismograms into 3-component characteristic functions of a multi-band picker (FilterPicker), plus the instantaneous modulus and inclination of the waveforms. We use these five time-series as input instead of the 3-component, raw seismograms to extend the deep-neural-network picker PhaseNet within the SeisBench platform. We compare the original, purely data-driven PhaseNet and our extended, domain-knowledge PhaseNet (DKPN), using identical training and validation datasets, with application to in- and cross-domain testing datasets.

We find that the explicit information targeting arrival-time detection and picking introduced by the domain-knowledge processing enables DKPN to be trained with smaller datasets than PhaseNet. Relative to PhaseNet, DKPN shows improved performance and stability for P picking and slightly improved S picking, especially for cross-domain application. With increasing training dataset size PhaseNet performance generally improves and converges to that of DKPN, except for cross-domain P picking. The results suggest that DKPN primarily needs to learn pick characterization, while PhaseNet additionally requires learning the more difficult task of arrival detection.

Enhancing Earthquake Detection through Machine Learning: An Application to the 2017 Mw 8.2 Tehuantepec Earthquake in Mexico

DOI: 10.57757/IUGG23-4755 - LINK

Marc Garcia[1], *Aaron Velasco*[1], *Chengping Chai*[2], *Monica Maceira*[2]
[1]*University of Texas - El Paso, Earth- Environment and Resource Sciences, El Paso- Tx, USA*
[2]*Oak Ridge National Laboratory, Research & Development, Oak Ridge- Tn, USA*

Detecting and monitoring earthquakes remains a persistent challenge in seismology. The ever-increasing volume of seismic data provides us with a great opportunity to develop more robust phase picking and association methods. While the application of machine learning models for earthquake monitoring has gained significant attention, there remains a gap in validating the efficacy of these models for unseen data. This study reviews a practical workflow that leverages machine learning techniques for phase picking and association following the September 8th, 2017, Tehuantepec earthquake (M8.2). The September 8th earthquake ranks among one of the strongest intraplate events recorded in the history of México, causing significant damage and deaths in the states of Oaxaca, Chiapas, Tabasco, and México City. The Servicio Sismólogico Nacional (SSN) alone has located over 30,000 aftershocks in six months following the mainshock. The volume of seismic recordings gathered from permanent and temporary networks deployed from collaborations of the University of Texas at El Paso, Universidad Autónoma Cuidad Jaurez, and SSN and the tectonic complexity of this rupture have made it strenuous to use traditional automated detection methods. Using *PhaseNet*, a convolutional neural network developed for picking arrival times of P and S waves, and the Gaussian Mixture Model Association, *GaMMA*, an unsupervised association method based on a Bayesian Gaussian Mixture Model, we aim to review a practical workflow for earthquake detection and a catalog of relative earthquake locations for this large number of aftershocks, contributing to studying the broader geotectonic setting of the Tehuantepec region.

Detecting and monitoring earthquakes remains a persistent challenge in seismology. The ever-increasing volume of seismic data provides us with a great opportunity to develop more robust phase picking and association methods. While the application of machine learning models for earthquake monitoring has gained significant attention, there remains a gap in validating the efficacy of these models for unseen data. This study reviews a practical workflow that leverages machine learning techniques for phase picking and association following the September 8th, 2017, Tehuantepec earthquake (M8.2). The September 8th earthquake ranks among one of the strongest intraplate events recorded in the history of México, causing significant damage and deaths in the states of Oaxaca, Chiapas, Tabasco, and México City. The Servicio Sismólogico Nacional (SSN) alone has located over 30,000 aftershocks in six months following the mainshock. The volume of seismic recordings gathered from permanent and temporary networks deployed from collaborations of the University of Texas at El Paso, Universidad Autónoma Cuidad Jaurez, and SSN and the tectonic complexity of this rupture have made it strenuous to use traditional automated detection methods. Using *PhaseNet*, a convolutional neural network developed for picking arrival times of P and S waves, and the Gaussian Mixture Model Association, *GaMMA*, an unsupervised association method based on a Bayesian Gaussian Mixture Model, we aim to review a practical workflow for earthquake detection and

a catalog of relative earthquake locations for this large number of aftershocks, contributing to studying the broader geotectonic setting of the Tehuantepec region.

Modeling the structure of the Água Bonita basin, Brazil, from the inversions of horizontal to vertical spectral ratio (HVSR) peaks

DOI: 10.57757/IUGG23-3629 - LINK

Daniele Ingredy Gomes Silva[1], George Sand França[1], Eveline Sayão[1]
[1]University of Brasília, Seismological Observatory, Brasília, Brazil

The advance in seismic acquisition requires more techniques compatible with urban means and environmentally friendly. A**ccordingly**, the horizontal-to-vertical spectral ratio (HVSR), is a method that is becoming much more popular and convenient. Used with a lot more frequency to help estimate structures and draw a better model for shallow structures. Following the tested and approved procedures described in the SESAME Project, we acquired 58 measurements in 6 profiles, including fixed and temporary stations. The study site is a strike-slip basin, called Água Bonita, located in the state boundaries of Tocantins with Goiás, in the center-North of Brazil. The deep structure of this basin is well-constrained based on geological and geophysical data. Therefore, we could compare the reliability of our depth estimates. Following the previous acquisitions, we used broadband and short-period seismometers for the acquisition, positioning the profile's location transversal to the basin length. Due to the basin geometry, we searched for a correlation between the HVSR frequency results and the sedimentary thickness, type of sediment, and overall location within the geological context. The inversion of the HVSR frequency peaks was used to estimate the depth of the layers observed. The preliminary results indicate an association between sedimentary thickness and lithology contrast. It obtained frequencies ranging from 0.2Hz at the edges to 11Hz in the basin's center. With the data acquired, we were able to trace a 3d model of the basin and possibly better identify other faults within the basin changing its geometry alongside its length.

Waveform based cluster analysis of seismicity in the Eastern Alps

DOI: 10.57757/IUGG23-3596 - LINK

Rens Hofman[1], Jörn Kummerow[1], Gesa Petersen[2], Simone Cesca[2]
[1]Freie Universität Berlin, Geophysik, Berlin, Germany
[2]Helmholtz-Zentrum Potsdam- Deutsches GeoForschungsZentrum, Geophysik, Potsdam, Germany

The Swath-D network was a temporal seismic array in the Eastern Alps, as part of the AlpArray project. The array consisted of 154 broadband stations and was active from late 2017 to late 2019. Using data from this network, we constructed a comprehensive local seismicity catalogue based on template matching. We developed a workflow to derive picks for these low magnitude events that typically have low signal to noise ratios. This allowed us to relocate part of the detected seismicity with high resolution, exploiting the densified station distribution in the area.

Based on this enhanced earthquake catalogue for the Eastern Alps, we identified multiple clusters with high seismicity rates. We perform an iterative template matching scheme to increase the number of detected events, and apply a relative relocalisation to further increase the spatial resolution. Graph theory was applied to visualise event interconnectivity based on waveform similarity between the clustered events. This allows us to derive network features, which we compare to the spatiotemporal characteristics of each of the clusters, as well as source properties of the clustered events.

Application of phase identification using deep learning-based technology for local earthquakes in the Southern Korean peninsula

DOI: 10.57757/IUGG23-2137 - LINK

Euihong Hwang[1], Seongheum Cho[1], Jae-Kwang Ahn[1], Sun-Cheon Park[1]
[1]Korea Meteorological Administration, Earthquake and Volcano Bureau, Seoul, Korea Republic of

In order to identify the phase of seismic waves, deep learning-based phase identification technologies have recently been developed.It is known that deep learning-based phase identification technology can accurately determine the arrival time of the phase and also identify S waves, which are relatively more difficult to detect than P waves. Approximately 2.4 million seismic data from STEAD and INSTANCE were used to develop deep learning-based phase identification techniques (Sheen, 2021).In this study, a deep learning-based phase identification technology was applied to 871 earthquakes with a magnitude of 2.0 or higher on the Korean Peninsula and compared to the manual seismic wave identification results provided by the Korea Meteorological Administration. As a result, it was confirmed that most of the P-waves of the seismic wave could be identified successfully, and the S-waves were also identified. In addition, the optimal criteria for determining the phase status of P and S-waves were established using deep learning-based seismic wave identification technology. To this end, the learning model predicted the probabilities of P&S-waves, and noise from the three-component seismic waveform, and judged the section where the probabilities of P&S-waves exceeded a specific threshold to be a phase. It was confirmed that the performance of the artificial intelligence model changed according to this specific threshold, and the optimal threshold yielding the highest performance of the AI model was selected. As a result, it was confirmed that as the threshold value increased, the model accuracy increased while the reproduction rate decreased.

We explore the ambient noise wave field recorded on different optical fibers interrogated during distributed acoustic sensing (DAS) campaigns in Iceland and Germany. DAS is a relatively new technology that allows for measurements of acoustic strain signals at densely spaced observation points along buried optical fibers. Ambient noise interferometry, in particular single-channel auto-correlation, is potentially a powerful technique for resolving the structure of the subsurface medium and characterizing its properties below a seismic sensor. Combining these two techniques to extract the ambient noise auto-correlation functions from horizontal strain rates all along the densely spaced locations on the fiber we obtain coherent signals that correlate over multiple observation points. We are challenged by the separation of the super-positioned non-stationary ambient noise field and the seismic response of the subsurface. We test our processing workflow and results against independent methods. (1) A controlled vibro-seis experiment and (2) seismic ambient noise analysis of a large-N three-component seismic nodal array which was co-located with the optical fiber in Iceland.

Automatic unsupervised classification of tectonic tremor signals in continuous seismic records

DOI: 10.57757/IUGG23-4852 - LINK

Yuki Kodera[1]
[1]*Meteorological Research Institute- Japan Meteorological Agency, Department of Seismology and Tsunami Research, Tsukuba, Japan*

Continuous seismic records include various earthquake signals such as ordinary fast earthquakes and slow earthquakes like tectonic tremors. A machine-learning-based automatic classification approach would allow us to process a large amount of waveform data and to understand geophysical phenomena around a target seismic network. In this study, we propose an automatic unsupervised classification algorithm for continuous records based on frequency characteristics.
Our proposed algorithm first extracts frequency features by calculating running spectra, and then the vector quantization is performed in the feature space. After that, the data points are converted by the kernel principal component analysis and are clustered by the Ward hierarchical clustering algorithm in the mapped space. Finally, classification results are obtained by cutting the dendrogram at 1/4 of the maximum height.
We tested the proposed algorithm by applying to one-week-long continuous waveforms recorded at five temporary ocean-bottom seismometers to observe aftershocks of the 2004 M7.4 off the Kii Peninsula earthquake (Yamazaki et al., 2008). For every station, tectonic tremors with large amplitudes were assigned for unique class(es) different from those for background noises and fast earthquakes, indicating that the proposed algorithm successfully detected tectonic tremors with a good S/N ratio. We also compared the classification results to a tremor catalog compiled by manual inspection and found that the detection rate was 87%, which suggested that the proposed algorithm could detect tremors with a high detection rate although the algorithm did not use specific knowledge of tectonic tremor such as template.

One of the contemporary trend in seismology is process huge data sets automatically with use of Neural Network (NN) formalism. We present seismogram onsets interpretation obtained both by Convolution NN as well as Recurrent NN approach. We investigated data from Acoustic Emission loading experiment with Westerly Granite. Such data appeared to be suitable for testing of NN approach as they are more homogeneous then data originated from natural earthquakes, but simultaneously they are complex enough not to be of trivial interpretation. We designed NN architecture, learned in and compare the results with biased interpretation. We were searching not only for onsets on individual seismograms but we try to identified the whole events. In addition to automatic onsets identification we (also automatically) determined event location and seismic moment tensor. Comparison with biased data proved that these automatically obtained values can be successfully used as preliminary estimation at least. Problems of multiple events identification are discussed as well. The method has a potential to be applicable on natural earthquake seismograms.

An earthquake swarm occurred during 2020-2021 at the Perachora peninsula, in the eastern Gulf of Corinth (Greece), one of the most seismically active areas in Europe. In this work, we analyzed the swarm using a high-resolution earthquake catalog and advanced processing techniques. We employed both single-station and multi-channel template matching to produce additional detections of over 7,600 and 24,000 events, respectively. The resulting catalogs have different completeness magnitudes and location uncertainties for the added events. The frequency-magnitude distributions were characterized using the Gutenberg-Richter scaling relation, examining possible b-value temporal variations. We found that the seismic bursts associated with the swarm were short-lived and dominated the catalogs. Spatiotemporal clustering methods were used to analyse the swarm's evolution, showing that the seismicity rate significantly increased, likely due to a pore-pressure transient, without stress transfer caused by a major earthquake. Migration velocities, high b-values and clustering effects of multiplet families, observed at all time scales, suggest a pore-pressure triggering mechanism. Some anomalies in the frequency-magnitude distribution of the enhanced catalogs were observed, mainly attributed to the poor network coverage of the area of interest. Despite these limitations, the enhanced catalogs can be quite useful in studying the spatiotemporal properties of microseismicity in the region. This study highlights the importance of high-resolution data and advanced analytical techniques in understanding earthquake swarms in tectonically active regions.

Acknowledgements

The research project was supported by the Hellenic Foundation for Research and Innovation (H.F.R.I.) under the "2nd Call for H.F.R.I. Research Projects to support Post-Doctoral Researchers" (Project Number: 00256).

The ICDP project "Drilling the Eger Rift" focuses on geodynamic processes in W-Bohemia and Vogtland, such as earthquakes and subsurface fluid flows. Therefore, three boreholes have been drilled and will be instrumented with 3D seismic arrays. The pilot 3D array has 10 borehole geophones with a 10 Hz corner frequency and is surrounded by a surface array with 12 4.5 Hz geophones. The data is recorded by Earth Data Loggers with a sampling rate of 1000 Hz.

The goal is to locate seismic noise sources up to a distance of 15 km that may be linked to fluid migration in W-Bohemia. We analyze continuous seismic noise records of more than 20 stations from regional networks and our seismic array. Differential PSDs were calculated in different frequency ranges to find continuous tremor-like seismic sources before the earthquake swarm in April 2021. Our next step is to locate these sources using regional networks and the 3D seismic array.

The analysis revealed an increase in seismic noise between 4-8 Hz for a 2-hour period on April 5th, 2021, one day before the earthquake swarm started. Seven stations in the region show a median differential PSD level at least three times higher than the differential PSD level for the entire day. These stations are located up to a distance of 12 km to the Nový Kostel focal zone, where most of the earthquakes occurred. The increase is also compared to Radon concentrations measured at Hartoušov (W-Bohemia) to find possible coincidence.

Supervision of velocity models used in Reykjanes Peninsula, SW of Iceland

DOI: 10.57757/IUGG23-0564 - LINK

Bohuslav Ruzek[1], *Jana Doubravova*[1], *Josef Horalek*[1]
[1]*Institute of Geophysics- Czech Academy of Sciences, Seismology, Prague, Czech Republic*

Processing of seismological data requires knowledge of appropriate velocity model. Due to ongoing investigations of prominent geological regions usually numerous velocity models by different authors have been developed there. The question which arises is which one to use. This is also the case for Reykjanes Peninsula (RP) in SW Iceland, where the REYKJANET seismic network was built to monitor local seismicity. At present, five velocity models come into consideration in RP (four 1D gradient models and, one 3D tomographic model).

We have tested all the five models by common methodology. It includes discussion of results of (i) hypocenter localization, (ii) P-wave polarization at station positions and, (iii) Rayleigh-wave dispersion. Alternatively, 1D velocity models have been combined with stations corrections thus yielding efficiently pseudo-3D models.

All the tested models provide hypocenters whose traveltime residuals can be classified into two groups ((i) 1D models without station corrections and (ii) 3D tomographic model and 1D models with station corrections). Hypocenter coordinates differ slightly according the used model. Bigger differences between the models are due to the predicted P-wave polarization and Rayleigh-wave dispersion. This issue is connected with bigger sensitivity of those parameters to the surface properties of the models.

Our proposition is to select the best one 1D velocity model supplemented with station corrections and use it anywhere possible. Using of a more complex 3D model would be usually not highly beneficial. 3D tomographic model is, however, one of not-so-many tools how to discover geological features of the underground.

On 2022-02-01, the mainshock of a seismic sequence that started in 2021 struck between l'Alt Urgell (Catalonia) and Andorra la Vella (Andorra) in the Central Pyrenees area. This magnitude (Mw) 4.0 earthquake, which alerted the population of the vicinities, was followed by low-magnitude aftershocks. In this work, we aim to obtain a new catalog through machine-learning procedures. We used the easyQuake python package, which allowed us to build new catalogs after detecting earthquake arrival times within seismograms recorded by several stations in the study area. Using different pickers, we obtain those machine-learning catalogs and compare them against data from regional agencies. We observed that, depending on the deep-learning model, the new catalog matched a high percentage of the original dataset recorded by the agencies. Besides that, we noted that some earthquakes passed undetected by the routine processing of these agencies. Then, using the new arrival times, we relocated the hypocenters using a 1D velocity model of the area following a non-linear location inversion approach. Our results show low uncertainties, which suggest that the arrival times detected by the machine-learning software are accurate enough to obtain constrained hypocenters. We conclude that this procedure could be advantageous for agencies and organizations that run a regional network in addition to the standard routine procedure carried out by expert scientists and technicians.

[3]Ludwig-Maximilians-University of Munich, Department of Earth and Environmental Sciences, Munich, Germany

La Réunion, an island in the Indian Ocean, hosts the shield volcano Piton de la Fournaise that recently tends to erupt up to twice per year. The seismic recordings show a great signal diversity including tectonic and volcano-tectonic (VT) earthquakes, eruption tremor, (very) long period events along with a variety of rockfalls.

With the aim of testing the rotational sensor performance in comparison with a conventional seismic array, one rotational sensor and an array of seven seismometers were installed within the Enclos-Fouqué caldera. A permanent station of the monitoring network of the Observatoire Volcanologique du Piton de la Fournaise (OVPF) is included in the temporal network. Recordings of (volcano-) seismic signals, detected by the OVPF's network, are compared to those of the rotational sensor and the array.

We calculate the signal-to-noise ratio (SNR), derive the rotation rate using three array stations for array derived rotation (ADR) and compare the backazimuth (BAZ) results using different approaches. The rotational sensor and the array BAZ are furthermore compared to the OVPF's localizations.

Whereas the array BAZ for summit VT events and the rockfall agree with the locations of the OVPF network, the rotational sensor BAZ indicates possible agreement for the rockfall event. Further BAZ results from the rotational sensor are interpreted to be affected by site inhomogeneity. The array stations show higher SNR results than the rotational sensor. As burying of the instruments on site was not possible, the sensors are affected by wind, increasing the noise floor and decreasing the instruments' sensitivity.

Historically, the study of the seismic structure beneath the Canary Islands using local earthquakes has been hampered by the sparse distribution of recording stations and by the moderate seismic activity. Recently, the number of permanent stations from monitoring networks has significantly increased, from barely one seismometer per island in the early 2000s to more than 10 stations in each the most seismically active ones. Similarly, temporary deployments of broadband stations have also taken place in most of the islands, further increasing the station density. On the other side, the number of recorded earthquakes has also greatly increased. This is due in part to the seismicity associated with the 2011-2012 El Hierro and 2021 La Palma eruptions, but also because of the improvements in the detection capabilities of the monitoring network.

Here we present new P and S wave velocity regional models of the Canary archipelago and higher resolution models for the islands of Tenerife, La Palma and El Hierro. The bulk of the arrival time data used to obtain these models comes from the Instituto Geográfico Nacional (IGN) permanent monitoring network. We have augmented this dataset by incorporating arrival time data from recent temporary deployments, obtained using Deep Learning phase pickers. Because of the increased coverage of this new dataset, we are able to image features such as crustal thickness variations, magmatic intrusions, and regions of shallow (crustal) and deep (uppermost mantle) magma storage.

Funding has been provided by Spanish Ministry of Science and Innovation projects PID2020-114682RB-C31 and PID2020-114682RB-C32.

Analysis of the 2016 Central Italy earthquake sequence by using a refined earthquake catalog

DOI: 10.57757/IUGG23-0985 - LINK

Louise Xiang[1], *David Marsan*[1]
[1]*ISTerre, Seismic cycles and transient deformations, Le Bourget-du-Lac, France*

The 2016 Central Italy seismic sequence occurred within an area dominated by normal-fault systems present along the Apennines. The sequence began with the Mw 6.0 Amatrice event on the 24 August 2016, followed by the Mw 5.9 Visso event on the 26 October 2016 and then, two days later, the Mw 6.5 Norcia event. In this study, we aim at modeling the seismicity of this complex earthquake sequence in order to determine the location of highly-pressurized fluids under the studied area through swarms occurring during the sequence. To do so, we take advantage of a high-resolution earthquake catalog based on arrival times derived using a deep-neural-network-based picker. As a first step, we apply a density-based clustering algorithm (DBSCAN) to group earthquakes into dense clusters. The majority of the resulting clusters highlight distinct fault planes which indicates an activation of a complex fault network. We further define a 4-dimensional seismicity model based on the « Epidemic-Type-Aftershock-Sequence » (ETAS) model, that we modified to include an earthquake detection probability, as required by the continuous change of completeness magnitude. This allow us to compute the seismicity rate of the DBSCAN clusters. Swarms are then deduced based on the ratio between observed and modeled seismicity rates. We finally analyze how the swarms occur, in relation with the development of the seismic sequence.

Recently low-cost, easily deployable nodal sensors initially developed for the petroleum industry, are widely used by seismologists to sample the seismic wavefield in dense arrays at unprecedented spatial resolution, and push the limits of resolution in microseismic events monitoring and subsurface imaging. With the increasing demand on the nodal sensors in the industry and seismological community, multiple commercial models of nodal sensors appear in the market and it becomes important to know the potential limitations and variabilities among these models. We conduct a number of laboratory and field experiments to better identify their fidelities. First, we carry out the shake-table tests to identify the sensitivities of these units, which enables us to convert sensor output to units of ground motion reliably. Then we estimate the self-noise of these sensors in a huddle test based on the three-sensor method, which defines the lowest signal that the sensor can discern. Finally all the models are deployed at several field sites for about one month, both the earthquake waveforms and green's function retrieved from ambient noise are compared to show their differences.

Automatic induced seismic event detection in low-seismicity areas

DOI: 10.57757/IUGG23-0469 - LINK

Viesturs Zandersons[1], *Jānis Karušs*[1], *Matīss Brants*[1]
[1]*University of Latvia- Faculty of Geography and Earth Sciences, Department of Geology, Riga, Latvia*

Seismological phase detection is a fundamental part of seismic observation process. The wave arrival tracking is complicated in sparse seismic arrays over low-seismicity areas, where the noise floor is high and signal-to-noise ratios are low. Classic automatic routines can fail to detect or falsely detect too many of the small induced seismic events.

In this research we compare the results of multiple automatic and machine-learning based phase picking algorithms around Baltic States. In a region of low seismicity, we intend to track induced events, occurring from military exercises and mining blasts. We analyze 11 seismological station data of year 2021 and compare manual phase picks against automatically detected ones. For phase detection we use variations of STA/LTA and deep neural network pickers from Ross et al., 2018 and Zhu & Beroza, 2018.

We show that automatic picking routines coincide very well with manual observations. Even regionally untrained neural networks outperform manual observations, resulting in increased event detections. Neural networks picks are also less susceptible to seismic noise than classic STA/LTA variations, however, false-detection problem cannot be eliminated entirely. We believe that improvements to neural network models could be made, retraining the model using local data or adjusting hyperparameters to better fit the low signal-to-noise ratios of the induced events.

Sardinia is a seismically quiet region: for this reason, it has been proposed as an excellent location to host fundamental physics experiments requiring low seismic ambient noise such as the Einstein Telescope, the third-generation gravitational wave observatory. In the framework of the instrumental deployment to characterise the formerly lead and zinc mine of Sos Enattos, currently dismissed and converted to a low-noise laboratory, we focus on the link between the records from seismic stations in different locations and the meteorological records collected in their vicinity. To do this, we use a scattering network, a convolutional neural network with wavelet filters, to extract relevant spectro-temporal features at different time scales of the signal. We then use a dimensionality reduction algorithm to reduce the features' dimensions and apply a hierarchical clustering algorithm to identify patterns in the continuous seismic data. We choose hierarchical clustering because it allows us to understand the inter-cluster similarity. We finally investigate the link between these clusters and the external meteorological data collected nearby and reveal the mutual information between the two datasets.

Understanding and Mitigating the Spatial Bias of Earthquake Source Imaging with Regional Slowness Enhanced Back-Projection

DOI: 10.57757/IUGG23-2185 - LINK

Yijun Zhang[1]
[1]*University of Chinese Academy of Sciences,*
Innovation Academy for Precision Measurement Science and Technology, Wuhan, China

We investigate characteristics of spatial biases in the Back-projection method and the effectiveness of the Slowness Enhanced Back-projection (SEBP). The spatial bias refers to the location error in Back-projection caused by travel time errors due to 3D Earth structure. SEBP reduces such bias by calibrating the gradient of travel time (slowness) in the source. We first analyze 22 M4-M6 earthquakes in the Commander Island and find the amplitudes and directions of spatial biases follow distinct regional patterns. In light of this, we propose a regional SEBP approach that introduces spatially variable slowness correction. The regional SEBP in the Commander Island resulted in a ~ 50% reduction in the average length of spatial bias from ~20 km to ~10 km, which is more effective than the uniform SEBP that gives a 25% error reduction. We then analyze 109 M4-M7 earthquakes in the Tohoku region and also find a 50% error reduction by regional SEBP. This indicates that half of the spatial biases are aleatory uncertainties that are caused by regional structural complexity and can be calibrated with SEBP, while the residue errors are epistemic uncertainties that are random and caused by local velocity heterogeneities. With regional SEBP applied to the 2011 Tohoku earthquake, we find that high-frequency radiators did not reach beyond the down-dip limit of interplate seismicity, indicating that the coseismic slip unlikely penetrated into the brittle-ductile transition zone. Such observations suggest that the enhanced dynamic weakening mechanism due to thermal pressurization effects may not be activated during this event.

Seismic methods have been widely used to image the subsurface for geological characterization and exploration. Due to the limitation of active experiments in populated areas, methods tapping the existing ambient noise as a source of excitation have gained increasing attention. The combination of this approach with Distributed Acoustic Sensing (DAS) is particularly appealing as vast telecommunication networks can potentially be used as sensors. However, seismic noise in urban areas is complex. Usually it is of anthropogenic nature and dominated by traffic. To extract coherent signals from recorded noise, the acquisition of long time series associated with high computational costs is required.

In the study presented, we analyzed the cultural noise along an urban road in Berlin. DAS data was collected at a spatial period of 8 m and a temporal frequency of 1000 Hz along a 3-km long segment of a dark telecommunication fiber. The recorded noise contains transient signals with frequencies between 1 and 40 Hz attributable to the passage of trains. As these signals inhibit the extraction of coherent Rayleigh Waves, we applied a denoising method based on the harmonic-percussive separation technique prior to the standard ambient noise pre-processing (data decimation, band pass filtering, temporal and spectral normalization, cross-correlation) . We compare processing results with and without denoising and conclude that our approach leverages the recorded data better and yields improved virtual shot gathers . This implies the possibility to conduct shorter campaigns for acquiring equivalent results with respect to ambient noise analysis.

Distributed acoustic sensing (DAS) allows for the deployment of a few tens of meters of seismometers along the length of the optical fiber cable. However, the data obtained from DAS, particularly amplitude information, can vary based on the installation environment of the optical fiber cables. Our proposal is to conduct seismic observations using DAS with optical fiber cables. In this study, we applied DAS to the cable along the bullet train in Kumamoto prefecture, Japan, where aftershocks from the 2016 Mw7.3 Kumamoto earthquake are still highly active. We successfully observed strong motions of the Mj6.6 earthquake on January 22, 2022 in Hyuga-nada and several small local earthquakes for distances over 75 km. An accelerometer that simultaneously recorded the event observed a maximum acceleration of approximately 80 gal. The shaking map (maximum strain distribution) for Mj6.6 was estimated by correcting for cycle skipping caused by the dynamic range. The differential phase data indicated cycle skipping at various channels. We estimated the data from cycle-skipped channels using data from adjacent channels that were not cycle-skipped. The attenuation properties of local earthquakes were identified by correcting for site effects, coupling, and amplification of seismic waves by the railway structure. We observed that the peak strain values as well as PGV decreased with increasing hypocenter distance for each magnitude category. Our results indicate that accurately correcting DAS amplitude values can allow for empirical estimation of earthquake magnitude.

Distributed Acoustic Sensing (DAS) is becoming increasingly popular for different seismological applications due to its high spatial sampling and potentially long cable lengths. So far, the ability of DAS records for seismic array processing has not been assessed systematically with observed data. We use one month of continuous data recorded on the newly deployed NORFOX DAS array in southern Norway, which is co-located with the 16-element NORES broadband seismic array. NORES has a current aperture of approximately 1.4 km. NORFOX consists of a total cable length of approximately 8 km arranged in 5 arms, with an array aperture of 3 km. Data were acquired from three branches of the array using two DAS interrogators for the full month of February 2023. We analyze this unique data set by first comparing waveforms and signal to noise ratios (SNRs) of local, regional and teleseismic events detected on NORES with the DAS records. We then apply beamforming to the DAS data to evaluate SNR improvements for P and S wave beams deployed for all recorded events. Finally, results of Frequency-Wavenumber analysis of NORFOX and NORES data are compared. We test the findings of a previous theoretical study on DAS array processing which considers the broadside sensitivity of the cable and give a final evaluation of the potential of using DAS arrays for continuous seismic monitoring.

Combined fiber-optic monitoring technologies to assist borehole completion

DOI: 10.57757/IUGG23-1486 - [LINK]

Johannes Hart[1], Christopher Wollin[1], Martin P. Lipus[1], Charlotte Krawczyk[1]
[1]GFZ German Research Centre for Geosciences, Geophysics, Potsdam, Germany

Reliable well completion and monitoring technologies are a prerequisite to achieve safe, sustainable and efficient use of geothermal reservoirs. Since borehole completion is a high-risk process, we tested how distributed fiber optic sensing technologies can aid monitor the completion process continuously in space and real time. To evaluate the success of the operation conventional well logging tools and other methods can only be used after the completion and show snapshots of discrete points in time.

We present results from a case study in Berlin, where a 450 m deep exploration well was completed for Aquifer Thermal Energy Storage (ATES) purpose. To simultaneously measure distributed temperature (DTS) and distributed elastic and static strain (DAS and DSS) a fiber optic cable was installed behind the production tubing. The combined evaluation of the different fiber optic technologies evidences the potential to observe previously untraceable processes, such as changes in subsurface flow paths due to clogging. Further, the unwanted process of caving can be identified and the rise of gravel or cement observed. This allows to react on site, and subsurface risks will be considerably mitigated.

Reliable well completion and monitoring technologies are a prerequisite to achieve safe, sustainable and efficient use of geothermal reservoirs. Since borehole completion is a high-risk process, we tested how distributed fiber optic sensing technologies can aid monitor the completion process continuously in space and real time. To evaluate the success of the operation conventional well logging tools and other methods can only be used after the completion and show snapshots of discrete points in time.

We present results from a case study in Berlin, where a 450 m deep exploration well was completed for Aquifer Thermal Energy Storage (ATES) purpose. To simultaneously measure distributed temperature (DTS) and distributed elastic and static strain (DAS and DSS) a fiber optic cable was installed behind the production tubing. The combined evaluation of the different fiber optic technologies evidences the potential to observe previously untraceable processes, such as changes in subsurface flow paths due to clogging. Further, the unwanted process of caving can be identified and the rise of gravel or cement observed. This allows to react on site, and subsurface risks will be considerably mitigated.

Distributed Acoustic Sensing (DAS), with its high-spatial and temporal resolution, low cost-per-sensor, and versatility, could transform how future geophysical surveys and network monitoring are performed, both on land and subsea. DAS, however, is still a relatively new sensing technology and features such as sensor response, calibration, and impact of installation environment are active areas of research. The need to compare measurements across deployments and make the data reusable by others warrants a standardization of DAS metadata in a machine-readable format. The capability to facilitate high-performance computing in a cloud environment is also highly desirable.

Long-standing metadata models developed for seismic data e.g., SEED, SAC or SEG-Y do not adapt well for DAS due to fundamental differences in sensor and data acquisition parameters. There may be thousands of measurement locations in one experiment, the installation environment can vary significantly along the cable, data acquisition equipment and parameters can be changed during an experiment or between repeated surveys. The optical fiber itself has intrinsic properties that influence measurements, and multiple fibers might be used over the course of an experiment or long-term monitoring project. We outline a proposed metadata model that could accommodate most deployment scenarios. The model can be represented in a JSON format but could be readily translated to XML and incorporated into hierarchical data formats such as HDF5 or Zarr. The model aims to enhance the interoperability of DAS data sets, maintain compatibility with more complex industry standards such as ProdML, and build reproducibility into DAS data products.

Distributed Acoustic Sensing (DAS) is used to record high-spatial resolution strain-rate data. For ground motion observation, the DAS data can be converted from strain rate to acceleration or velocity by array-based measurements with coherent plane waves. DAS provides an opportunity to map high-resolution shaking patterns near faults. We installed collocated geophones and optical fiber in Hualien City (a very seismically active area in Taiwan) from the end of January to the end of February in 2022. Earthquakes with magnitudes (Mw) between 3.2 and 5.4 have been recorded. These records illustrate the typical magnitude-distance dependence of ground-motion but also show saturation for higher magnitudes and/or at shorter distances (e.g for an earthquake of Mw 5.2 earthquake recorded at 100 km). For frequency-based analyses, clipped signals on DAS result in challenges not present in classical instruments (seismometers). The upper limit in dynamic range of seismometers results in easily identifiable trapezoidal signals. The dynamic range of DAS interrogators is limited by gauge length, sampling frequency, and wrapped phase in the interferometric phase demodulation. We observe that clipped DAS signals not only affect time series but also contaminate their spectra on all frequencies, due to the random nature of clipping in DAS—contrasting to the flat plateaus in clipped time series on seismometers. Therefore, the identification of the start and end points of clipped DAS records poses a major challenge, which we aim to resolve with a neural network. This approach enhances the efficiency for quality control of massive DAS datasets.

We introduce a Distributed Acoustic Sensing (DAS) array deployed for one month between February and March 2023 and which utilized ~25 km-long telecommunication fibers running roughly parallel and perpendicular to the Alpine Fault near Haast. A key goal of this DAS deployment and planned further work is to improve characterization of natural hazards in southern New Zealand including Alpine Fault seismicity and rockfalls, and to demonstrate the feasibility of DAS studies using dark commercial telecommunications fibers in New Zealand. DAS, with its high spatial (~1 m) and temporal (1 kHz) resolutions, can improve the detection of weak seismic sources, including low-magnitude earthquakes diagnostic of fault activity, rockfalls and avalanches in remote mountainous region, and sediment transport in river systems. The dense sensor deployment across the Alpine Fault further allows us to make high-resolution images of the fault zone including the near-surface fault geometry and velocity structure across the Alpine Fault where it crosses the sole highway in the area. The DAS acquisition was scheduled to coincide with the operation of the ~450 km-long Southern Alps Long Skinny Array (SALSA), which includes 45 mostly broadband seismometers installed 10–12 km apart within ~3 km of the fault trace, to provide new opportunities for interpreting DAS and conventional seismometer data to study seismicity and fault geometry.

Horizontal-to-vertical (H/V) spectral ratios have proven to be an inexpensive and easy tool to gain insight into local site effects. Here we attempt to extend the method to distributed acoustic sensing data by combined processing of records from an array of 26 broadband seismometers and a 1.5 km long fibre optic cable on the North-East flank of Etna volcano. Using the same processing steps as for conventional H/V computing on seismometers, we derive spectral ratios along the trajectory of the fibre.
Results show, that this approach is suited to assess the site response in higher spatial resolution than with broadband seismometers only. The H/V peak frequency distribution generally agrees with results from the array, in some parts indicating otherwise not resolved geological structures. Localized strong amplitude changes in the spectral ratio, coincide with the cable crossing known fault zones.

Distributed acoustic sensing (DAS) has an exceptional potential of high temporal and spatial resolution capable of revolutionizing geophysical ground motion measurements. Furthermore, existing telecommunication fiber-optic cables, “dark fibers”, offer cheap seismic measurement system particularly in a challenging and busy urban city, such as Istanbul. In this piece, we present results of data recorded by the first 8km segment of a 30km long dark fiber, along the Anatolian side of Istanbul. This includes recordings of the recent East Anatolian earthquake in Turkey, 6th of February 2023 with magnitude M_w 7.8, and its aftershocks.

Using the same recorded data, we additionally aim to present initial results of applying a novel workflow that combines advantages of DAS recordings with recently developed waveform imaging techniques. Our goal is to build a comprehensive initial 2D shallow shear velocity model using a trans-dimensional Bayesian inversion of dispersion curves obtained from ambient noise interferometry. Constrained by available geological and engineering knowledge, the initial 2D shear velocity model will serve as an input for preforming an ambient noise full waveform inversion (FWI), to produce a high-resolution accurate model. The result is expected to greatly increase the understanding of the city's shallow subsurface (first hundred meters) and the assessment of its seismic hazard maps.

In recent years, it has become clear that Distributed Acoustic Sensing (DAS) is capable of capturing many seismic signals, including earthquakes across a range of magnitudes. Given the vast networks of fibre optic cables beneath urban areas, there is great potential for the utilisation of existing telecommunication fibres for the purpose of seismic monitoring and hazard analysis. However, it is crucial that we first understand the capabilities and potential limitations of applying DAS in this way.

In late 2021, we collected over one month of urban DAS data beneath North-East Athens, Greece, using ~ 24 km of telecommunication fibre owned by the OTE group. This urban dataset contains a broad range of signals, including local anthropogenic activities, as well as numerous seismic events.

We build a catalogue of events observed within the DAS data, and assess differences between our DAS event catalogue and that of the regional seismic network managed by the National Observatory of Athens (NOA). This includes an analysis of to what extent sensitivity to events is influenced by event magnitude, depth, distance and azimuth. The dense spatial sampling offered by DAS facilitates the use of novel array processing methods, which can be used to detect smaller events. We determine whether the benefits of using DAS and applying such methods within a regional seismic network justify the additional costs.

We also explore the influence of the exact fibre deployment and local geological conditions on the seismic events recorded, and how this information can be considered for future DAS earthquake-monitoring experiments.

Detection of microearthquakes triggered by hydraulic fracturing using time- and frequency-domain DAS-trace stacking techniques

DOI: 10.57757/IUGG23-3068 - LINK

William Tegtow[1], *Nepomuk Boitz*[1], *Serge Shapiro*[1]
[1]*Freie Universität Berlin, Applied and Earthquake Seismology, Berlin, Germany*

In our study, we analyzed high-frequency DAS data from the FORGE EGS facility in Utah to develop signal-stacking-based detection algorithms for detecting microearthquakes triggered by hydraulic fracturing.
In terms of data structure, it is found that the DAS data considered is constituted by a high-frequency coherent noise, while microearthquakes are characterized by irregularities of this noise structure in the time- and frequency-domain.
We evaluate different preprocessing steps (e.g., different frequency-filters, trace-normalisations, coherent noise supression methods,...) with the goal of improving the SNR of stacked DAS-quantities.
It turns out that, that unlike in conventional seismic signal-stacking, the components of the background noise do not cancel each other out during summation in the time-domain. Instead, the numerous frequencies of background noise interfere with each other, which causes respective large noise peaks in sections of particularly strong constructive interference, which is an additional limiting factor of the detection threshold.
In addition, we used the Power-Spectral-Density (PSD) method, that analyzes the signals in the frequency-domain.
We show, that the background noise interference do not occur during stacking of PSD-traces, since it neglects unwanted frequency-components in the calculations before summation. However, the PSD method responds to another DAS-data characteristic noise-burst-type, that is not resolved by the stacked quantities in the dime-domain.
We present an detection algorithm, which superimposes the individual threshold exceedances of time- and frequency-domain DAS-stacks, to filter both observed noise sources from the results.
This algorithm was tested on a subset of 3-hours continuous recordings, where it captured all microearthquakes with magnitudes greater than -1.4 with a reliable true/false ratio.

Distributed Acoustic Sensing (DAS) is increasingly being used in various applications and is gaining particular importance in rail and train monitoring. When connected to an optical fiber, DAS systems create a reliable solution for continuous monitoring, that can often be used with the existing optical fiber cable infrastructure. Besides being an effective complement or even replacement for conventional rail monitoring techniques, DAS can be used as a powerful data acquisition tool for understanding different underground geological processes. In this case study, we describe the use of a DAS system connected to an optical fiber cable installed parallel to a railway for use as a distributed sensor for seismic monitoring. Railway lines in Europe form a dense network, which mostly have telecommunication FO-cable running parallel to the network. Utilizing these lines for DAS monitoring could provide an important contribution to seismic observations. This case study discusses how fiber coupling, length and spatial position of monitored object together with the DAS configuration parameters can affect the data. Within the current project, the DAS was connected to ~40 km of fiber along an L-shape track and data was acquired with a frequency of 1 kHz and a spatial sampling interval of 5 m. Due to the L-shaped track, both perpendicular and parallel incoming earthquake wave fronts to the fiber could be recorded. The acquired data clearly show the different seismic waves arrivals. Besides earthquake monitoring, DAS-equipped railway network has a great potential for near-surface characterization, allowing geological processes to be monitored in time.

Distributed Acoustic Sensing (DAS) has proven to be a valuable tool for monitoring seismic signals by providing high spatial and temporal resolution sensing of dynamic strain along fiber optic cable. Furthermore, every DAS channel records the seismic wavefield essentially synchronously at each sampled time because the interrogator samples each channel at the speed of light in the fiber. Here we investigate the capabilities of a unique, subsurface, three-dimensional array with spiral-like portions in the Sanford Underground Research Facility (SURF), the former Homestake mine, between 1250- and 1478-m depth for detecting local, regional, and teleseismic sources of ground vibrations. Our pilot array finds that DAS records high-frequency (above 5 Hz) vibration sources, including mine activities and local and regional blasting events. Furthermore, we find that fiber resting on the surface with rocks placed every meter or so may contribute to low-frequency noise that contaminates the interpretation of teleseismic waves, particularly lower-frequency S-wave arrivals. Finally, this loosely coupled cable was compared with a 200-meter section grouted in a shallow saw-cut groove for sensitivity and noise levels. This three-dimensional DAS array provides significant data for future analysis and for improving and expanding the DAS array in SURF.

With the development of Distributed Acoustic Sensing (DAS), vast telecommunication networks hold the potential to serve as dense seismic sensor arrays. As such, they may facilitate the seismic microzonation as well as exploration and monitoring of utilizable and utilized subsurface volumes at favorable costs – particularly in densely populated areas. However, numerous technical aspects remain under investigation to further maturate this innovative seismological approach.

In this study, we investigate how loops of slack fiber affect the results of passive ambient tomography, a particularly appealing exploration approach due to its low footprint. We present results obtained with DAS recordings on both purposefully installed as well as dark telecommunication optic fiber. Sledgehammer blows were recorded on an optic fiber laid out in an urban heating tunnel before and after introducing several loops of slack. Discontinuous wavefronts can be observed once the arclength of the coiled fiber exceeds the gauge length. Similar observations were made on the virtual shot gathers calculated along a 4.5 km long segment of dark fiber along a major road in the city of Berlin, Germany. We present how the results of ambient noise tomography along this linear DAS array are affected by the presence of loops of slack.

We conclude that DAS channels recording within a loop of slack can be identified during the data processing and require removal prior to final processing.

[2]Istituto Nazionale di Geofisica e Vulcanologia, Pisa, Pisa, Italy

Intensity Prediction Equations (IPEs) allow predicting the possible macroseismic intensity values at any site, as a function of epicentral distance and epicentral intensity or magnitude. In Italy, different approaches have been proposed in the last years for developing intensity attenuation models. We evaluated the performance of the five most recent IPEs valid for the Italian area comparing their predictions with intensities documented at Italian localities.

We built two different testing datasets using the data contained in the most recent versions of the Italian Parametric Earthquake Catalogue CPTI15 and of the Macroseismic Italian Database DBMI15. Dataset 1 contains 213 earthquakes with instrumental location and magnitude from 1907 to 2020, whereas Dataset 2 includes 357 events that occurred from 1117 to 1978 with the epicentral parameters estimated from macroseismic intensity data. We computed the residuals between documented intensity values and predicted intensities using the IPEs. Analyzing these results as a function of the epicentre-to-site distance, of the values of documented intensities and of the magnitude of each considered earthquake, we observed a systematic underprediction for high intensity values in both datasets for all the considered IPEs.

We also investigated the between-event residuals to highlight spatial and temporal patterns. The results did not show any particular spatial trends, but a significant temporal dependence of the results for Dataset 2, with an underestimation of the documented values for all the considered IPEs for earthquakes in the period 1000-1700.

Intensity Prediction Equations (IPEs) allow predicting the possible macroseismic intensity values at any site, as a function of epicentral distance and epicentral intensity or magnitude. In Italy, different approaches have been proposed in the last years for developing intensity attenuation models. We evaluated the performance of the five most recent IPEs valid for the Italian area comparing their predictions with intensities documented at Italian localities.

On 10 February 1871, a damaging earthquake of intensity VII EMS occurred in the former Grand Duchy of Hesse (today State of Hesse, Germany) at about 05:30 local time. The earthquake in the Upper Rhine Graben near Lorsch has been the subject of several individual investigations (e.g. Landsberg 1933; Gutdeutsch, Hammerl 1999). Within the framework of a study by the Federal Institute for Geosciences and Natural Resources, Germany (BGR), this earthquake and its aftershocks were re-investigated. 85 contemporary newspapers were evaluated, containing about 210 reports on the main earthquake. The newspaper reports were evaluated with regard to their quality according to the criteria time of writing of the report, indication of times and places, extent of macroseismic observations, eye-witness report, and grades from poor to good were assigned. In addition, archival research was conducted in Darmstadt, Strasbourg and Lorsch, which, however, yielded only a few additional sources. For 125 locations, the macroseismic observations of the main earthquake are suitable to assign intensities (≥ III). The information on the main earthquake is satisfactory, despite the Franco-Prussian War of 1870/71, which took up a large part of the newspapers' coverage at the beginning of 1871. The written record of aftershock reports is considerably worse, apart from two stronger aftershocks on 12 and 25 February 1871 (intensity VI EMS). For the period from 10 February to 19 March 1871, 55 aftershocks were identified, of which only 11 had been recorded in earthquake catalogues so far.

Historical earthquake catalogs are one of the building blocks for the assessment of seismic hazard. Despite many years of research in the archives, many earthquakes remain poorly known. New sources of informationare hence required.

Among these, historical buildings are witnesses of natural catastrophes recorded in their walls as structural disorders, repairs, and restorations. Our project aims to study past earthquakes using buildings as "stone seismometers", analyzing the seismic ground motions required to explain building repairs/disorders, or their absence. The goal is to demonstrate that archaeological characterization of post-seismic repairs on buildings can be successfully used to infer key ground motion and earthquake source characteristics of historical earthquakes.

An interdisciplinary connecting "ArChaeology, inventory of RecOnstruction, Seismology and Structural engineering" (ACROSS) is introduced to gain such knowledge. Based on innovative techniques to inventory repairs in the building archaeology; seismic input signals consistent with the seismotectonic context; digital building models implementing realistic geometry and construction materials as well as robust modelling of masonry behaviour, the ACROSS method is declined in five steps,

1. Collecting the data produced by the archaeology of the buildings and the study of historical sources.

2. Identification of damage mechanisms.

3. Definition of the digital building model used for seismic dynamic analysis.

4. Comparison of the numerical analysis results, based on previous steps, with repairs and damage mechanisms.

The method is applied to six bell towers located in the Mugello basin (Tuscany, Italy). They were affected by many historical earthquakes at least from the middle of the 16th century.

Reanalysis of historical earthquakes - case study: The great Zagreb (Croatia) 1880 earthquake

DOI: 10.57757/IUGG23-0370 - LINK

Snjezana Markusic[1]*, Ivica Sovic*[1]*, Davor Stanko*[1,2]*, Kristina Sariri*[1]
[1]*University of Zagreb- Faculty of Science, Department of Geophysics, Zagreb, Croatia*
[2]*University of Zagreb- Faculty of Geotechnical Engineering, Department of Geotechnics, Varaždin, Croatia*

In areas with medium to moderate seismicity, data on historical earthquakes are crucial in the seismic hazard assessment. Therefore, it is necessary to invest considerable effort in their verification and/or reanalysis. In March 2020, the city of Zagreb (Croatia) was hit by an earthquake of magnitude 5.5 (certainly the strongest one in the last 100 years, and perhaps the strongest after the Great Zagreb 1880 earthquake). Its analysis provided interesting information about the geodynamics of the wider Zagreb area and the Medvednica Mt. Due to these findings, the reanalysis of the Zagreb 1880 event (of magnitude 6.0, and which largely defines the seismic hazard of northwestern Croatia) proved to be a necessity. A detailed macroseismic survey was carried out again, resulting in a new intensity map. Macroseismic field modeling and comparison with empirical intensities were also done, and new geophysical measurements were performed. Based on all the collected information, it can be concluded that the 1880 earthquake was caused by a similar mechanism as in the case of the 2020 earthquake (with hypocenter location in an almost identical place). However, there is a possibility that shortly after the main earthquake there was an aftershock whose location was several kilometers western than the location of the main earthquake. These resulted in the observation of cumulative intensities (cumulative impact of the main earthquake and the strongest aftershock), which has an implication on the epicentral intensity assessment of the main earthquake.

Preliminary Shallow depth estimation by HVSR in Nova Ponte Dam

DOI: 10.57757/IUGG23-4518 - LINK

Eveline Alves Sayao[1], *Daniele Ingredy Gomes Silva*[1], *George Sand Franca*[1]
[1]*University of Brasilia, Seismological Observatory of the University of Brasilia, Brasília, Brazil*

Reservoir-Triggered Seismicity is an unnatural phenomenon, recorded concomitantly and/or after the filling of a hydroelectric plant reservoir, where previously there was no record of seismic activity. The local geology is commonly the main parameter for seismic risk analysis, although recent studies suggest that the environmental noise also plays an important role. Thus, a study of the local response analysis was carried out in the hydroelectric reservoir in Nova Ponte, in the state of Minas Gerais. This reservoir was selected because it is classified as a case of seismicity triggered by the reservoir. Data was collected with short-period and broadband seismometers in 74 stations with spacing up to 2 km. These measures were used for the calculation of the Fundamental Frequence (f0) using the Nakamura technique, from which the depth of layers could be constrained. Layer-depth values could be compared with previous seismicity and microzonation maps, as well as with geological structures. From the correlation of shallow crustal structures (such as faults) with layer-depths, it is possible that these structures can be forced by the change of direction and intensity in the field of local tensions, generating the seismicity events triggered by the reservoir.

[4]Istituto Nazionale di Geofisica e Vulcanologia, Osservatorio Vesuviano-, Naples, Italy

The goal of MATISSE is to develop and implement technologies needed for successfully detecting and quantifying hazards connected with geo-energy operations in the sub-surface, in particular induced seismicity. Anthropogenic earthquakes constitute one of the major environmental impacts associated with geo-resources exploitation. Injection induced events are an undesired dynamic rockmass response to technological processes. Water injection operations taking place during industrial activities such as oil, gas and geothermal exploitation often induce microseismic activity and, under specific circumstances, reactivate existing faults, causing events of considerable size. These industrial activities can also determine air pollution and ground water contamination.
Induced seismic hazard is evaluated through the computation and update of ground motion prediction equations, the time-lapse of velocity, attenuation and seismic noise tomography and the computation of pore pressure time variations. All these parameters are correlated with operational activities. A multi-hazard approach aimed at evaluating the adverse effects on environment caused by the sub-surface exploitation of geo-resources is developed.

This work has been supported by PRIN-2017 MATISSE project, No 20177EPPN2, funded by Italian Ministry of Education and Research.

Sources of vibrations within buildings – a case study from Johannesburg

DOI: 10.57757/IUGG23-2688 - LINK

Michelle Grobbelaar[1]
[1]*Council for Geoscience, Infrastructure and Land Use, Pretoria, South Africa*

Following the experience of significant vibrations felt in a multi-storey office, the Council for Geoscience (CGS) was requested to monitor and record the vibrations in an effort to determine its source. The vibrations on the premises were monitored by means of five temporary seismograph stations, with two in the office building and three located around the premises. From the start of the analyses, it was very clear that the sensors installed at the sites located around the premises did not record the vibrations documented by the staff within the building. The sites within the building did record the vibrations, but the vibrations did not exceed the limits of the international standards. Thus, the source of the vibration was either within the building, or very close to the building. Alternatively, the vibration may originate further from the building but may coincide with one of the natural frequencies of the building or its components thereby amplifying the vibrations. The frequency of almost 7 Hz was surprisingly low and indicated that it is unlikely caused by machinery in the building which is typically at higher frequencies.

Human-induced earthquakes in the Zagros fold-and-thrust belt, Iran

DOI: 10.57757/IUGG23-0172 - LINK

Mohammadreza Jamalreyhani[1]
[1]*University of Tehran, institude of geophysics, Tehran, Iran Islamic Republic of*

The Arabian Plate's convergence towards Eurasia led to the building of the Zagros fold-and-thrust belt. This region is one of the most seismically active mountain ranges and the greatest loci of oil and gas production on Earth. The folded and faulted sediments of Zagros contain 90% of Iran's proven hydrocarbon reservoirs including the world's second-largest gas reserves, ~17% of Earth's total. Although Zagros is known as a naturally elevated seismicity zone, the occurrence of anthropogenic earthquakes has been reported in some studies (e.g. attributed to reservoir impoundment, mining, and groundwater pumping). Here, using geodetical and seismological measurements and models, I report the different cases of induced seismicity related to operations in the gas and oil fields of Zagros. Because of the significant number of highly productive hydrocarbon reserves in Zagros, studying seismicity from a new point of view is essential in this region. However, discrimination of anthropogenic earthquakes from natural events in the Zagros is challenging, and detailed source analysis, notably the determination of the depth of earthquakes is required to discriminate.

Microseismic monitoring is an important tool to characterize the reservoirs and delineate the growth of small-scale fractures. In addition, microseismic events are crucial for describing detailed fault geometries, stress changes, and spatial-temporal evolution of seismogenic activities. Deep learning has been extensively and successfully utilized for seismic event detection and phase picking. In this work, we propose an integrated workflow of waveform denoising, event detection, and seismic phase detection based on convolutional neural network (CNN) and unsupervised clustering, aiming at identifying and classifying microseismic P- and S-wave arrivals accurately. First, we preprocess (e.g., bandpass filter) the continuous waveforms and extract statistical features, and then feed the features into CNN for deep feature extraction and learning. The microseismic phase detection is then performed using clustering from waveform feature distance (similarity), which is retrieved from both statistical features of waveforms and the deep features extracted by CNN, yielding microseismic P- and S-wave arrival detections. We use synthetic data with different source mechanisms and signal-to-noise ratios, along with field microseismic data collected from the Hengill Geothermal area in Iceland, to verify the effectiveness of the proposed workflow in detecting weak microseismic phases. The refined phase detections also improved the resolution of stacking-based source imaging.

Near-surface P-wave velocities near West Miami, Florida from quarry blast records

DOI: 10.57757/IUGG23-3599 - LINK

Stephen McNutt[1], *Elham Moslemi*[2], *Glenn Thompson*[2], *Jochen Braunmiller*[2]
[1]*University of South Florida, School of Geosciences, Saint Petersburg, USA*
[2]*University of South Florida, School of Geosciences, Tampa- Florida, USA*

We used blast records from several limestone quarries in the Miami Lakes area (25.6°N, -80.3°W) northwest of Miami, Florida to estimate shallow P-wave velocities. Prior knowledge of the velocity model was lacking. We deployed a network of ten Raspberry Shake seismometers (six 3-component, four 1-component with collocated infrasound) at residential homes in the Miami Lakes region and visually identified 1639 blasts from July 2019 to February 2023. We manually picked 1450 P-phase and air-wave arrivals using the earthquake analysis software SEISAN. We know the exact locations of 350 blasts (November 2021 to June 2022) from the Miami Dade Pilot Program report and used a subset of 200 blasts with small location uncertainties in our catalog (average difference estimate-to-true: 0.9 km). The blasts occurred in three quarry areas known as White Rock Quarry (WRQ), Cemex, and Titan. We obtained average P-wave velocities from the quarries to the seismic stations of 4.36 to 4.56 km/s via linear regression. Blasts at WRQ that were nearest to the network (2 to 7 km) allow precise picking and result in a well-constrained velocity of 4.36 km/s (R-squared 0.9). Blasts at the Cemex quarries occurred between 1 to 12 km distance and we obtained a velocity of 4.56 km/s. Blasts at the Titan quarries, 8 to 15 km from the network, result in an average near-surface P-wave velocity of 4.45 km/s. The velocities are consistent with expectations for the Pleistocene Miami Limestone that is extracted, and the small variations suggest relatively homogeneous material properties.

Several target reservoirs for Enhanced Geothermal Systems comprise hot, dry rock lithologies characterized by low matrix permeability. To improve the permeability of these formations and thus to increase the productivity of power plants, hydraulic stimulation is a common practice. For this purpose, water is injected into the reservoir, causing a local change in the effective stress state that can potentially trigger fault slip seismicity. However, seismicity can be triggered even during normal operation, as in the case of the Blue Mountain geothermal field, Nevada, USA. Here, a significant increase in microseismic activity is observed during the annual maintenance shutdown of the power plant pumps, suggesting more complex processes, such as poroelastic stress transfer, contributing to seismicity. To better understand induced seismicity and explore the underlying mechanisms, we conducted triaxial experiments on intact and faulted reservoir rock samples from the DB2 well at the Blue Mountain geothermal site and determined the effective pressure sensitivity of flow and poroelastic properties over a range of pore (<40 MPa) and confining (<50 MPa) pressure conditions. Laboratory results are compared with permeability estimates previously determined from tidal responses in idle wells, supplemented by a seismicity catalog of continuous waveforms records from 2016 to 2019 to identify seismicity migration patterns associated with operational changes. The integration of cross-scale field and laboratory data aims to improve the characterization of the permeability structure of the fault zone at Blue Mountain and to better understand the coupling between matrix permeability, fault zone hydrology and mechanical behavior.

Several target reservoirs for Enhanced Geothermal Systems comprise hot, dry rock lithologies characterized by low matrix permeability. To improve the permeability of these formations and thus to increase the productivity of power plants, hydraulic stimulation is a common practice. For this purpose, water is injected into the reservoir, causing a local change in the effective stress state that can potentially trigger fault slip seismicity. However, seismicity can be triggered even during normal operation, as in the case of the Blue Mountain geothermal field, Nevada, USA. Here, a significant increase in microseismic activity is observed during the annual maintenance shutdown of the power plant pumps, suggesting more complex processes, such as poroelastic stress transfer, contributing to seismicity. To better understand induced seismicity and explore the underlying mechanisms, we conducted triaxial experiments on intact and faulted reservoir rock samples from the DB2 well at the Blue Mountain geothermal site and determined the effective pressure sensitivity of flow and poroelastic properties over a range of pore (<40 MPa) and confining (<50 MPa) pressure conditions. Laboratory results are compared

‘Seismic monitoring of deep geothermal power plants and possible seismic impact’ – results of the joint research project SEIGER

DOI: 10.57757/IUGG23-4087 - LINK

Thomas Spies[1], *Seiger Team*[2]
[1]*Federal Institute for Geosciences and Natural Resources BGR,*
Federal Seismological Survey- Nuclear Test Ban, Hannover, Germany

During hydraulic stimulation as well as during production of deep geothermal wells induced seismicity might occur. To keep perception of seismicity and seismic risk at a low level, the use of local seismic networks is an established monitoring measure. Based on its results, parameters of operation of wells like injection pressure can be adjusted to maintain acceptable levels of seismicity.

The joint research project SEIGER was part of the 7^{th} Energy Research Programme of the German federal government. It was a collaboration of 27 scientists from universities, research institutes and private companies in Germany. Their work included automation of monitoring, optimization of the seismic research network in the area of Landau in the Upper Rhine Graben in southwestern Germany as well as the use of seismic arrays. The latter can serve as supplement or alternative in respect of local seismic networks and they can monitor a larger area than local networks. Geomechanical modelling techniques were extended to investigate possible triggering of existing faults near geothermal wells. Induced seismic events were attributed to existing fault patterns by improvement of seismic location techniques using 3D seismic velocity models. Passive and active seismic methods were adopted to reveal the shallow ground structure and to estimate the possible amplification of seismic motion (site effect) efficiently, for instance in the urban area of Munich. The data base of seismic hazard assessment of induced seismicity was improved in respect of local ground motion prediction equations, temporal changes of seismicity and consideration of site effects.

Reliability of moment tensor inversion for different seismic networks

DOI: 10.57757/IUGG23-3465 - LINK

Anna Tymińska[1], *Grzegorz Lizurek*[1]
[1]*Institute of Geophysics PAS, Seismology, Warszawa, Poland*

The work investigates the reliability of moment tensor (MT) inversion, a method used to determine the source mechanisms of earthquakes, across four different seismic networks. The study compares the synthetic test results of MT inversion for two underground mining and two artificial reservoir monitoring seismic networks with different geological settings and network geometry. For research, the time domain first P-wave onset amplitude and polarity inversion was applied in synthetic tests. The analysis was performed to assess how the consistency and accuracy of the results depend on different factors like network configuration, velocity model, events depth, focal mechanism of event, and applied noise. The work provides insights into different factors which have to be considered to enhance MT accuracy. The findings highlight the impact of the velocity model in MT inversion. Particular attention was paid for non-shearing mechanisms and the presence of non-shearing components artifacts in inversion results of shearing mechanisms. The influence of variables, especially the network geometry related to depth and data quality on the reliability of moment tensor inversion was described in the context of other considered factors.

Using deep learning and spectrograms to identify anthropogenic signals in an urban setting

DOI: 10.57757/IUGG23-4743 - LINK

Aaron A. Velasco[1], Solyma Ayala Cortez[1], Marc Garcia[1], Karplus Marianne[1], Leah April[1]
[1]University of Texas at El Paso, Earth- Environmental- and Resource Sciences, El Paso, USA

El Paso, Texas, USA, along with its sister city Ciudad Juarez, Mexico, is the second largest binational city worldwide, and lies in a tectonically-active rift zone: the Rio Grande Rift. The rate of rifting is relatively slow, ~2 mm/year, but historic earthquakes suggest the potential of large earthquakes in the area. From June 5-14, 2021, a 50 Magseis Fairfield Z-Land 5-Hz 3-component nodal seismic network was deployed to record seismic data in El Paso, Texas in order to characterize local site response in an urban setting. We utilize data from this local network to create a seismic event catalog and attempt to differentiate anthropogenic sources from naturally-occurring ones using a suite of approaches, including machine learning, time-frequency analysis, beamforming, power spectral density, and cross-correlation. We first use a deep neural network-based seismic algorithm to identify seismic arrivals from natural and possibly mining events. We then will run an optimized STA/LTA detector to identify emergent, long duration signals, typical of trains, and then compare our results to the train schedule, where train traffic is very active. Trains can also be identified using spectral and beamforming analysis. We will use these techniques to compare our results with those from the STA/LTA and machine learning approaches. Finally, we will compare the differences in energy recorded by stations with variable site surface geology, incorporating signals recorded by a permanent broadband station as a reference.

Application of machine learning methods to detection and interpretation of reservoir triggered seismicity

DOI: 10.57757/IUGG23-3286 - LINK

Jan Wiszniowski[1], *Grzegorz Lizurek*[1], *Monika Staszek*[1], *Beata Plesiewicz*[1]
[1]*Institute of Geophysics Polish Academy of Sciences, Seismology, Warszawa, Poland*

By using machine learning (ML) techniques we can increase the efficiency of the detection of clusters and mapping the rupture areas, which may be further analyzed in the context of the seismogenic process related to local tectonics and hydrogeological background. We are currently seeing an eruption in ML applications from seismology, however, reservoir-triggered seismicity (RTS) has some aspects that require an individual approach. It is mainly due to the following factors: a small number of mainly weak earthquakes limiting the training of deep learning, and seismicity often appears in unexpected areas and as swarms. Above all, such type of seismicity depends on anthropogenic and hydrological conditions. We compared deep learning methods of event detection and location, our own artificial neural network, and other similarity detection methods.
We study also the possibilities of ML in searching for seismic clusters in the time and space domain, in the interpretation of the event locations and focal mechanisms of the repeaters with the tectonics, and in dynamic relationships between hydrodynamic changes and the RTS with the use of recurrent neural networks. This work was supported by research project no. 2021/41/B/ST10/02618, funded by the National Science Centre, Poland under agreement no. UMO-2021/41/B/ST10/02618.

Seismic Waves Interpretation Program, version 5 (SWIP5), in the interpretation of reservoir-triggered seismicity.

DOI: 10.57757/IUGG23-3297 - LINK

Jan Wiszniowski[1], *Grzegorz Lizurek*[1], *Beata Plesiewicz*[1]
[1]*Institute of Geophysics Polish Academy of Sciences, Seismology, Warszawa, Poland*

The Seismic Waves Interpretation Program version 5 (SWIP5) was designed to work in seismological data processing centers, where waveforms from stations are routinely analyzed. This program aims to facilitate the routine analysis of seismic recordings such as manual and automatic phase picking, magnitude counting, focal mechanism, etc. Its development efforts were made to take into account the experience and inconveniences of using the earlier programs for the interpretation of small and induced seismicity.
The SWIP5 program is modular. It consists of a core that enables basic operations and controls modules that can be developed independently of the core, added to, or removed from the SWIP5 package during its lifetime. Thus, the user can create his own functionality of the program. The cooperation of the program with other programming environments also allows creating of extensions in Matlab and Python using ObsPy.
The program was applied to surface water reservoir-triggered and mine-induced seismicity. Cooperation with the industry requires individual interpretation (e.g. counting energy instead magnitude) and the program allows for a particular configuration. We present its application both in the routine analysis of tremors and in the study of the seismicity of these areas. Results are kept in the QuakeML database adopted for anthropogenic seismicity. Some tool allows cooperation with the EPOS Anthropogenic Hazards TCS platform EPISODES (https://tcs.ah-epos.eu/).

Underground aquifer pore fluid volume changes can induce ground deformation, detectable by seismometers as ultra-long period tilt signals. To study evolution of the hydraulic-induced ground deformation, we deployed a dense seismic array during a water pumping experiment, which withdrew groundwater from a nearby borehole well in Shuangxi, mountainous region in northern Taiwan. Nine shallow borehole broadband seismometers were installed around the pumping well within 3-40 m away. We conducted two stages of pumping tests: a step-drawdown pumping for 6 hours and later on a 24-h continuous drawdown with a constant pumping rate. In the first stage, the tilt signals from four seismometers near the pumping well show ground bulge with radially directional tilts up to 10 μrad for a drawdown of 10 meters. We interpret the bulge as the crustal response to the unloading of discharged groundwater in this relatively homogenous crust, as imaged by our reflection seismic survey. In the second stage, the tilt signals show that the spatially complex deformation patterns are related to local fracture attitudes. However, the arrayed observation can still detect the deformation enhanced by supplementary water from outside of the array after 6 hours of the continuous pumping. Our study demonstrates that dense broadband seismic arrays may offer a relatively less expensive and non-invasive tool to study temporal and spatial evolution of ground motions and groundwater flow patterns during pumping tests.

A study on induced seismic activities in southeast of Sichuan basin, China, using a local temporary network

DOI: 10.57757/IUGG23-1089 - LINK

Yang Zang[1], *Lingyuan Meng*[1], *Yanyan Han*[1]
[1]*China Earthquake Networks Center, Department of Earthquake Prediction, Beijing, China*

Induced seismic activity is becoming more and more severe in recent years near the southeast of the Sichuan basin, China, as the rapid development of Shale Gas exploitation around the local area. An M_S 5.7 earthquake occurred near Xingwen County on 16 December 2018 within the Sichuan basin which is the largest hydraulic fracturing (HF) earthquake in China to date and caused ground motions intense enough to be felt, triggered landslides, caused ￥50 million in direct economic losses, injuries, and resulted in the first fatalities. Besides, 8 $M_S \geq 5.0$ earthquakes have occurred Southeast of the Sichuan basin since 2018 supposedly either caused by HF operation or induced by wastewater disposal, where seismic activity has been low historically. The tomoDD double-difference tomography method has been applied to get the high-resolution three-dimensional structures, along with accurate locations of small earthquakes in the study area, taking advantage of 21 mobile stations' temporary network. Combined with the inverted structure and events' location data, along with the local geological structural information, we had a better understanding of the seismogenic structures of some moderate to strong earthquakes that occurred in the Sichuan basin. This study can help to establish a suitable regulation controlling system for the safe development of shale gas resources in the Southeast of the Sichuan basin as there is no one yet to date.

Seismic Hazard Assessment for Sylhet City – A Critical Review

DOI: 10.57757/IUGG23-4192 - LINK

Tahmeed Malik Al-Hussaini[1]
[1]*Bangladesh University of Engineering & Technology, Civil Engineering Department, Dhaka, Bangladesh*

Sylhet, the 4th largest city of Bangladesh, is located in the north-eastern Division of Sylhet with the highest seismic zone coefficient (Z=0.36) of the recently updated Bangladesh National Building Code (BNBC-2020). Major faults capable of generating large magnitude (M≥7) earthquakes are located within and in the vicinity of the Sylhet Division. Most prominent historical earthquake is the 1918 Magnitude 7.6 Sri Mangal Earthquake with epicenter near Sri Mangal, a town about 75 km south of Sylhet city. The east-west trending Dauki fault along the northern Bangladesh-India border and much closer to the Sylhet city, is also considered as a potential seismic source. A brief review of the research work done related to seismic sources and seismic hazard assessment for Sylhet city is presented. Critical review of published probabilistic and deterministic seismic hazard assessment studies have been performed. More recently, the effect of a large magnitude earthquake on the Dauki fault on the seismic input motion for the city of Sylhet is studied using an advanced version of the Neo-Deterministic Seismic Hazard Assessment (NDSHA) software based on higher frequency computations developed at University of Trieste, Italy. Estimated ground motions from various seismic hazard assessment studies are compared with code provisions of BNBC-2020 and neighbouring Indian building code. Differences exist and the implications of such differences will be addressed. It is concluded that the estimated ground motion may exceed code specified values and more source specific studies need to be carried out for this region.

[2]*National Institute for Earth Physics, Seismic Network, Bucharest - Magurele, Romania*
[3]*National Institute for Earth Physics, Applied Geophysics Laboratory, Bucharest - Magurele, Romania*

The Vrancea region is one of the most active intracontinental seismic areas in Europe, and main source of seismic hazard in the extra-Carpathian zone of Romania.

The frequency content of the earthquake ground motion is an important characteristic of earthquake loading for the seismic response of engineering systems.

Our study is focused on two frequency content – based parameters: the ground motion dominant frequency and the mean period T_m.

The study data consist of horizontal acceleration records of 19 earthquakes with moment magnitude ≥ 4.5: four strong earthquakes (M_w between 6.4 and 7.4) recorded with analogue instruments in the period 1977-1990, and 15 moderate-size events (M_w in the range 4.5-6.0) digitally recorded in the period 2004-2022.

To point out the relative contribution of the travel path and seismic source to the formation of the frequency content indicators, we examine separately the effects of hypocentral distance, focal depth and earthquake magnitude on the two parameters.

The analysis does not evidence a significant effect of attenuation, up to hypocentral distances of about 350 km. Likewise, no effect of source depth ($85 < h < 150$ km) is detected. The influence of earthquake magnitude is considerably stronger than the influence of distance, while the effect of site conditions is prevailing on the dominant frequency and mean period.

Finally, we develop simple empirical predictive relationships for the investigated parameters. The proposed models predict the frequency content indicators as function of magnitude, focal distance and local site conditions.

Ecole et Observatoire des sciences de la terre EOST, Strasbourg, France

Although located along the Africa - Eurasia plate boundary with about 6 mm/yr NNW-SSE convergence, Tunisia is classified as an area with moderate seismicity. However, with the large historical earthquakes, the probability of occurrence of destructive seismic events can be significant. This work aims to analyze the distribution of seismic sources, and estimate of the seismicity rate in order to establish a seismic hazard map for southern Tunisia. The estimation of the seismic behavior of a source area requires the collection of geological (tectonic and seismotectonic), historical and instrumental seismicity and geodetic data. Recent investigations in active tectonics, GPS results, seismotectonics, paleoseismology and archeoseismology provide new data that are integrated in our analysis. The first step is devoted to the construction of the homogeneous seismicity catalog in moment magnitude (Mw) from the ISC and regional catalogs. Then we integrate the available seismicity, geodetic and tectonic data into a database for the seismic hazard calculation using the CRISIS software. It is then essential to evaluate to what extent the application of methodologies and relate parameters (GMPEs) for the characterization of the seismic hazard, developed in regions with high seismicity (e.g., Italy, Turkey, Algeria, California) is valid for areas with present-day moderate seismicity comparable to Tunisia. The new results show an estimate of the return period, probability of exceedance of ground acceleration that can be injected into the Probabilistic Seismic Hazard Assessment (PSHA), and subsequently in the construction of seismic hazard and risk maps for Tunisia.

A workflow for rapid time-dependent estimates of earthquake-induced mass-movement likelihood and associated impacts in Switzerland

DOI: 10.57757/IUGG23-4930 - LINK

Carlo Cauzzi[1], *Jann-Andrea Knupfer*[1], *Stefan Wiemer*[1], *Laurentiu Danciu*[1],
Athanasios Papadopoulos[1], *Philipp Kästli*[1]
[1]*ETH Zürich, Swiss Seismological Service SED, Zürich, Switzerland*

Earthquake-induced mass movements are a substantial threat to mountainous areas in seismically active regions like the Valais, the most seismically hazardous region of Switzerland. We present a strategy to deliver rapid time-dependent predictions of mass-movement likelihoods in the Valais and their impacts on lifelines in near real-time during major earthquake sequences. We rely on the Swiss Seismic Hazard and ShakeMap frameworks and on the availability of a Swiss-specific empirical model for the prediction of seismically induced mass-movement likelihoods, and combine them with rapid earthquake shaking estimates based on short-term seismicity forecasts following a triggering seismic event. The obtained probabilities of mass-movement are spatially associated with exposed assets in the region to estimate the associated risk. This procedure can provide stakeholders with alarm levels and other decision-making tools based on risk-cost-benefit considerations for critical lifelines.

Earthquake-induced mass movements are a substantial threat to mountainous areas in seismically active regions like the Valais, the most seismically hazardous region of Switzerland. We present a strategy to deliver rapid time-dependent predictions of mass-movement likelihoods in the Valais and their impacts on lifelines in near real-time during major earthquake sequences. We rely on the Swiss Seismic Hazard and ShakeMap frameworks and on the availability of a Swiss-specific empirical model for the prediction of seismically induced mass-movement likelihoods, and combine them with rapid earthquake shaking estimates based on short-term seismicity forecasts following a triggering seismic event. The obtained probabilities of mass-movement are spatially associated with exposed assets in the region to estimate the associated risk. This procedure can provide stakeholders with alarm levels and other decision-making tools based on risk-cost-benefit considerations for critical lifelines.

ShakeMap model with deviation correction method of the 21 may 2021 M6.5 Yangbi, Yunnan, China

DOI: 10.57757/IUGG23-1173 - LINK

Kun Chen[1]
[1]*Institute of Geophysics, China Earthquake Administration, beijing, China*

On May 21, 2021, a magnitude 6.4 earthquake struck Yangbi County, Yunnan Province, China. This article used the collected 21 seismometers and the strong seismic observation data of 304 intensity meters, comprehensively considered the geological structure background, source mechanism solution and aftershock distribution of seismic faults. As a result, the ground motion intensity distribution map of this earthquake was quickly calculated using the deviation correction method of magnitude translation. The strong seismic observation data showed that the maximum horizontal peak acceleration was 720.3cm/s^2 observed at the Yangbi Observatory with an epicenter 79km away. The peak horizontal acceleration observed by 14 stations > 45cm/s^{2,}. A large number of long-range, small-scale observation records reflect the ground motion attenuation characteristics of this earthquake to a certain extent. The deviation correction method for magnitude translation used in this paper can minimize the relationship between station observations and attenuation. It is a systematic deviation of the estimates, thereby reducing the uncertainty of the estimation of ground motion parameters in areas where stations are missing.

On February 13, 2023 a significant seismic sequence with two main earthquakes of moment magnitude M_w=4.8 and M_w=5.4, occurred in the proximity of Targu Jiu city (Romania) in the lower crust. The second shock was the largest recorded ever in this area, exceeding the magnitude of 1943 event, having an estimated magnitude of M_w 5.2 for the event occurred on June 20. The second shock was followed by hundred of aftershocks detected and located by the Romanian seismic network. Immediately after the first shock the macroseismic applications implemented by National Institute for Earth Physics (NIEP) were accessed by the observers to record their experiences regarding the felt earthquakes, information used to define the macroseismic field of ground shakings. According to the macroseismic information, the epicentral intensity reached V Mercalli for the first shock and VI Mercalli for the second one, and the seismic events were felt on the extended area (up to a distance of 300 km from the epicenter). The earthquakes caused general panic, but the buildings damages were minor to moderate only. The main purpose of this paper is to investigate the macroseismic effects associated to these earthquakes using the intensity scale in use in order to evaluate the impact on the regional seismic hazard assessment, and to improve fault characterization from the studied area.

This paper was carried out within Nucleu Program SOL4RISC, supported by MCI, project no PN23360201 and AFROS Project PN-III-P4-ID-PCE-2020-1361, supported by UEFISCDI

Real-time forecast of long-period ground motions by Green's function obtained from seismic interferometry

DOI: 10.57757/IUGG23-2334 - LINK

Teppei Enari[1], *Takashi Furumura*[1]
[1]*The University of Tokyo, Earthquake Research Institute, Tokyo, Japan*

We developed a real-time forecast method for long-period (4-10 s) ground motions that appear in the distant basins when a large earthquake occurs.
The Green's functions (GFs) from the vicinity of the source to the forecast points are obtained from ambient noise interferometry, recently used by e.g. Viens et al. (2017) and Denolle et al. (2018). Since the absolute amplitude of the GFs obtained by interferometry is unknown, it is calibrated by comparing it to the earthquake waveform according to Viens and Denolle (2019).
In this study, one station in the northern Kanto, Japan was selected as the input station, and three stations in the Kanto and Nobi basins were selected as the forecast target stations. The Z-component ambient noise waveforms of the input station and the target stations were deconvolved and stacked for 1-year period to retrieve GFs. The amplitude calibration factor is calculated by comparing Fourier spectra of the forecasted and observed waveform of a Mw7 earthquake in the 4-10s period band. By convolving the obtained GFs with the input waveform of any earthquake, the long-period waveform at the target sites can be forecasted.
The method has been tested against a Fukushima-Oki earthquake (Mw7.4). The shape of forecasted waveforms and their Fourier spectra were compared to those observed at each target site and found to be in good agreement. For the practical application, application to horizontal motion of a larger earthquake, such as Tohoku-Oki Earthquake (Mw9.0), is required.

We present the status of ShakeMap-EU, an initiative initially proposed in 2018 to: (i) provide an integrated archive of ShakeMaps at the European level built on EPOS Seismology (www.epos-eu.org/tcs/seismology) services & data products and modern community software; (ii) serve as a backup to authoritative ShakeMap implementations; (iii) deliver ShakeMaps for regions where no local capability is yet available.ShakeMap-EU is accessible at the shakemapeu.ingv.it web portal since 2020, and is jointly governed by participating institutions through voluntary contributions and EC-funded projects. It has become a reliable European seismological service, integrating authoritative models and workflows consistently. The system is based on: (a) the latest version of ShakeMap®; (b) the earthquake information delivered by the EMSC (www.emsc-csem.org); (c) the earthquake shaking data distributed by ORFEUS (orfeus-eu.org/data/strong); (d) the ground motion models adopted within EFEHR (www.efehr.org) for mapping seismic hazard across Europe; (d) the official ShakeMap configurations of some of the most hazardous countries in Europe. Configuration of, and input to the system are managed via a GitHub repository that allows automatic/manual triggering and interaction by authorized users. ShakeMap-EU provides a collaboration framework and laboratory for seismological agencies to address the challenges posed by the heterogeneity of ground-shaking mapping strategies across Europe and the need to promote homogenization and best practices in this domain. ShakeMap-EU is used in research projects as the test platform for novel international collaborative research: among recent examples are the ongoing enhancements towards an evolutionary hazard information system including real-time seismicity characterization and information on earthquake-induced phenomena.

Seasonal variations of the high-frequency ground-motion site response

DOI: 10.57757/IUGG23-2888 - LINK

Annabel Haendel[1], *Marco Pilz*[1], *Fabrice Cotton*[1]
[1]*GFZ Potsdam, Seismic Hazard and Risk Dynamics, Potsdam, Germany*

Site effect assessment captures how seismic waves are amplified or attenuated on their way from bedrock depth to the surface due to the geological, geophysical and geotechnical properties of a given site. The parameter κ0 is generally utilized to describe the site attenuation at high frequencies. It is measured from the decay of amplitudes of the Fourier acceleration spectrum above the event's corner frequency. κ0 is not a simple parameter since it is influenced by e.g. the installation and housing of the sensor, high-frequency site amplification or dataset and data processing choices. This leads to a large within-station variability of the parameter.

We computed κ0 at around 200 surface-borehole station pairs of the Kik-net network in Japan and investigated its time-dependency to better understand the large within-station variability of κ0. For at least 13 sites we observe strong seasonal variations with a higher value of κ0 in winter and a lower one in summer. The difference in κ0 between summer and winter due to temperature variations is of the order of several tens of milliseconds and might therefore have an impact on the observed ground response at high frequencies.

Implications of site effect variations close to two geothermal power plants in Southwest Germany for seismic hazard assessment

DOI: 10.57757/IUGG23-3095 - LINK

Manuel Hobiger[1], *Andreas Steinberg*[1], *Thomas Spies*[1]
[1]*Federal Institute for Geosciences and Natural Resources, Federal Seismological Survey, Hannover, Germany*

The two geothermal power plants of Insheim and Landau in the Upper Rhine Graben in Southwest Germany are located close to the village of Rohrbach. Around Rohrbach, two seismic stations monitor the induced seismicity as part of a research network. One of these stations is surface station TMO54, the other one, ROTT, a combined surface and borehole station at 300 m depth.

We used passive seismic arrays to characterize the shallow underground around Rohrbach, and evaluated seismograms to assess amplification effects. Velocity profiles were obtained by inverting the obtained Love and Rayleigh wave dispersion curves and Rayleigh wave ellipticity. Around station ROTT, we found small-scale variations of the site effects. Close to a creek, we identify a 4 m thick layer of very soft sediments with shear-wave velocity below 100 m/s, which is not present at a different investigated location at a distance of only 100 m. The V_{S30} values of these two locations are about 210 m/s and 270 m/s, respectively. For other locations around Rohrbach, V_{S30} ranges between 290 m/s and 340 m/s, where the highest value corresponds to the location of station TMO54.

The seismograms of a catalog of around 3000 induced earthquakes were analyzed to verify the amplification effects. Furthermore, the assessed site effects were incorporated to improve the deterministic estimation of ground motion for several strong events in the framework of seismic hazard assessment of induced seismicity.

The installation of seismic instrumentation (broadband seismometers and/or accelerometers) in the immediate vicinity of a sensitive facility (e.g., nuclear site) may be considered a significant investment, but it provides important information to improve the reliability of site-specific seismic hazard studies. Beyond the use of these data to estimate the amplification between a local reference station and a station subject to site effect (classical SSR approach), the introduction of these local records in regional or national databases allows an analysis of the soil-response of these sensitive sites with respect to more global references. In the case of a generalized inversion technique (GIT), it is possible to determine the response of the sites of interest with respect to the same reference as the one used to constrain the inversion. Similarly, in the case of a ground motion models (GMM) derivation, it is possible to analyse the dS2S terms in order to estimate the response of sites of interest relative to the median of the prediction model. This work shows the results obtained using these approaches for two sensitive industrial sites with local instrumentation implemented over a period of about ten years, located in the South-East of France (low to moderate seismicity zone). We discuss the advantages and disadvantages of these approaches with respect to other methods used in site-specific seismic hazard estimation, as well as the minimum deployment duration required.

Probabilistic seismic hazard assessment for Attica (Greece) utilizing crustal and slab seismotectonic models

DOI: 10.57757/IUGG23-0811 - LINK

George Kaviris[1], Angelos Zymvragakis[1], Pavlos Bonatis[2], Ioannis Spingos[1], Vasilis Kapetanidis[1], Spyridon Mavroulis[1], Evelina Kotsi[1], Kostas Makropoulos[1], Efthymis Lekkas[1], Nicholas Voulgaris[1]
[1]National and Kapodistrian University of Athens, Geology and Geoenvironment, Athens, Greece
[2]Aristotle University of Thessaloniki, Geophysics, Thessaloniki, Greece

In this work, seismic hazard is evaluated for the Administrative Region of Attica (Greece) and its islands. The assessment is performed by computing Peak Ground Acceleration (PGA) and Peak Ground Velocity (PGV) values for return periods of 475 and 950 years for five separate groups to cover the entirety of the study area in detail. In addition, PGA hazard curves and Uniform Hazard Spectra (UHS), in terms of Spectral acceleration (Sa), are constructed for Athens and the capital of each island of Attica. The computational scheme contains two crustal seismotectonic models, i.e., the Euro–Mediterrenean Seismic Hazard Model 2013 (ESHM13) and its update ESHM20, and one slab seismotectonic model. Ground Motion Prediction Equations (GMPEs) proposed for the Greek territory are adopted and ranked for the crustal seismotectonic models. Each GMPE is re–constructed as a weight–specific model to account for both normal and non–normal fault plane solutions for each area source. The final results are obtained by implementing a logic tree, whose major branches are the three seismotectonic models and the minor branches the GMPEs. The latter reduces epistemic uncertainties due to the implementation of multiple logic tree paths per area source. The results indicated that seismic hazard is higher in groups that are close either to the Gulf of Corinth or the slab interface. The results could aid in the update of the building code in Attica.

Acknowledgements:The present study is co-funded by the Special Account for Research Grants (S.A.R.G.) of the National and Kapodistrian University of Athens.

The Earthquake Early Warning System Laboratory, Centre of Excellence in Disaster Mitigation & Management, Indian Institute of Technology Roorkee has developed an earthquake early warning system for Uttarakhand, a Himalayan state of the Republic of India. The Uttarakhand region is seismically active region. Large earthquakes have not occurred in this region for a long time. The return period of strong and higher magnitude earthquakes have already surpassed. So, there are likely high chances of occurrence of large earthquake in this region in the near future. The laboratory has installed ~170 sensors in the whole Uttarakhand region. They are connected through the dedicated telecommunication network. The central server is established in the laboratory. Bhukamp Disaster Early Vigilante (BhuDEV), an earthquake early warning dissemination system has been developed (here Bhukamp means earthquake). This system send the early warning on the BhuDEV mobile app and siren units installed in the Government owned buildings of the states, district emergency operation centers, state emergency operation center, schools, colleges, community centers, hospitals etc. After hearing the loud voice warnings, people can take necessary precautionary measures to save themselves and their near and dear ones. In this article, details of instrumentation, networking, processing of data and successfully issued alerts and notifications has been elaborated.

Earthquakes have caused enormous tragedies for human beings all the time, especially in this century. A more recent tragic earthquake that has already taken four more thousand of lives is still a living tragedy nowadays in the border area between Turkey and Sialia. How to avoid this kind of tragedy becomes an important mission to almost everybody who ever works in the related field, yet the challenge is too difficult to overcome. Many approaches have been tried such as to understand the vibration source and try to predict the occurring cycle or to detect the trembling signal and try to warn the surrounding area as early as possible. All of those methods are important but not easy to approach, especially for an area that is remote, underdeveloped but populated. A more effective but cheap approach must be provided as in this research, where a typical TLCD (Tuned Liquid Column Damper) device combined with a TMD (Tuned Mass Damper) device was installed in a structure to mitigate the earthquake-induced vibrations. It is found from the results of the study that for vibrations with either a long period or short period the amplitudes of the vibration can be eased by 70% in terms of the transfer function of the displacement. According to the results in this study the method is also applicable to large and heavy buildings and structures.

Shenzhen Academy of Disaster Prevention and Reduction, Shenzhen, China

The loss of earthquake disaster is mainly caused by the damage and collapse of buildings caused by ground motion, and most of civil buildings in our country are greatly affected by high-frequency ground motion. The real and accurate high-frequency ground motion is of great significance for building seismic design and earthquake damage simulation. Therefore, when evaluating the high frequency ground motion, it is particularly important to consider a variety of uncertain factors of source parameters to obtain reasonable and reliable near-field high frequency seismic motion which is more in line with the actual situation. Based on the abundant strong earthquake data and scientific research results of the Lushan earthquake, this project plans to take the Lushan earthquake affected area as the demonstration area, use the empirical Green's function method as the simulation tool. The logic tree method and statistical empirical relationship are used to comprehensively deal with various uncertainties of parameters. The non-uniform stress drop and dynamic corner frequency are introduced into the key source parameters. By establishing the sliding distribution characteristic source model considering the parameter uncertainty, the high frequency strong ground motions with higher probability of different set magnitudes are obtained. The quantifiable scheme to verify the reliability of ground motion evaluation results is tried to be given. The practical high frequency ground motion evaluation method based on real small earthquake records and parameter uncertainty is also developed. It can provide more real and reliable high frequency ground motion input for seismic design and damage simulation of buildings.

Surface seismic record estimation by borehole record correction with ambient noise

DOI: 10.57757/IUGG23-1487 - LINK

The Korea Meteorological Administration is installing new seismic stations or replacing from surface to borehole in order to improve earthquake monitoring. A borehole station has advantage of monitoring because of reducing influence of ambient noise. However, a noticeable difference for the amplitude of the seismic record between borehole and surface seismometers because of a site effect. Thus, a surface record is necessary for calculating a seismic intensity or a structure impact assessment.
To correct the data from the borehole station, we use the amplification factor from Borcherdt (1994). This amplification factor was developed to estimate a seismic record of a surface station on a soil layer from a seismic record of a surface station on a bedrock. Applying amplification factor to the borehole record underestimates of the amplification effect. Another method is calculate the transfer function through a direct comparison of borehole and surface records. The method is that the amplification effects are well reflected as they are calculated from actual records.
In this study, We proposed a model for calculating the transfer function through direct comparing of surface and borehole records. We used 20 station that temporary surface station was installed and collect earthquake event and ambient noise data. Transfer function was calculated using ambient noise of borehole and temporary surface station. We compared temporary surface record with corrected borehole record that apply transfer function and amplification factor. As a result, borehole record corrected by transfer function was estimated more similar with surface record than corrected by the amplification factor.

Our research uses a supervised machine learning algorithm (XGBoost) and strong-motion earthquake recordings from the available seismic networks in India to create a simple but powerful ground motion attenuation model for the seismically hazardous Himalayas, Indo-Gangetic plains, and Kachchh (Gujarat). Our dataset includes 564 Peak ground acceleration (PGA) and pseudo-spectral acceleration (PSA) from 145 events from 75 three-component strong-motion accelerographs in India and surrounding areas. Moment magnitudes, epicentral distances, focal depths, and Vs30 (average seismic shear-wave velocity from the surface to 30m) are our input parameters, and PGA and PSA at twenty-five periods are our output variables.

Our XGBoost model predicts ground motion using the entire dataset and a 30% randomised test dataset. Our predictability on the randomised test dataset is 0.986, and the correlation coefficient of observed and predicted PGA values for the whole dataset is 0.998. Our XGBoost ground-motion attenuation model predicts PGA and PSA datasets at four Himalayan and three Kachchh (Gujarat) stations for four events of M_w7.9, M_w6.8, M_w6.2, and M_w5.6, suggesting it would work for the Himalayas, Indo-Gangetic plains, and Kachchh (Gujarat). Another GMPE model was created using the LightGBM gradient boosting algorithm on our dataset. Finally, we compared our XGBoost model predictions to the three Himalayan GMPEs and LightGBM. The XGBoost model predicted ground motion most accurately. Period-dependent log10 output variable standard deviations range from 0.459 to 0.780. Our model predictability plots show that the current ML model can accurately predict the response spectrum for seismically high-hazard zones of India.

Smart base-isolation systems for enhanced seismic resistance in regions prone to earthquakes: A simulation study

DOI: 10.57757/IUGG23-3086 - LINK

Shima Naderi[1], Elvia J.Benedith[2], Shakila Naderi[3]
[1]*University of Applied Science, Architecture and Civil Engineering Department, Tehran, Iran Islamic Republic of*

The increasing frequency of seismic events highlights the need for improved seismic resistance in buildings. This study investigates the potential benefits of implementing smart base-isolation systems composed of base-isolation devices and Magneto-Rheological (MR) elastomers. The proposed system provides a semi-active solution to reduce the impact of earthquakes by adjusting its properties based on external stimuli. A smart base-isolation model was developed to simulate the behavior of MR elastomers accurately.

Numerical simulations were conducted on a five-story building subjected to various earthquake loadings, demonstrating the efficacy of the system in reducing floor accelerations and inter-story drifts during near-fault and long-duration earthquakes over a broad range of magnitudes. The simulation results suggest that the proposed system could be an effective way to enhance the seismic resistance of buildings and mitigate the damage caused by future seismic events.

The recent earthquake in Turkey and Syria, which occurred in February 2023, highlights the urgent need for developing effective seismic resistance strategies. Smart base-isolation systems could play a crucial role in enhancing the earthquake resistance of structures, potentially reducing the impact of seismic events on buildings and communities.

In conclusion, by adopting innovative and advanced technologies, we can effectively prepare for and mitigate the impact of earthquakes on our communities. Such proactive measures are crucial in ensuring the safety and resilience of our built environment in the face of inevitable natural disasters.

Reconstructing ground motion from past earthquakes in the Vrancea Seismic Zone using ambient seismic noise

DOI: 10.57757/IUGG23-4077 - LINK

Laura Petrescu[1], *Anica Otilia Placinta*[1], *Felix Borleanu*[1], *Mircea Radulian*[1]
[1]*National Institute for Earth Physics, Research, Magurele, Romania*

The Vrancea Seismic Zone (VSZ), located in Romania, at the sharp bend of the South-East Carpathians, is an anomalous intra-plate seismic nest releasing the largest strain in continental Europe. The last powerful earthquake in Vrancea occurred in 1977 causing significant damage to the densely populated cities in South-East Romania. The seismic infrastructure was underdeveloped at that time and the earthquake was not well-recorded locally. Using ambient seismic noise recorded at modern broadband seismic stations around Vrancea in the year 2020, and the approximate moment tensor solutions of historical earthquakes Mw>6 since 1977, we reconstruct ground motion waveforms recorded by modern seismometers decades after their occurrence. The Virtual Earthquake Approach uses empirical Green's functions from ambient noise cross-correlations between pairs of seismic stations and adds the signatures of a model earthquake: double couple mechanism, buried source and a realistic earth model in the epicentral area. Ambient noise data capture the signatures of complex subsurface structures and the 3D path effects, providing a more physically accurate representation of the seismic wavefield than purely synthetic data. Our new results demonstrate the viability of this innovative method and provide a unique opportunity for more accurate seismic hazard analysis in intra-plate seismic zones with insufficient historical data.

Recording ground motions is essential to estimate the seismic hazard. Signals from the databases are often considered to be in free-field, i.e. at the natural surface of the ground, without disturbances due to buildings or neighbouring structures. Nevertheless, the analysis of seismological networks has highlighted many installation modalities, including the coupling of seismometers, coexist. Recent studies have also shown that the installation conditions of these seismological stations can have a significant impact on the recorded motion, compared to true free-field measurements. Similarly, the effects of topography on a metric or decametric scale are poorly studied but also impact on the measurement at high frequency.

This study focuses on a qualification of the effects of installation of seismometers, through several experiments that have been set up in Greece, mainly in Cephalonia Island, chosen for its high seismicity. The influence of the coupling methods of the seismometers is studied using the experiment called "ArgoSlab", where around thirty seismometers have been installed on slab or on seismic pillar of different size and shape, outdoor or sheltered, and compared to the recordings obtained by free-field sensors. The effect of topography at the metric and decametric scale is addressed by the analysis of about fifteen seismometers installed in the hill of Krani, near Argostoli (« ArgoScarp » experiment). Finally, the analysis of soil-structure interaction is carried out by the comparison of sets of sensors in free-field (several tens of metres from the building), very close to buildings and inside buildings (basement and top floor).

A moderate earthquake struck the Cianjur Regency, in West Java, Indonesia, On 21 November 2022 at 13:21 local time, the hypocenter is 6.86°S 107.01°E depth of 11.0 km, with moment magnitude Mw 5.6 with an epicenter located about 100 km Southeast Jakarta, this event is possibly related to Cimandiri fault system. The mainshock also followed by a landslide in Cugenang District. This moderate earthquake causing extensive damage, great economic loss and casualties especially in the Rawa Cina, Cugenang, Warung Kondang and surrounding regions. The focal mechanism is dextral strike-slip fault, the faulting orientation of the mainshock was strike = 347°, dip = 83, the strike direction still controversy. In this research we want to find scientific proof of the true strike direction using aftershock analysis. The mainshock was followed by aftershocks productivity may due to complex faulting systems and relatively heterogeneous stress state in that region. We deployed 6 portable seismographs and analyzed aftershock distribution join with data of the permanent seismograph network (InaTEWS Network). The result shows that aftershock tend to distribute in the North-East direction. We also compute Peak Ground Acceleration (PGA) based on the event, Peak Ground Acceleration is 290 gal. It is relatively high acceleration of magnitude 5.6 may because of volcanic sediment amplify the ground shaking.

Topographic effects result from the influence of the surface geometry on the seismic ground motion and may generate strong amplifications, generally at hilltops and crests. They have caused significant damage during past earthquakes. They must therefore be accurately estimated even in areas of moderate seismicity. Despite numerous studies conducted over the last fifty years (Massa et al., 2014), the main parameters responsible for this phenomenon are not all identified, notably because of the difficulty in differentiating in recordings the effects of the surface geometry from others such as lithological site effects due to subsurface heterogeneities, faults, fractures and so on. Furthermore, topographic effects are mentioned in the Eurocodes8 in the form of simplified coefficients, independent of the frequency and subjected to interpretation. Therefore, topographical effects are rarely taken into account when generating site-specific response spectra. Thus, we propose to compare alternative approaches based on simple and easily accessible parameters. They are: - the FSC method developed by Maufroy et al. (2015) and - SuperTau method developed by the BRGM based on the previous French seismic regulation (PS92). Here, we firstly compare the estimations of topographical amplification computed by both methods for two case studies: the district of Menton in the south of France and the Dembeni site on the island of Mayotte. In a second step, we discuss how to consider topographic effects at these two sites in the associated response spectra.

Assessing the seismic hazard of the Campotosto Lake dams by near-source ground motion simulations

DOI: 10.57757/IUGG23-3259 - LINK

Luca Moratto[1], Marco Santulin[1], Alberto Tamaro[1], Angela Saraò[1], Alessandro Vuan[1], Alessandro Rebez[1]
[1]National Institute of Oceanography and Applied Geophysics - OGS, Center for Seismological Research, Trieste, Italy

We apply the Probabilistic Seismic Hazard Analysis (PSHA) and Physics-Based Simulations (PBS) to compute the ground motion for three dams in the Campotosto area (Central Italy). The dams, which confine an artificial water reservoir feeding hydroelectric power plants, are located in an active seismic zone between the areas that experienced the 2009 L'Aquila and 2016–2017 Central Italy seismic sequences. The probabilistic disaggregation estimated for a return period of 2475 years, corresponding to the collapse limit state for critical facilities, indicates that the most dangerous fault is associated with a maximum magnitude of 6.75±0.25 within a distance of 10 km. This fault is used in PBS to emulate the Maximum Credible Earthquake scenario. To capture the ground motion variability, we input a pseudo-dynamic source model to encompass spatial and temporal variations in the slip, rise time and rupture propagation, heavily affecting the near-source ground motion. Indeed, the ground motion above the rupture volume is mainly influenced by the epistemic uncertainties of rupture nucleation and slip distribution. The computed broadband seismograms are consistent with the near-source shaking recorded during the 2016 M_W 6.6 Norcia earthquake and constrain the upper bound of the simulated ground motion at specific sites. Our modelling reinforces the importance of considering vertical ground motion near the source in seismic design. It could reach shaking values comparable to or larger than those of the horizontal components. This approach can be applied in other areas with high seismic hazard to evaluate the seismic safety of existing critical facilities.

Region Specific Ground-motion Prediction Equations for Small to Moderate Shallow Crustal Seismicity in Uttarakhand Himalaya

DOI: 10.57757/IUGG23-1505 - [LINK](#)

Nitin Sharma[1], M. Ravi Kumar[1], R. Vijaya Raghavan[1], K. Satish Kumar[1]
[1]CSIR-National Geophysical Research Institute, Seimology, Hyderabad, India

Ground-motion prediction equations (GMPEs) are a reliable and fast means to predict strong ground motions. They play a crucial role in estimating seismic hazards levels for any region using either deterministic or probabilistic approaches. Due to the scarcity of ground motion data, GMPEs are assumed ergodic and are borrowed from the host region and adapted/adjusted to target regions which results in large aleatory variabilities. Development of regional GMPEs is challenging because it requires a lot of data to constrain the uncertainties, which are not always available. Therefore, we developed region specific GMPEs for shallow crustal earthquakes in western Himalayan region. We used data from 80 earthquakes in the magnitude (M_L) range of 3 and 5.5 recorded at 27 strong motion seismic stations. The hypocentral distance range varies between 5km and 262km. We developed GMPEs for PGV, PGA and PGD values employing a non-linear mixed effect regression. We developed the reference model by initially considering the source and medium effects and subsequently incorporate the Vs-30 values to account for the local site effects and obtain the final model. It is emphasized that the model is able to explain the observations even with limited number of parameters without making the equation too complex, which otherwise becomes difficult for engineers to implement while evaluating seismic hazard. The residual values at each station are analyzed to quantify the role of epistemic uncertainties. The inter-event and intra-event residuals are also analyzed with respect to magnitude and distance.

Site specific seismic Hazard analysis for central Alborz basin

DOI: 10.57757/IUGG23-2218 - LINK

Saeid Soltani[1], *Ebrahim Haghshenas*[2]
[1]*IIEES/ ISTerre, Seismic Risk, Tehran, Iran Islamic Republic of*
[2]*IIEES, Geotechnical Engineering, Tehran, Iran Islamic Republic of*

The Alborz mountain range is part of the Alpine–Himalayan seismic belt that passes through northern Iran and considers as an active region within the Arabia–Eurasia collision zone. The southern part of central Alborz is the most populous regions in Iran, home to over 15 million people. The central Alborz basin is located between longitudes 50.5°E and 51.5°E, and includes the cities of Tehran and Karaj, as well as approximately 50 smaller developing towns. While the empirical site amplification from temporary seismological network deployed in the region revealed significant ground motion amplification over a broad frequency range from 0.3 Hz to 4 Hz in Tehran, amplification in Karaj is moderate. Recently, Soltani et al. (2023) derived a 3D velocity model of the Tehran's basin using active and passive surface waves methods. This velocity model exhibit a very thick sedimentary cover on the southern part of the Tehran basin with a seismic bedrock depth around 900 m, consistently with a fundamental resonance frequency of about 0.4 Hz. In this study the same peak observed in the southern part of Karaj shows the possibility of deep alluvium structure in this area and suburb towns. We extend the existing model to the west and south in order to develop the first site specific hazard map in central Alborz. With total amount of data include 19 temporary seismic, 800 single station measurements, 38 passive and over 50 active array measurements we also develop the first 3D shear wave velocity for central Alborz basin.

The Alborz mountain range is part of the Alpine–Himalayan seismic belt that passes through northern Iran and considers as an active region within the Arabia–Eurasia collision zone. The southern part of central Alborz is the most populous regions in Iran, home to over 15 million people. The central Alborz basin is located between longitudes 50.5°E and 51.5°E, and includes the cities of Tehran and Karaj, as well as approximately 50 smaller developing towns. While the empirical site amplification from temporary seismological network deployed in the region revealed significant ground motion amplification over a broad frequency range from 0.3 Hz to 4 Hz in Tehran, amplification in Karaj is moderate. Recently, Soltani et al. (2023) derived a 3D velocity model of the Tehran's basin using active and passive surface waves methods. This velocity model exhibit a very thick sedimentary cover on the southern part of the Tehran basin with a seismic bedrock depth around 900 m, consistently with a fundamental resonance frequency of about 0.4 Hz. We present our contribution to the UCIS4EQ (Urgent Computing Integrated Services for EarthQuakes) workflow, where multiple realizations of ground motion fields are required to account for input and model uncertainties under emergency conditions. Our focus is on the initialization and update of an ensemble of scenarios describing the seismic source uncertainty for Urgent Computing (UC) applications.

We propose an algorithm to reduce the size of the ensemble for UC usability, such that source uncertainty can be propagated to shaking with numerical simulations of a subset of seismic sources while preserving the key statistical properties of the full ensemble. As target distribution representing the expected shaking variability in the earthquake-hit area, we use the distribution of PGA (Peak Ground Acceleration) values predicted by local GMPEs (Ground Motion Prediction Equations) for the seismic scenarios in the full ensemble. Besides accounting for source uncertainty, our approach estimates the uncertainty associated with the ensemble sampling method and available GMPEs. By sampling an increasing number of seismic scenarios from the full ensemble, the algorithm estimates the total variability of the subsample and assesses its convergence to the target distribution.

Besides reducing the time and cost of shaking scenarios simulations, it also enables the retrieval of probabilistic shakemaps, an evolved version of the traditional shakemaps where each POI (Point Of Interest) is assigned a probability distribution of PGA values quantifying both the source and GMPEs uncertainty.

Our algorithm is written in Python and makes use of OpenQuake and Shakemap libraries.

Ground motion models (GMMs) are one of the fundamental ingredients of probabilistic seismic hazard analysis (PSHA). Usually, to capture epistemic uncertainties, alternative GMMs are adopted in PSHA applications and merged using the traditional logic tree/ensemble approach. In such approach, each GMM needs a weight that reflects its relative importance. Data-driven methods suggest using weights based on the performance of GMMs against actual observations (i.e. ground motion recordings). The classical score used for this performance evaluation is the average sample log-likelihood (LLH). LLH is defined as the average log-likelihood score of the GMM against observations. In this work, we introduce a method to move from the classical average to a weighted average, i.e., an average where the weights are not equal to 1/N (where N is the total number of observations). We based our weighted average on fragility functions, to assign the performance of the GMM according to the target infrastructure type that will be the subject of the PSHA (e.g., masonry buildings, earth dams, bridges, levees). We compared the proposed approach with the classical LLH using instrumental data from Central Italy. Finally, we discussed the advantage and drawbacks of our approach in PSHA applications and outcomes. Applying this novel approach provides different values of the relative importance of each analysed GMM and changes ranking positions in a meaningful and repeatable manner.

A forecast of long-period ground motions by using a convolutional neural network

DOI: 10.57757/IUGG23-2681 - LINK

Daiki Taya[1], Furumura Takashi[1]
[1]The University of Tokyo, Earthquake Research Institute, Bunkyo-ku- Tokyo, Japan

In this study, we propose a CNN based forecast model for long-period (2-10 s) ground motions that occur in large basins of populated cities in large earthquakes.

The CNN model consists of seven convolutional layers with ReLU activation functions, which are flattened and finally fed to a fully connected layer. The forecast takes as input the 5-min waveforms of two horizontal components at five stations near the epicenter and outputs a velocity response spectrum for periods between 0.1 to 100 s. 56 inland earthquakes with Mw>4.5 and 5 earthquakes with Mw>6 that occurred in central Japan during 2004-2010 were used as training data. To compensate for the lack of larger events, 3D-FDM simulation of seismic waves for Mw>6 earthquakes were conducted. Using these training datasets, the CNN was trained for 50 epochs.

Using the trained model, we examined the forecast performance for 11 earthquakes with Mw>4.5 occurred in the same area during 2011-2022. The model performance is evaluated by the average of the ratio of the sum of forecasted spectrum to observed values over period of 1 to 10 seconds. The result shows a good performance (0.9-1.2) except for the largest earthquake (Mw6.7), which was out of the data set. This problem was solved by adding numerical simulated waveforms for large earthquakes to the training dataset, which improved forecast performance for all events, including Mw6.7. Hybrid learning using observation and simulation data is considered to be an effective technique to compensate for the small amount of large earthquake data.

[1]German Research Centre for Geosciences, Section 2.6 Seismic Hazard and Risk Dynamics, Potsdam, Germany
[2]German Research Center for Geosciences, Section 2.6 Seismic Hazard and Risk Dynamics, Potsdam, Germany

Turkey is home to two major fault systems, which make it the most seismically active country in Europe. These are namely the right-lateral North Anatolian Fault (NAF) and left-lateral East-Anatolian Fault Systems (EAF) with lengths of á ~1500 km and ~500 km, respectively. They are capable of producing moderate to large earthquakes in given time periods. Starting from the most western point, on 26 September 2019, a sequence of moderate-sized events (Mw 5.8; Mw 4.1 and Mw 4.7) occured on the Main Marmara Fault (westernmost branch of NAFZ). Only 3 years later the central part of the NAF produced (after a silence of 23 years) a Mw 6.0 earthquake close to Düzce province (Gölyaka Earthquake), the region that was hit in 1999 by an Mw 7.2 event that killed more than 700 people. Most recently, the EAF ruptured in three different segments and generated two large earthquakes just within a time-span of 9 hours: Mw 7.8 (Pazarcik Earthquake) and Mw 7.7 (Elbistan Earthquake). The events have killed so far over 45,000 people and are the most destructive earthquakes with the highest death toll in modern times. Based on the dense Turkish seismic network (AFAD-TADAS), we analyze the strong ground motions in terms of their spatial variation and realize azimuthal variations in peak-ground acceleration (PGA) and peak-ground velocity (PGV) with regard to rupture propagation, coupled with evidence of strong velocity pulses. This trend has been interpreted as directivity effects which systematically occur on sites located towards rupture propagation.

Soil liquefaction is causing great damage to the structure during earthquake. Many soil liquefaction damage reduction methods have limitations in their application to existing structures. Therefore, in this study, a 1-G Shaking table test was performed, a soil liquefaction damage reduction method applicable to existing structures was studied using the grouting method. The effect of reducing structural damage was analyzed according to various grouting mixing ratios, and the separation distance between the grouting chemical injection point and the structure. As a result of the analysis, when the ground was reinforced by applying the grouting method, the structure settlement was smaller than when the ground was not reinforced, and the mixing ratio with the smallest settlement was 0.45. In addition, when there was no separation distance between the structure and the grouting chemical injection point, it was confirmed that the effect of reducing structural damage was the greatest. This study will be used as basic data for the development of grouting methods applicable to existing structures..

Multi-hazard insurance premium rate-making using earthquake-tsunami risk model for the district of Tofino, British Columbia, Canada

DOI: 10.57757/IUGG23-0237 - LINK

Katsuichiro Goda[1]
[1]*Western University, Earth Science, London, Canada*

Canada has a high likelihood of facing significant earthquake threats in the future. On the Pacific coast, southwestern British Columbia is exposed to significant seismic and tsunami hazards, originating from the Cascadia subduction zone. A scenario of particular concern to residents and emergency managers is the future occurrence of a moment magnitude (M) 9.0-class megathrust earthquake in Cascadia. The scientific challenges in assessing the potential hazards and risks for residents and assets in British Columbia include the characterization of the earthquake rupture of future major Cascadia events and the modeling of their multi-hazard cascades which affect the population and built environment simultaneously. To protect households from potential financial risks due to the Cascadia events via insurance, it is necessary to quantify the monetary losses from ground shaking and tsunami. However, such multi-hazard risk assessments have not be carried out to determine insurance premiums. This study presents a probabilistic earthquake-tsunami loss model for the Cascadia subduction zone by focusing on the District of Tofino, British Columbia. The earthquake occurrence and rupture models for the Cascadia subduction zone are developed by incorporating the time-dependency of earthquake occurrence and by adopting a stochastic source modeling approach, which allows considering heterogeneous earthquake slip distributions. The results produce single-hazard and multi-hazard exceedance probability loss curves for strong motions and tsunamis. These loss curves can be used for determining the insurance rates for the multi-hazard risk coverage for Tofino. The results are beneficial for providing more risk financing options via insurance against the future Cascadia events.

State Key Laboratory of Geohazard Prevention and Geoenvironment Protection, Chengdu, China

The Main Recent Fault (MRF) is an important boundary fault that accommodates the oblique convergence motion between the Arabian and Eurasian plates. Several large earthquakes including the 1909 mb 7.4, 1958-1963 three events with magnitude larger than Mw 6.0, and the 2006 Mw 6.1 earthquake had ruptured the central segment of MRF. However, there is no large earthquakes occurred in the northwest segment in the past hundred years. In this study, the interseismic surface deformation along the northwest segment of the MRF has been firstly mapped from the Synthetic Aperture Radar (SAR) images observed by the Sentinel-1 satellite. Then, the ununiformed fault slip rate, locking and deficit are estimated based on the measured interseismic surface deformation. The results show that the fault slip rate varies from 1.0 mm/yr to 4.0 mm/yr in the northwest segment of MRF. In addition, the fault locking pattern is very complex in this segment, and 13 sub-segments could be divided based on the fault locking distribution and historical earthquakes. A seismicity gab is identified from the historical earthquakes, which has a good space consistency with the transition between the significant shallow locking and deep free creeping zones. According to the potential seismic magnitude and estimated recurrence interval, it is found that five segments are approaching the end of their interseismic recurrence interval.

Effect mechanism of earthquake-induced landslide surge on collapse resistance of RC bridge structure

DOI: 10.57757/IUGG23-0203 - LINK

Shuai Huang[1]
[1]*National Institute of Natural Hazards- Ministry of Emergency Management, National Institute of Natural Hazards- Ministry of Emergency Management, Beijing, China*

In order to determine the collapse mechanism of seismic landslide surge induced bridge structure, this paper takes reinforced concrete bridge as the research object, an analytical calculation model of surge wave considering the impact characteristics of sliding body on fluid was established; on this basis, the influence law of sliding body velocity of entry into the water on surge propagation is analyzed, the wave pressure distribution law of landslide surge along RC bridge structure is studied, the plastic hinge development sequence of RC bridge structure under landslide surge is determined, and the influence mechanism of earthquake landslide surge on the anti-collapse performance of bridge structure is revealed. The findings show that considering the impact force of sliding body on water, the velocity of entry into the water has great influence on the wave height and the height climbing on RC bridge structure, but has no obvious influence on the shape of the surge wave; the influence of surge on RC bridge structure is related to the initial wave height, and the influence degree of surge on bridge structure increases with the increase of the first wave height; the vertical wave force caused by landslide surge could not be ignored, which will lead to the change of the emergence time of different plastic hinges in RC bridge structure, and in the anti-collapse analysis of RC bridge structure, the formation of all plastic hinges of RC bridge cannot only be taken as the discriminant index, but the ultimate curvature of each plastic hinge should be combined to judge.

An analysis of elements at risk using weight of evidence method for seismically induced landslide susceptibility

DOI: 10.57757/IUGG23-0549 - LINK

Nimrah Khalid[1], *Mashal Riaz*[1]
[1]*Bundesanstalt für Geowissenschaften und Rohstoffe Federal Institute for Geosciences and Natural Resources BGR, Promoting Natural Disaster Resilience NADIR in Pakistan, Islamabad, Pakistan*

Landslide is the most prominent and frequently occurring geophysical phenomenon in the Northern and Northwestern region of Pakistan and Azad Jammu & Kashmir. The landslides are not only induced by topographic and environmental factors, but the seismically induced events are frequently experienced. This research uses the technique on theorem of Bayer's bivariate statistics (weight of evidence) which predicts the events geographically using the input layers and the relationship of event. The use of Landsat (30m) data along with the integration of statistical method is an effective tool in predicting the landslide prone areas. A statistical relationship between event of landslide and factors was studied and analyzed using this method. Subsequently a prediction of the occurrence of the spatial location of the landslide event was established successfully. The relationship of distribution of landslide and factors layers was calculated using the statistical methods which enabled to predict the landslides zones in different areas. The methodology adopted resulted in success rate of 80% indicating that the landslide events occurred in 18% area with the prediction rate of 70% using Area under Cover (AUC). The result of the assessment will be integrated into exposure and risk analysis for landslide taking population, infrastructure and other key elements at risk for determining a holistic risk picture of the study area.

We present the activities of EMERSITO, the INGV emergency task force with skills and experience in seismic response studies and in seismic microzonation, in the follow-up to the Mw 5.5 (ML 5.7) earthquake of November 9, 2022 06:07:25 UTC localized in the Costa Marchigiana Pesarese area (Central Italy).

Based on geological information and damage estimates in the epicentral areas, EMERSITO focused its intervention in Ancona, the capital of Regione Marche, located at about 40 km south of the epicenter. This city is located in an area characterized by a remarkable seismic hazard, as evidenced by the extensive damage of the 1972 earthquakes (Mw up to 4.7), with part of the urban territory susceptible to landslide phenomena.

A temporary seismic network consisting of 11 seismic stations equipped with velocimeter and accelerometer was installed in different urban areas of the city, acquiring data in continuous mode for about 4 months. The analysis of ambient vibrations and aftershock recordings collected by the network suggests a variability of the site response depending on the outcropping lithologies. The peak frequencies from spectral ratio analysis range between 1 and 3 Hz for 6 stations, while other stations are characterized by peak frequencies between 3.5 and 9.5 Hz. The H/V noise spectral ratios do not show peaks with very high amplitudes (< 3), likely indicating the lack of strong impedance contrasts, at least in the shallow part of the subsoil.

Performance of different ANNs on microtremor H/V peak classification

DOI: 10.57757/IUGG23-4665 - LINK

Miriana Di Donato[1], *Silvia Castellaro*[1]
[1]*University of Bologna, Physics and Astronomy, Bologna, Italy*

Recent applications of ANN, in geophysics include, e.g., the prediction of site amplification response (Boudghene Stambouli et al. 2017; Salameh et al. 2017; Bergamo et al. 2021) and seismic site classification (Zhao et al. 2006; Ghasemi et al. 2009; Ji et al. 2021; Díaz et al. 2022).

The identification of significant peaks on microtremor H/V curves is traditionally assessed by means of the popular SESAME (2004) criteria, which, however, cannot discriminate between the stratigraphic and non-stratigraphic nature of them.

Non-stratigraphic peaks are typically caused by machineries acting in the proximity of the recording station or result as an effect of vibrations induced from large nearby structures. Low frequency artefacts perturb the noise wavefield up to large distances from the source.

The frequency of anthropogenic peak can also coincide or be very close to the frequency of a peak of stratigraphic origin. H/V curves are easily affected by artefacts that it is mandatory to discriminate them, before attempting any interpretation of the H/V curve itself.

Given the worldwide extended use of H/V methods in seismic microzonation, being altered about the possible presence of non-stratigraphic peaks is important to avoid misclassifications of soil resonance frequencies or wrong stratigraphic interpretations when the H/V method is combined with, e.g., surface wave multichannel methods to achieve Vs profiles. Given the limited capability of standard techniques in this type of signal classification, we decided to explore the performance of different NNs in this sorting problem consisting in discriminating between stratigraphic and non-stratigraphic features in microtremor signals.

Vs30 and depth to bedrock estimates using H/V measurements and geology and slope approach in the Oslo area, Norway

DOI: 10.57757/IUGG23-2718 - LINK

<u>Federica Ghione</u>[1,2], *Andreas Köhler*[1,3], *Anna Maria Dichiarante*[1], *Volker Oye*[1,2]

Common practice to perform a seismic hazard study at regional scale is to present the results computed at bedrock condition. Site effects are usually not considered because soil information is not always available. Our goal is to carry out a site-specific seismic hazard study for the city of Oslo (Norway), conducting a microzonation study that will include site effects. More specifically, the average shear wave velocity in the upper 30 meters of the ground (Vs30) has been introduced to become the main attribute to characterize the soil type and subsequently account for soil type related seismic amplification

Vs30 values are missing for the Oslo area, therefore we propose an integrated approach that estimates Vs30 using Horizontal-to-Vertical Spectral Ratio (HVSR) method together with a combined geology-slope approach. A campaign with 61 H/V measurements has been performed between March and June 2021 at specific locations in Oslo. Topographic slope attributed are extracted from DTM10 (10 m horizontal-scale resolution Digital Terrain Model), provided by the Norwegian Mapping Authority agency. In addition to resulting Vs30 values, this method will also allow us to define depth to bedrock estimates, which will likely be required for an updated Eurocode. This procedure is applied in specific areas in the Oslo urban environment that are susceptible to site effect amplifications.

[3]National Institute For Earth Physics, Seismology and Lithospheric Structure, Magurele, Romania

The paper investigates the seismic response of highly populated, or economically important areas for a wide range of magnitudes. Intermediate-depth earthquakes occurring in Vrancea, Romania, are the most hazardous seismic source at national scale, affecting large parts of the country territory.

The sites are representatively chosen for their different local soil conditions given by the specific rocks content, layering and impedance contrast in the shear waves velocity. The response at each site is investigated through spectral composition by comparing the processed elastic response spectra of strong earthquakes to those of medium or smaller magnitude. For this reason pairs of collocated (depth, hypocentral distance) stronger-lower magnitude are chosen, in order to minimize the effect of propagation path. The local amplification in correspondence to the site characteristics is highlighted and spectral ratios for each of the pairs of elastic response spectra were performed, in order to correlate the specific site's behavior to the local effects as influenced by the seismic source strength.

The influence of local conditions is enhanced by the increase in magnitude, as higher magnitudes probably set in motion thicker package layers, and an increase in the soil predominant period values may be encountered. For some other areas the oscillating period corresponding to the peak spectral amplitude is rather stable, hence the local site conditions are primarily controlling this behavior. The stabilization tendency for the spectral content offers the possibility to predict the characteristic values even for the future strong seismic events in these areas.

Mount Cameroon is an active volcano located at the junction of the continental and oceanic part of the Cameroon Volcanic Line and has so far experienced effusive, explosive and hydromagmatic type eruptions. During the last century, it experienced 7 major volcanic eruptions, including the March-April 1999 eruption. Interring in its premonitory phase, it released a series of precursor earthquakes, one of which occurred on March 28 at 8:12 PM with a moment magnitude of only 5.1. Against all odds, this earthquake caused very significant damage in certain buildings in Buea, a city located at the foot of the volcano. The fact that a building by its typology and the nature of its materials has a natural frequency which when it is on a ground vibrating at equal frequency will get into resonance, bring us to think that it is possible to face here a phenomenon of site effects. In this work, we bring a beginning of explanations to this unequal distribution of the damage observed in the buildings of the city of Buea. Using the ambient noise recordings carried out between January 2005 and February 2007 by the stations of the project ''Cameroon Broadband Seismic Experiment'' in the area of Mount Cameroon and its surroundings we proceeded to the computation of the horizontal to vertical spectra ratio. This reveals that seismic waves are amplified at some specific frequencies.

Keywords: Mount Cameroon, site effects, HVSR, ambient noise and seismic waves.

Are the homogenous micro-zones really homogeneous from a seismic response point of view?

DOI: 10.57757/IUGG23-3412 - LINK

The seismic shaking of an area is strongly affected by the local geological stratigraphy (e.g., the presence of soft soils overlaying a rocky bedrock). The so-called local site effects are deeply investigated in literature and must be considered for the estimation of seismic effects on structures and urban planning. Thus, the Seismic Microzonation (SM), is the process aimed at identifying and mapping, usually at urban/municipality scale and in terms of ground shaking parameters and susceptibility to ground instabilities, the subsoil local response in a given area. The Italian Guidelines for Seismic Microzoning have been in used in Italy since 2008. According to these guidelines a modular approach that identify three levels of details is proposed. The aim of the level is to identify areas characterized by the same seismic response. These areas are called homogenous micro-zones in the seismic perspective and are defined on the basis of available data, new geological/geomorphological surveys, and low-cost geophysical measurements. These homogenous micro-zones in the seismic perspective are expected to have the same resonance frequency and to amplify the seismic input more or less in the same way. In this work the results of a single station seismic noise campaign carried out in the city of Trieste (Italy) are presented. Thirty three measurements, analysed according to the horizontal to vertical spectral ratio (H/V) techniques, were carried out over four different homogenous micro-zones in the seismic perspective. Results show that the hypothesis of homogenous micro-zone in the seismic perspective is not always verified.

Thus, the Seismic Microzonation (SM), is the process aimed at identifying and mapping, usually at urban/municipality scale and in terms of ground shaking parameters and susceptibility to ground instabilities, the subsoil local response in a given area. The Guidelines for Seismic Microzoning (SM) have been in used in Italy since 2008. According to them a modular approach that identify three levels of details is proposed. The second level aims at quantify the seismic amplification (Amplification Factor, AF) of the different homogenous micro-zones in the seismic perspective (identified in the SM first level) and eventually re-shape these areas. To do that a simplified approach (tables of correspondences called seismic abacuses and available for the whole national territory) is proposed for areas that can be schematised thanks to a 1D subsoil model (e.g., alluvial plain). In this work the results of the comparison between the AF values retrieved from national abacuses applied in the Friuli Venezia Giulia (Italy) plain municipalities and those from numerical simulations are presented. In general, AFs from abacus are lower excepted for the area of Pordenone municipality or some isolated sites. Moreover, the response spectra derived applying the AF values (both from abacuses and numerical simulations) have been compared to those proposed by the Italian Building regulation. These last in most cases underestimate the soil effects.

The Kathmandu Valley is filled with soft lake sediments with a thickness of more than 650 m in the central part. The thicknesses of these sediments vary a lot in the valley. The site amplification characteristics of this sedimentary structure resulted in significant damage during past large earthquakes. During the 2015 Gorkha, Nepal earthquake (M_w 7.8, 8.2 km), the observed damage was concentrated in a few areas which can be considered as a function of the local site effect. Constructing the shallow to deep sedimentary velocity model is important to reduce damage by future earthquakes. Strong motion seismometers have been installed at 14 sites in the Kathmandu Valley. The deep velocity structures under these stations have been discussed with strong ground motion records. In this study, we explored 18 sites using small-sized equilateral triangle microtremor arrays at the strong motion stations and in the damage-concentrated area of the 2015 Gorkha earthquake to understand the shallow S-wave velocity structure. We applied the spatial autocorrelation method to the observed microtremor records and obtained the phase velocities of the Rayleigh wave between 5 to 30 Hz. The phase velocities in the high-frequency range differ at sites on bedrock, lacustrine sediments, and fluvial sediments. We inverted S-wave velocities from these phase velocities dispersion curves using genetic algorithms. The average S-wave velocities of the upper 30 m of each site calculated from the estimated velocity structures are 130-400 m/s and correspond with geological formation classification.

This work presents a preliminary study focused on a site characterization conducted in the Bucharest area using a dense temporary seismic array. The aim is to obtain a more in-depth understanding of the subsurface velocity structure at the location of a seismic station that is a part of the Romanian Seismic Network (RSN), and located in the wider central region of Bucharest, at Cutitul de Argint. The seismic data were collected using 15 newly released Atom-3C wireless seismographs. The Atom-3C seismograph is a turnkey solution for assessing subsurface conditions, much quicker than traditional land seismic surveys, requiring no spread cables. It has separate acquisition units with 24-bit A/D conversion, GPS-controlled timing, 4 GB of internal data storage, a configurable sample rate and batteries that can last up to 70 hours before they need to be recharged. The seismic surveys were performed adopting different array geometries, such as an L-shaped array for microtremor array measurements (MAM) and a linear array for multichannel analysis of surface waves (MASW). We show some preliminary results in terms of the shear wave velocity (Vs) structure for each active and passive survey, and for the combination of active and passive survey data along the linear configuration of the array.

We present the results from a temporary seismic network of 24 stations installed in the urban area of Rome (Italy) from January 10, 2021 until April 08, 2021, with the aim of studying the city's urban subsoil through analysis based on ambient seismic noise.

Rome is the largest Italian city (with about three million people) with a history of art, architecture and culture that influenced the world and dating back almost 3000 years ago. The city retains a monumental heritage characterized by a high fragility due to its age. Both the high number of inhabitants and the fragility of its monuments make the city particularly vulnerable to possible earthquakes, even if the seismic hazard of the area is considered as moderate.

The continuous recordings from the network allowed the use of ambient seismic noise to derive spectral ratios at sites located in different geological and lithological contexts. Moreover, signals from regional earthquakes were surprisingly well recorded despite the high anthropic noise-level, showing a clear areal variability referable to site effects. In this case, we also benefit from a low-noise period due to the partial lockdown for COVID pandemia. Interferometric analyses based on seismic noise cross-correlation of acquired data, show that it is possible to reconstruct the surface waves at station pairs in the frequency band between 0.2 and 1 Hz. It is then possible to perform a 3D velocity model through Ambient Noise Tomography to characterize shapes, thickness and properties of different geological/lithological units of the subsoil of the city.

Site effects associated with local geological conditions constitute an important part of any seismic hazard assessment. The horizontal-to-vertical spectral ratio (HVSR or H/V) was carried out in pre-selected major KZN cities, including: Pietermaritzburg (PMB), Port Shepstone (PS), Richards Bay (RB) and St Lucia (SL). A total of 159 sites across all four cities were surveyed. The data collection was in line with the recommendations of the Site Effects assessment using Ambient Excitations (SESAME) by the European Commission 2004. The Tromino 3G instrument was placed on the ground facing the North direction at all sites. The sampling frequency was set at f = 128 Hz. The recording duration was set at 30 minutes to be able to record a minimum expected fundamental frequency (f_0) of 0.5 Hz. The collected data was processed using a software called Grilla for a window length of 30 minutes, window size of 20 seconds, a Triangular window smoothing type and 5% sampling frequency rate of 128 Hz. The H/V response curves were obtained for each site. The H/V response curves obtained were used to estimate the predominant frequency and peak amplitude (lower bound approximation of site amplification) for each site. The spatial distribution of obtained predominant frequencies for sites close to soft sediments (closed to the sea) were generally higher compared to those inland (rocky areas). The predominant frequency was classified to 5 identified classes which varied although majority of the sites are between 0.5 Hz and 50 Hz across all cities.

GNSS observations are available at a high temporal frequency and accuracy. Their usefulness in capturing coseismic deformation during large earthquakes is here tested. Precise point positioning (PPP) is used to compute coordinate time series for 61 stations of the TUSAGA-Aktif network during the 2023 earthquake sequence. Precise GPS, GLONASS and Galileo satellite orbits and clock offsets computed by GFZ are used, together with GNSS observations with a sampling interval of 1 s, 30 s or 5 minutes. The difference between postseismic and averaged preseismic coordinates provides displacement time series with generally centimeter-level horizontal accuracy. The time series computed with a 5 minute temporal sampling rate captures coseismic displacement greater than nominal uncertainties at a few stations, peaking at ~30 cm on either side of the East Anatolian Fault (EAF) for the largest shock (Mw 7.8) and at ~4 m for the Mw 7.5 event, which occurred on a fault very close to station EKZ1. The time series computed every 30 s and (using interpolated satellite clock offsets) every 1 s show no evidence of significant pre/post-seismic creeping. Estimates of coseismic displacement from PPP GNSS solutions are compared with those from seismology and InSAR. Although the sensitivity of these solutions with high sampling rates can only capture significant coseismic displacement, this work serves as a preliminary exploration of a future system for automatic near-real-time imaging of surface displacement during ruptures capable of detecting complex sequences of ruptures and creeping.

The Mw 7.8 Turkey-Syria earthquake occurred on 6th of February 2023 in central Turkey at a depth of 20 km on the active East Anatolian Fault. Approximately 9 minutes later, a ML 3.1 earthquake occurred ~1500 km away in the Vrancea Seismic Zone in Romania, at 22 km depth. Ground motion records from broadband seismic stations located near the epicentre of the Vrancea earthquake clearly show high-frequency P-wave arrivals recorded during the passage of long period, high amplitude Rayleigh waves radiated by the Turkey-Syria earthquake. We interpret this observation as first-hand evidence of dynamic triggering of crustal earthquakes in Vrancea by remote earthquakes. We estimate the probability that this particular event is a random occurrence based on the observed local seismicity rates. Furthermore, using information such as epicentral distance, hypocentral depth and source mechanism for the Vrancea earthquake, we model the transient stress tensor on the fault plane due to the passage of Rayleigh waves at discrete periods.

Centre for Ocean- River- Atmosphere and Land Sciences, Kharagpur, India

Earthquakes are natural disasters that are severe threat to the society and infrastructure. Recent devastating earthquakes in Türkiye has reminded us about the need for an urgent mapping the vulnerable areas, and associated risks. Recent earthquakes in Himalayas such as 2005 (M~7.6) Kashmir earthquake, Sikkim Himalaya earthquake (Sept. 2011, M~6.9), Gorkha earthquake (April 2015, M~7.8), and a more recent earthquake of 9th Nov. 2022 (M~6.6) have severely affected the whole region. We use seismological, remote sending and GIS techniques besides the multi-criteria decision models (MCDM) and artificial neural network (ANN) to estimate the earthquake risk, and coping capacity in the Himalayan region. We have integrated the Analytical Hierarchy Process (AHP), the Criteria Importance Through Intercriteria Correlation (CRITIC), and the ANN to estimate the earthquake risk. The AHP-Entropy method have been used to evaluate earthquake vulnerability and disaster coping capacity, whereas ANN have been used to estimate the earthquake probability. Our results indicate that more than 31% of the area may be under high to very high risk, whereas about 27% of the population and 31% of the infrastructure may be at high to very high risk due to seismic hazard in the region. The estimated receiver operating characteristic curve with an area under the curve ~0.83 indicates that results are reliable. The study would provide important inputs to the agencies to develop disaster mitigation strategies during any future earthquake in the region.

Velocity structure and its relation to the seismicity of Datong windows region in Shanxi Province, North China

DOI: 10.57757/IUGG23-0416 - LINK

Meiqing Song[1], Xia Wang[1]
[1]Earthquake Administration of Shanxi Province, Earthquake prediction research centre, Taiyuan, China

On October 19, 1989, a surface-wave magnitude M_S 5.9 earthquake occurred in Datong-Yanggao,Two M_S 5.8 and M_S 5.6 earthquakes occurred on March 26, 1991, and November 1, 1999, respectively. Since then,aftershocks continued in this region, and this region serves as a "window" of aftershocks, it is at the junction of Datong Basin and Liulengshan Range in the northern part of Shanxi Graben, China.A high-resolution 3D P-wave velocity model of the crust was obtained with double-difference tomography using seismic data from July 2009 to June 2019. The results show that the Datong-Yanggao seismic sequence occurred, in general, within the NE rupture zone of the earthquake swarm of 1989. The sequences from 1991 and 1999 were in the rupture zone of 1989. A series of earthquakes developed in this region,which is at the intersection of multiple faults and a low-velocity anomaly of the intermediate-lower crust. A gap of length of about 3 km was found at the southwest end of the NE Dawangcun Fault. Several moderate earthquake ruptures failed to break through it. It was speculated that it may be a potential asperity. There is a possibility of an earthquake with magnitude about 5 from the gap. The relocation results for the earthquakes show that intensive small-earthquake events in Datong Window corresponding to moderate-to-strong earthquakes in Shanxi Graben were highly clustered horizontally and distributed vertically in a column.In contrast, when there was no moderate earthquake after intensive small-earthquake events, the spatial distribution of these events was scattered and dispersive.

The recent sequence of devastating earthquakes in Turkey (February 6, 2023) coincided with the activation of the Râmnicu Sarat seismic zone in Romania. After the first 7.8 R earthquake in Central Turkey, 2023-02-06 01:17:36.1 UTC, a 4.6 R earthquake followed shortly in Romania, 2023-02-06 01:26:20.6 UTC. This magnitude activated the NIEP (National Institute of Earth Physics) seismic warning system. On 13.02.2023, the Targu Jiu area was reactivated with a 5.2R earthquake, 2023-02-13 14:58:07.4 UTC, and three aftershocks. Shortly after, an earthquake with magnitude 4R also occurred in Croatia, 2023-02-13 15:18:49.5 UTC. Are we witnessing an overlap of events in which earthquakes with a magnitude above 7R in Turkey have reactivated other seismic zones? Before these events, we recorded an anomaly in the temperature and level of the Black Sea by the monitoring stations in Mangalia and Constanta. An analysis of the level of the Black Sea and the Mediterranean Sea before and after the devastating earthquakes in Turkey does not indicate the production of a tsunami, although an alert of this type was generated in Italy, but it shows a movement of a large volume of water that can induce seismicity. The analysis of these overlapping events in a short period of time does not indicate a direct interdependence, but an indirect one is possible. The large displacements of the faults as a result of the devastating earthquakes in Turkey can push the Black Sea microplate and affect the Vrancea seismic zone characterized by deep earthquakes with large effects.

Method for Determining the Accumulated Potential Energy of Deformation in Lithospheric Plates, Blocks of the Earth's Crust and Earthquake Prediction

DOI: 10.57757/IUGG23-3019 - LINK

Mher Aghalovyan[1], *Lenser Aghalovyan*[1], *Lusine Ghulghazaryan*[1]
[1]*Institute of Mechanics of National Academy of Sciences of the Republic of Armenia, Department of Thin-Walled Systems, Yerevan, Armenia*

In the middle of the XX century, it was found that in earthquake-prone zones of the Earth, significant deformations (displacement of points) of the Earth's crust occur before the occurrence of earthquakes. The problem arose (Rikitake) – knowing the structure of the terrain (layering, elastic, temperature characteristics) and measuring data of the displacements of the points of the facial surface or the surface located at some depth from the facial surface (to exclude the influence of atmospheric phenomena) of the Earth, what measurement data by inclinometers and strainmeters placed there, determine the stress-strain state (SSS) of the corresponding block of the Earth and track its change over time. Thus, it is possible to trace the entire process of earthquake preparation. This process covers two stages: slow (quasi-static), fast-flowing, jump-like (dynamic: Foreshock, Earthquake, Aftershock). The first stage can last for decades.

The authors have found solutions to the corresponding quasi-static and dynamic 3D problems of elasticity theory for a layered package of isotropic plates. The accumulated potential energy of deformation is determined by the values of stresses and displacements (deformations) found. Based on regular measurements, it is possible to trace the process of accumulation of critical potential energy, leading to global destruction – an earthquake.

Based on the obtained solution, mathematically computational programs have been created to determine the potential energy of deformations and analyze SSS. According to the well-known Gutenberg-Richter formula, the magnitude of the expected earthquake is estimated. The approach can be applied in all earthquake-prone zones of the Earth.

Time-dependency of the b-value across earthquake sequences (SUlzQUAjvbl5rAE9UCvSAY8Arp3b)

DOI: 10.57757/IUGG23-4692 - LINK

Andres Hernandez[1], Philippe Gueguen[1]
[1]Universite Grenoble Alpes, ISTerre, Grenoble, France

The b-value, obtained from the Gutenberg-Richter distribution, is a critical parameter for probabilistic seismic hazard assessment. It describes the relative ratio of small to large earthquakes in a scale-free population. However, in earthquake sequences, this parameter experiences variations not accounted for in conventional seismic hazard models. Therefore, understanding the nature and impact of these variations is crucial, particularly in regions with high seismicity or prone to aftershock sequences that can last several days, weeks, or even months. Different techniques and methods are commonly employed to estimate the b-value, but they could introduce uncertainties or biases in the calculation. The amount of data used to estimate this parameter is critical in its estimation. Despite this, the behavior of the b-value during aftershock sequences and its influence on seismicity rates are not yet fully understood. In this study, we evaluate how various factors in an aftershock sequence can influence the estimation of the b-value by analyzing real and synthetic data from different contexts and characteristics. We aim to enhance the accuracy of probabilistic seismic hazard assessments and advance our knowledge of earthquake physics. The findings of this study have significant implications for improving the understanding of earthquake processes and hazard assessments. Accurate estimates of the b-value are essential for forecasting earthquake activity and assessing potential risks in seismically active regions.

Flexible estimation approach of background stress changes based on the rate- and state-friction seismicity model

DOI: 10.57757/IUGG23-2459 - LINK

Takaki Iwata[1]
[1]*Prefectural University of Hiroshima, Comprehensive Education Center, Hiroshima, Japan*

The seismicity model based on the rate- and state-dependent friction law [Dieterich, 1994, JGR] (Dieterich model) can follow the Omori-Utsu (power-law) decay. Because the exponent (p-value) of the Omori-Utsu decay has some variety in actual aftershock sequences, the assumption of the constant background stress rate, which is often used in the Dieterich model, is inadequate. For this variety, Dieterich [1994] proposed stress increase with the logarithm of time. However, the temporal evolution of an actual aftershock sequence may have a complex feature. For such complexity, this study proposes an approach of a flexible estimation of background stress changes to fit an examined aftershock sequence.

The outline of the approach is as follows: The seismicity is decomposed into two components; a cluster and background seismicity. These two components are represented by the ETAS and Dieterich models, respectively. For the Dieterich model, the stress rates are represented with a step function; they are assumed to be constant between the occurrence time of two successive earthquakes and can vary at each occurrence time with a smoothness constraint. The stress rates, the weight of the smoothness constraint, and the parameters of the ETAS and Dieterich models are estimated simultaneously with the Markov chain Monte Carlo method in the framework of the full Bayesian approach. As a demonstration, this approach was applied to the aftershock sequence of the 1995 Kobe earthquake, and the stress rate similar to a logarithmic change with a complex feature was estimated.

Institute of Physics of Earth's Interior and Geohazards- UNESCO Chair on Solid Earth Physics and Geohazards Risk Reduction, Heraklion, Greece

Seismic swarms frequently exhibit spatial migration of event hypocenters with time attributed to external aseismic stresses, such as pore-fluid pressure diffusion, aseismic creep, or magmatic intrusion, that may act as the driving mechanism. Earthquake diffusion, observed in such cases, can be highly anisotropic, occurring preferentially along fractures and zones of weakness over wide spatial and temporal scales. The efficient modelling of the complex spatiotemporal evolution of seismic swarms, hence, represents a major challenge. Herein, we develop a stochastic model, based on the Continuous Time Random Walk (CTRW) theory, to map the spatiotemporal evolution of seismic swarms. Within this context, we describe the spatiotemporal evolution of seismicity with an appropriate master equation and the time-fractional diffusion equation (FDE). The applicability of the model is demonstrated in two seismic swarms associated with pore-fluid pressure diffusion, the 2001 Agios Ioannis (Corinth Rift) and the 2014 Long Valley Caldera (California) swarms. The analysis shows anomalous earthquake diffusion, with diffusion exponents less than unity in both cases, as well as broad waiting-times distributions with asymptotic power-law behavior. Such properties are intrinsic characteristics of a sub-diffusive process. Furthermore, the asymptotic solution of the FDE can successfully capture the main features of earthquake progression in time and space. Overall, the results demonstrate that the CTRW model can efficiently be used to map earthquake diffusion in seismic swarms.

In slow-moving fault systems, where the observation time window is very small compared with the long seismic cycles and the seismicity rate, the variability of the seismic hazard can be high. To assess this variability, this study develops a PSHA (Probabilistic Seismic Hazard Assessment) using synthetic seismicity. The selected site is the Eastern Betics Shear Zone (EBSZ), located at the SE of the Iberian Peninsula, the most active seismic region of Spain. The synthetic seismicity consists of a million-year catalog generated with the physics-based earthquake simulator RSQSim. This is based on a complex fault model containing slip rates, rakes, and friction properties of major faults. From the synthetic earthquake catalog, we obtained 20 sub-catalogs with random temporal distribution. The duration of each catalog was selected to replicate the historical and instrumental record used in the evaluation of the seismic hazard in the EBSZ, i.e. a thousand years. The results show a significant variability in the maximum magnitude, the slope of the Frequency Magnitude Distribution (FMD) and the annual rate of earthquakes for the different sub-catalogs. This variation has a direct effect on the seismic hazard curves calculated using the PSHA software R-CRISIS. Each return period has associated several PGA (Peak Ground Acceleration) for the different scenarios, showing the dependence of the estimated seismic hazard on the time window analysed.

The advances in machine learning have led to a renewed interest in the challenging task of earthquake prediction. Analysis of the global geomagnetic field has shown promising results in earthquake precursors study. However, applying this approach to develop an accurate earthquake prediction model has proven to be difficult partly because of the sophistication of the data. This study presents an Automatic Machine Learning (AutoML) technique for handling complex geomagnetic data and imbalance earthquake events by selecting the optimum machine learning model through Bayesian optimization. Global geomagnetic data and earthquake events that occurred between 1970 to 2020 was used in this study. Sampling techniques approaches showed promising results to solve the problem of an imbalance dataset, essential features were extracted and a multi-class classification model was developed using sample dataset that consists of oversampling and undersampling data. Sample and Raw models were developed from two different dataset, the result shows that the Sample model selects Neural Network as the best model, outperforms Raw model. Raw model shows 94% accuracy, 44% Matthew Correlation Coefficient (MCC) and 0% F-1 score, meanwhile Sample model shows 89% accuracy, 86% MCC and 89% F1-score. It is found that a neural network multi-class classification model addresses the solution to earthquake prediction challenges when using global geomagnetic data.

Forecast of maximum amplitude immediately after a large earthquake through the extreme value analysis of continuous seismogram

DOI: 10.57757/IUGG23-0542 - LINK

Kaoru Sawazaki[1]
[1]*NIED, Earthquake and Tsunami Research Division, Tsukuba- Ibaraki, Japan*

As aftershock activity follows the Omori-Utsu law and is at the highest in the early lapse times, detection capability of earthquakes becomes poor at this stage. At the same time, however, it is strongly desired to provide reliable aftershock forecast as early as possible. To overcome this issue, we have proposed to use interval maximum amplitude (IMA) of a continuous seismogram, instead of the deteriorated earthquake catalog, and apply the extreme value statistics. Theoretically, the IMAs follow the non-stationary Frechet distribution, which is one of the three extreme value distributions. By applying the maximum likelihood method to the IMAs, we can estimate parameters that control the NFD. Using the Markov Chain Monte Carlo (MCMC) method, we can randomly select the NFD parameter sets from the posterior distribution. These parameter sets can be used to compute the number and probability that the IMA exceeds arbitrary values within assigned time periods. We applied this method to seismograms of four aftershock sequences occurred in Japan. Among them, only one case (Mw6.2 largest foreshock of the 2016 Kumamoto earthquake) was followed by the larger event (Mw7.0 mainshock of the Kumamoto earthquake) 28 hours later. Statistical analysis of one hour IMAs showed very high probabilities of further large amplitude after the Kumamoto foreshock, while relatively small probabilities for other three aftershock sequences.

The U.S. Geological Survey releases aftershock forecasts following large (M5+) earthquakes in the U.S. and associated territories. Forecasts show the expected number (and range) of aftershocks in a specified area for various magnitude thresholds and time durations. Forecasts are released using a product template that contains tables and text. Visualizing these aftershock forecasts can more effectively communicate this information. In particular, we seek to identify which forecast visualizations (including maps) can serve a variety of user groups. First, we hold workshops with members of target user groups, including emergency managers, civil engineers, critical infrastructure operators, science communicators, and the media. In these workshops, users perform activities to elicit specific user needs on the dimensions of aftershock forecast information needed by their role (informational needs) and how this information would optimally be displayed (product needs). We then develop a suite of forecast graphics and maps based on these informational and product needs. We furthermore plan to run a user experiment to test a subset of these forecast products. In the experiment, participants from these target groups will use different forecast products to perform decision-making tasks based on common use cases of aftershock forecasts. Such an experiment can reveal the characteristics of forecast products that can effectively communicate the forecast across user groups. Workshops and experiments will be held with participants from the U.S., Mexico, and El Salvador to identify cross-cultural components of effective forecast communication. We present preliminary results from several user workshops and discuss next steps in the research agenda.

Characteristics of b-value and envelope of MS ≥ 6 earthquake sequence with foreshocks in Chinese mainland

DOI: 10.57757/IUGG23-1320 - LINK

Mengyu Xie[1], *Yue Wang*[1], *Yawei Ma*[1], *Lingyuan Meng*[1]

Large earthquakes are usually followed by decaying aftershocks. In some cases, a large earthquake is followed by even larger earthquakes. To estimate seismic hazards of earthquake sequence, it's necessary to make sure whether the mainshock has already happened. There is no effective method yet to distinguish foreshocks from aftershocks. However, statistical analysis may tell us some useful clues. Since 2010, 35 $M_S \geq 6.0$ earthquakes have occurred in Chinese mainland, of which 6 $M_S \geq 6.0$ earthquakes have foreshocks with magnitude larger than 5. Based on foreshock traffic light system (Gulia and Wiemer, 2019), *b*-positive (van der Elst, 2021) and envelope method (Lippiello *et al.*, 2021), we explored the temporal characteristics of *b*-value in the Gutenberg–Richter law and the envelope of foreshocks with $M_S \geq 5.0$ by using catalog and waveform of 6 $M_S \geq 6.0$ earthquake sequences and tried to propose a real-time foreshock classification method. The preliminary studies show that the temporal variation and the envelope may be useful to recognize foreshocks. For example, the evolution of foreshock sequence of 2019 Yangbi M_S 6.4 earthquake can be divided into 3 periods. In the first and second period, the foreshock sequence varied like common aftershock sequence, but the seismicity rate unusually accelerated preceding the mainshock. And the study of waveform of $M_S \geq 5.0$ foreshocks before Yangbi M_S 6.4 earthquake shows that the envelope presents an atypical sawtooth profile and the corresponding β-value is smaller than 0.4 which is much lower than the normal value.

[3]National Institute for Earth Physics, Seismology and Lithosphere Structure, Magurele, Romania

The purpose of this study consists in the analyses of statistical parameters of seismicity, the released energy and the Coulomb stress change (deltaCFS) for the ongoing sequence started with a foreshock (Mw4.8) on 13.02.2023, followed by the main shock on 14.02.2023 (Mw5.4) in Romania, Targu Jiu area. The maximum macroseismic intensity reported in the area was VII MSK and PGA 0.15g. The seismic sequence (700+ events in less than one week) occurred at the contact between the Getic Depression, to the south, and the Southern Carpathians, to the north. The epicentral area is tectonically complex with various types of faults. The sequence may have activated normal faults, oriented WSW - ENE, as indicated by the focal mechanisms. Another sequence was recorded in the study area in 2012 (Radulian et al., 2014), with smaller earthquakes (maximum magnitude of 4.5), which occurred on reverse faults located south-east from the current sequence. The aftershocks will continue in the following months, but their number will decrease over time, according to the Omori law, which fits the preliminary data well. The seismic energy release will be computed using Mw resulted from the seismic moment (Mo). Aftershocks distribution and macroseismic maps will be used to improve fault characterization, which will facilitate the estimation of deltaCFS. We may tackle as well the debated question of a possible connection between the major earthquakes in Turkey on February 5 and 6 and the crustal earthquakes in Romania.

This paper was financed by Nucleu PN23360201 SOL4RISC, and AFROS PN-III-P4-ID-PCE-2020-1361.

The seismic activity of Romania, is part of the Mediterranean-Asian seismic belt. It follows the chain of young mountains starting from Southern Europe, continuing through Turkey, Iran, the Caucasus and Central Asia. In this framework, the identification of series of strong earthquakes allows, through the application of advanced techniques of artificial intelligence and data science, to extract certain patterns of global, regional and local seismicity. Our paper has as final goal the forecast of crustal and subcrustal strong events in Romania, considering the application of advanced AI and Data Science techniques to extract hidden patterns from data sets, and to provide analytical arguments for the correlation of seismicity. We review seismic patterns involving adjacent tectonic plates, the migration of earthquakes along plate boundaries, but also intraplate seismic models involving Romanian crustal and subcrustal earthquakes. In the continent-continent collision between Eurasia, Africa and India we remarked not only eastward but also a westward migration such as the one in the years 2020-2022 originated in Indonesia and Myanmar then moving from Hindukush, Iran, East Turkey, Syria, West Turkey, and ended with a moderate intermediate depth earthquake in Vrancea. A much higher velocity migration of two month only started in the Indian Ocean, Indonesia, Iran and culminated in Turkey-Syria with the Mw 7.8 event of February 6, 2023. The highly debated connection of the crustal seismic activity from Vrancea and Targu Jiu, Romania, starting immediately after the 7.5 earthquake from Turkey (5.02.2023) will be discussed. Work funded by SOL4RISC Nucleu and AFROS Projects

Self-similarity of active fault systems and distribution of earthquake epicenters

DOI: 10.57757/IUGG23-0383 - LINK

Anastasia Nekrasova[1], *Ivan Tsvetkov*[1,2], *Vladimir Kossobokov*[1,3]
[1]*Institute of Earthquake Prediction Theory and Mathematical Geophysics- Russian Academy of Science, IEPT RaS, Moscow, Russian Federation*
[2]*Russian Technological Universit, MIReA, Moscow, Russian Federation*
[3]*International Seismic Safety Organisation, ISsO, Arsita, Italy*

We analyse the fractal dimension of active fault systems versus the fractal dimension of earthquake epicentres in the Greater Caucasus, Altai-Sayan, Baikal, and Kamchatka Regions. In particular, for each of the four regional systems of active faults the box counting and correlation dimensions, D_0 and D_2, were computed based on the Active Faults of Eurasia Database (Bachmanov et al., 2017). The data permit distinguishing fractal dimensionality of the vertical, lateral and extensional displacement faults. The obtained regional values of D_0 and D_2 are compared to the regional distributions of the C-coefficient of the Unified Scaling Law for Earthquakes (USLE) that compliments to the a- and b-values of the classical Gutenberg-Richter relationship with C, an estimate of fractal dimension of earthquake epicentres at a given site. We used maps of the USLE coefficients in the selected four regions from (Kossobokov&Nekrasova 2018a, 2018b; Nekrasova&Kossobokov 2020, 2022).

The comparison of fractal dimensions of active faults and earthquake epicentres has shown up higher values of dimensionality of regional fault systems, which evidence, presumably, a large number of locked, dormant, silent, or seismically inactive faults. From the viewpoint of instrumental/operational seismology, the tectonically active systems of blocks-and-faults reflect fragmentation of the lithosphere with a significant redundancy.

In addition, for each of the four regions a cross-comparison of D_0 and D_2 versus C at the site of the observed largest earthquake is performed.

The study is carried on in the framework of the Russian State Task of Scientific Research Works of IEPT RAS (0143-2019-0006).

Modelling out-of-plane signals in the global Earth: first results from a flat subducted slab

DOI: 10.57757/IUGG23-4917 - LINK

Angelo Pisconti[1], Christine Thomas[1]
[1]WWU Muenster, Institut für Geophysik, Muenster, Germany

Traditional seismology often assumes that seismic waves travel through the mantle within the great circle path, in the sagittal plane along sources and receivers. Since the 1990s it was already known that subducted oceanic lithosphere in the mantle could laterally deviate the path of seismic signals, which arrive with different angles (out-of-plane) at an array of sensors at teleseismic distances. Detecting these signals with array processing techniques, and the consequent back-projection, have provided valuable information on the location of both ancient and actual subducted slabs. This hypothesis was also tested with synthetic seismograms by a study which carried out a preliminary modelling of P-to-P out-of-plane signals, providing hints on "how and where to look".

In this work, we conduct 3D waveform modelling to assess to which extent these out-of-plane signals can be used to infer physical properties of the slabs (e.g., thickness, age, orientation, velocity, and density contrasts). An important aspect to investigate is how these slabs affect the waveforms of both P and S out-of-plane signals, and if these signals are influenced by the presence of oceanic crust. Conversions P-to-S and S-to-P could provide additional constraints. Although still at the initial stage, the experiment shown here provides already useful information for more complex and realistic setting which will be tested in the future.

Furthermore, LLSVPs will be tested as cause for deep mantle out-of-plane signals generated from their boundaries.

Mapping strong topography of mantle reflectors beneath southern Asia

DOI: 10.57757/IUGG23-4918 - LINK

Federica Rochira[1], *Christine Thomas*[1]
[1]*WWU-Muenster, Institut für Geophysik, Münster, Germany*

Precursor signals are a powerful tool for mapping topography of mantle discontinuities, which are sensitive to the thermal and compositional structure of the mantle. The depth of mantle discontinuities is usually estimated by using the measured differential traveltime between the main arrival and its precursor. However, this method ignores potential travel path deviations which influence the traveltime of precursor signals. Here, we use a different approach that considers directivity information as well as traveltime measurements to infer depth and location of mantle reflectors. We analyze events occurred in Indonesia and recorded at the broadband stations in Germany and in Morocco. Applying seismic array techniques, we measure slowness, backazimuth and traveltime of the signals and use this information to back-project to the point of reflection. We observe SS and PP reflections located beneath southern Asia and in the depth range between 100 and 1600 km in the Earth's mantle. SS reflections show a clear trend from shallower depths (< 500 km) in the south-eastern part of the studied area to lower depths (> 500 km) in the north-western part. The location of most of deeper reflectors seems to correlate with a high velocity anomaly located beneath south Asia. Instead, shallower reflectors correlate with a prominent low velocity anomaly beneath south-east Asia. We compare the observed data with synthetic seismograms using 3D waveform modelling and test which structures in the Earth's mantle (i.e., plume and slab) can potentially generate the strong topography observed in the data.

We investigate the effect of various geodynamic contexts on the reflection coefficients of P and S waves underside reflections off the 410 km discontinuity, to detect seismic anisotropy at this boundary layer due to textures above and below the 410 discontinuity. We calculate the reflection coefficient for P and SH underside reflections using velocity perturbations resulting from aligned minerals above and below the 410 km discontinuity for different deformation scenarios. Our results indicate some differences in amplitude and polarity patterns of reflection coefficients of different deformation geometries in the case of an anisotropic olivine layer above an anisotropic wadsleyite layer, compared to the case of anisotropic olivine above an isotropic wadsleyite layer. The amplitudes of P and SH waves are influenced by the effect of angle of incidence and polarity reversal of the P and S waves are observed for some deformation styles. Furthermore, water content of wadsleyite plays an important role in creating the polarity reversal of the waves compared to the case of dry wadsleyite.

We investigate the effect of various geodynamic contexts on the reflection coefficients of P and S waves underside reflections off the 410 km discontinuity, to detect seismic anisotropy at this boundary layer due to textures above and below the 410 discontinuity. We calculate the reflection coefficient for P and SH underside reflections using velocity perturbations resulting from aligned minerals above and below the 410 km discontinuity for different deformation scenarios. Our results indicate some differences in amplitude and polarity patterns of reflection coefficients of different deformation geometries in the case of an anisotropic olivine layer above an anisotropic wadsleyite layer, compared to the case of anisotropic olivine above an isotropic wadsleyite layer. The amplitudes of P and SH waves are influenced by the effect of angle of incidence and polarity reversal of the P and S waves are observed for some deformation styles. Furthermore, water content of wadsleyite plays an important role in creating the polarity reversal of the waves compared to the case of dry wadsleyite.

Source parameters of recent moderate-size subcrustal earthquakes of Vrancea region (Romania)

DOI: 10.57757/IUGG23-0431 - LINK

Luminita Angela Ardeleanu[1], *Cristian Neagoe*[2], *Andreea Craiu*[2], *Marius Craiu*[2], *Anca Otilia Placinta*[1]

The seismic source parameters (seismic moment, corner frequency, source radius, static stress drop) of the moderate-size earthquakes which occurred in the Vrancea intermediate-depth seismogenic region (Romania) during the last decade are determined using the spectral analysis of S waves. The events have moment magnitudes between 4.5 and 5.7, and depths in the range from 90 to 150 km.

The observed data are high-quality horizontal acceleration records. The source parameters are estimated from the displacement amplitude spectrum of the transverse component of motion. The duration of the time windows selected to compute the Fourier spectra is dependent on the earthquake magnitude and amplitude behaviour of the wave trains.

The relations between the retrieved source parameters have also been examined. The trend of increasing fault radius with increasing seismic moment is visible, however the slope of the regression line is clearly smaller than the theoretical value predicted by the theory of self-similarity. The tendency of decreasing stress drop with decreasing seismic moment can also be noticed, which might indicate a deviation from the constant stress drop model.

The source parameters estimation of the intense seismic sequence recorded in 2023 - Tg. Jiu area, Romania

DOI: 10.57757/IUGG23-4457 - [LINK]

Andreea Craiu[1], Iulia Ștefania Armeanu[2,3], Marius Craiu[1], Alexandru Marmureanu[1], Mihail Diaconescu[4], Marius Mihai[1,3]

An intense seismic activity started in February 2023, close to Targu Jiu city, in the Oltenia region (Romania). The strongest events, characterized as doublet earthquakes, occurred on 13th and 14th February, the first shock with ML=5.2, and respectively the second shock with ML=5.7. These main shocks were followed by specific seismicity bursts (in the first week, about 800 foreshocks were registered). The focal depth of the events ranges from 1 to 20 km, most of them being situated in the 10-20 km depth interval. The area of interest is tectonically complex with various types of faults and it takes place at the contact between the Getic Depression, to the south, and the Southern Carpathians, to the north. The seismic sequence of Tg. Jiu occurred in the northern part of the Valea Motrului-Valea Oltetului area (part of Getic Depression) and is characterized by extensional faults, which show a general direction of ENE - WSW. The aims of this study are the estimation of the source parameters (MW, M0, f0), along with the focal mechanisms for events with ML≥3. For the seismic source delineated in Tg. Jiu area, the stress field has an extensional stress regime (σ1 almost vertical), with maximum horizontal stress (SHmax) oriented in the NW-SE direction. The resulting SHmax orientation and normal fault regime with a radial component (R′=0.5) are consistent with the observed geological setting. The results of this study are useful for assessing past and current tectonic activities and future research of the epicentral area.

[3]Universidad Nacional Autónoma de México- Instituto de Geofísica, seismological service, Mexico City, Mexico

In the historical catalog published by the SSN, discrepancies have been detected in the depths and magnitudes of ancient earthquakes with epicenters in Mexico City and the State of Mexico; in most cases, due to wrong velocity models used to calculate the hypocenter of these earthquakes (mainly those recorded before 2010). Recently, structure models have been estimated for some areas of Mexico City, which has allowed for a more reliable depth calculation. Regarding the magnitudes, several earthquakes were reported with a few readings, allowing for a misdetermination of magnitude value. In this research, we made a careful relocation of these events, and the magnitude previously calculated was also corroborated with the determination of the seismic moment magnitude; additionally, for the events meeting requirements such as being of magnitudes greater than 2.5 and recorded in more than five stations, we obtained focal mechanisms through several techniques such as Focmec, Fpfit, and Hash, all of them inside the Seisan package. In addition, the inversion was performed using the ISOLA method, which occurred between 2010-2021.

Repeating earthquakes in Northern Chile, from true repeaters to deep repeaters

DOI: 10.57757/IUGG23-3201 - LINK

Jonas Folesky[1], *Jörn Kummerow*[1], *Rens Hofman*[1]
[1]*Freie Universität Berlin, Geophysik, Berlin, Germany*

At the northern Chilean subduction zone, the IPOC network has been monitoring seismicity since 2006. For the observation time until 2021 a recent catalog has been published holding more than 182,000 events. We have performed a complete template matching run on the continuous seismic data using this catalog, enabling us to identify a large amount of repeating earthquake families. Many identified family members were not in the original catalog, but solely identified by the template matching. High data quality and long observation time allow analyzing these sequences in detail.

Using a relative relocation approach based on wave phase based cross correlation refined s-p travel time differences, we are able to compute highly precise relative locations for these events. Paired with very recently obtained stress drop information, we are able to distinguish between true repeaters and similar events. This distinction is important, especially when the families are utilized as creep proxies and are being compared to the plate convergence rate or plate coupling.

The repeaters in the vicinity of the Mw8.1 2014 Iquique earthquake show different characteristic behavior reflecting signatures corresponding to pre-, inter-, and post-seismic phase of a megathrust event. We observe clear precursor patterns, burst reactions and unresponsive families simultaneously. Their cumulative slip and characteristic decay rates correspond well with the slip and after slip patterns reported for the Iquique event.

Interestingly, repeating series are also found in deeper parts of the subduction channel, where the classical repeating earthquake theory loses validity.

In the Physics-Informed Neural Networks (PINNs) approach, we construct neural networks that can solve the physics-based equations by minimizing the loss function which involves the differential equations and initial / boundary conditions [Raissi et al., 2019]. This approach has been recently adopted in many research fields because it not only provides the mesh-free framework for forward problems but also easily obtains solutions for inverse problems. In seismology, a spring-slider model is often used to simulate fault slip evolution [Yoshida and Kato, 2003]. In this study, we applied PINNs to this simulation in the spring-slider model that combines quasi-dynamic equations of motion [Rice, 1993] and rate and state friction law [Ruina, 1983]. By assigning appropriate frictional parameters, we successfully reproduced slow slip events (SSEs). Unlike the time-adaptive Runge-Kutta approach that is usually used in solving these equations, PINNs can solve the equation with equidistant collocation points. This indicates the high interpolation ability of PINNs. To incorporate the temporal causal structure, we also applied the Causal-PINNs [Wang et al., 2022] to the same problem. We found that the Causal-PINNs obtained a similar simulation result with faster calculation speed and higher accuracy compared to original PINNs. In addition, we estimated the frictional parameters by adding the misfit term between the observed and calculated slip velocity data to the loss function. As a result, all frictional parameters are optimized from the synthetic data with added noises. These results imply that the PINNs approach is effective in earthquake cycle simulation and frictional parameter estimation.

A series of strike-slip faults developed in China, such as the Xianshuihe Fault, Honghe Fault, etc. Moderate intraplate strike-slip earthquakes are more active and hazardous in China. A series of moderate intraplate strike-slip earthquakes occurred around Tibet Plateau in 2022, including the Menyuan Mw6.6 earthquake, the Luding Mw6.6 earthquake, and the Maerkang Mw5.8 earthquake.

An Mw6.6 earthquake struck Menyuan, northeast of Tibet Plateau in China, on 7th January 2022. The earthquake destroyed the high-speed railway near the epicenter. An Mw6.6 earthquake struck Luding, southeast of Tibet Plateau in China, on 5th September 2022, which caused severe damage.

The bend, step-over, and other local tectonic structures play a key role in the beginning and ending of strike-slip earthquakes. The geodetic and regional seismic data make it possible to investigate the rupture process of earthquakes of moderate magnitude. The updated China Earthquake Network included over two thousand broadband stations, three thousand strong motion stations, and ten thousand MEMS sensors.

The rupture processes of the two earthquakes are investigated based on regional, teleseismic, and geodetic data. Combined with the relocated aftershocks distribution by other researchers, the results show that the rupture started at the bend of the strike-slip fault and was stopped by the local tectonic structures. It implies that it would be possible for us to estimate the earthquake potential rupture zone based on the tectonic structures in the strike-slip fault zone.

Source mechanisms of the earthquake swarms linked to the 2021 Fagradalsfjall volcanic eruption (SW Iceland)

DOI: 10.57757/IUGG23-1741 - LINK

Josef Horalek[1], *Jan Šílený*[1], *Jana Doubravová*[1]
[1]*Institute of Geophysics- Czech Academy of Sciences, Seismology, Prague, Czech Republic*

We retrieved source mechanisms in the moment-tensor description (MT) of an intense earthquake-swarm activity on the Reykjanes Peninsula (SW Iceland) in 2020 to 2021 preceding the Fagradalsfjall volcanic eruption in March 2021. We inverted displacement amplitudes of the direct P- and S-waves from a local network REYKJANET complemented the network of the *University of Cambridge* and by the near stations of the regional SIL network; a total of about 30 stations covering well the Fagradalsfjall are used. For a sufficient resolution of the source mechanism an accurate enough response of the medium the Green's function (GF) is demanded. For this purpose we used a 1-D velocity model for the Reykjanes Peninsula by Vogfjörd et al. (2002). For the GF construction, we applied the ray theory. Substantial effort has been devoted to facilitate a batch processing of the events, first of all it means to allow the ANRAY to work in a semi-automatic regime, which is not its inherent mode of work. As a result, we have a comprehensive tool for retrieval of MTs on the Reykjanes Peninsula. We demonstrate its usefulness by treating a set of several tens of events. Source mechanisms of some of them are compared to those obtained by ISOLA, a software for processing of regional earthquakes, which however applies different data and different approach. Our set of MTs retrieved provides a deeper insight into the mechanism of faulting due to dyke propagation in the region in question from the beginning of 2020 to March of 2021.

Time sequence of the seismicity and relationship with the mid-crustal reflector in Iwaki area, northeastern Japan

DOI: 10.57757/IUGG23-0766 - LINK

Takashi Iidaka[1], *Yuta Usuda*[2]
[1]*The University of Tokyo, Interfaculty Initiative in Information Studies, Tokyo, Japan*
[2]*UNIC Corporation, Numerical analysis, Tokyo, Japan*

The 2011 Tohoku-Oki earthquake with M 9 occurred on March, 11, 2011. Many remarkable changes of crustal activity were observed in Japan after the earthquake. The Iwaki area, northeastern Japan, is one of the places that the seismic activity increased drastically. The high seismic activity area is located in a triangle area with one side length of about 50 km. The two boundaries at the depth of around 30 km and 15-23 km were detected in this area by the analysis of waveforms (Usuda et al., 2022). The two boundaries were identified as Moho and mid-crustal boundaries. It was suggested that the mid-crustal boundary was related to crustal fluid. The relationship between the time sequence of the seismicity (data of Japan Meteorological Agency) and the reflector of the mid-crustal boundary (Usuda et al., 2022) is researched in this study. The mid-crustal boundary dips northeast direction. The seismic activity began at just above the mid-crustal reflector at the southern part of the reflector. The seismicity spread to wide area on and around the mid-crustal reflector. The seismicity gap was found at the central part of the area. The large intraplate earthquake, 2011 Hamadoori earthquake (Mw 6.6), occurred on April 11, 2011 at the seismicity gap. The active seismicity area formed large triangle area. In Japan, it has been suggested that the source of large earthquake is related to crustal fluid. It is considered that the crustal earthquakes in Iwaki area are also related to the crustal fluid.

Megathrust complexity delimited the up-dip extent of slip during the 2021 Chignik, Alaska Peninsula earthquake

DOI: 10.57757/IUGG23-1186 - LINK

Chengli Liu[1], *Yefei Bai*[2], *Thorne Lay*[3], *Yashan Feng*[1], *Xiong Xiong*[1]

The up-dip extent of slip during large megathrust earthquakes is important for both tsunami excitation and subsequent tsunami earthquake potential, but it is unclear whether frictional properties and/or fault structure determine the up-dip limit. A finite-fault slip model for the 2021 M_W 8.2 Chignik, Alaska Peninsula earthquake obtained by joint inversion and modeling of geodetic, seismic, and tsunami observations provides unusually good constraints on the up-dip edge of the slip. Rupture initiated ~35 km deep and propagated unilaterally northeastward with large-slip (up to 8.4 m) distributed over a depth range of 26 to 42 km beneath the continental shelf. Aftershocks concentrate up-dip of the coseismic slip around a strong megathrust reflector with high Coulomb stress change. The ~25 km deep up-dip edge of slip strongly correlates with a change in plate interface reflectivity apparent in reflection profiles, indicating that a structural and frictional transition provided a barrier to shallower rupture.

Revised Empirical Relationships for Estimation of Earthquake Magnitude: Application of Machine Learning

DOI: 10.57757/IUGG23-4891 - LINK

Sukanta Malakar[1], *Abhishek K. Rai*[1]
[1]*Indian Institute of Technology Kharagpur,*
Centre for Ocean- River- Atmosphere and Land Sciences CORAL, Kharagpur, India

In this study, we developed a new empirical relation between various source and rupture parameters such as moment magnitude (M), surface rupture length (SRL), subsurface rupture length (RLD), rupture width (RW), rupture area (RA), and average (AD) and maximum slip (MD), based on an extensive updated database. A log-linear regression was used to study 402 earthquakes that occurred between 1857 and 2018, ranging in magnitude M~4.5-9.2, with various faulting mechanisms. All fault mechanisms correlate well with M-SRL, M-RLD, M-RW, and M-RA. In contrast, the M-AD and M-MD correlate moderately for reverse faulting, whereas the correlation is relatively better for other fault types. The results were compared with previous studies and found to be revised. On the other hand, the log-linear equations predict a single magnitude value as a function of a single fault parameter independent of the values of other fault parameters, which may lead to inconsistency. This limitation has been addressed by applying machine learning techniques to estimate the earthquake magnitude while simultaneously using all fault parameters to ensure consistency. We also investigated the performance and applicability of an artificial neural network (ANN) and a gradient-boosting machine (GBM) regression technique. Our analysis shows that GBM outperforms regression equations in estimating earthquake magnitude, but ANN outperforms both. The result of this study would be extremely useful for paleoseismic studies where reliable estimates of earthquake magnitudes and other source parameters are often unavailable from published literature.

Modelling dynamic rupture in olivine-based subducting slabs: From a microscopic to a mesoscopic perspective

DOI: 10.57757/IUGG23-0919 - LINK

Jaime de la Serna Valdés[1], Maurizio Mattesini[1], Elisa Buforn[1], Carolina López Sánchez[1], Carmen Pro[2], Agustín Udías[1]
[1]University Complutense of Madrid, Earth's Physics and Astrophysics, Madrid, Spain
[2]Universidad de Extremadura, Departamento de Física- Centro Universitario de Mérida, Mérida- Badajoz, Spain

A common mineral for subducting material is olivine, which is a magnesium-ferrosilicate with varying amounts of iron and magnesium. The purpose of this work is to investigate the rigid rupture process of crystalline olivine from an atomistic perspective and to estimate the energy released during the breakdown process of the material. In this study, ab initio calculations have been performed based on the well-known Density Functional Theory (DFT). As a first step, we calculated the electro-structural energy minimum of the unit cell of olivine at 24 GPa, which corresponds to the pressure condition of the subducting slab at a depth of 700 km. To obtain reference stress-strain curves, the relaxed unit cell was strained under a variety of shear distortions. In this way, we were able to calculate the theoretical total energy released by the subducting material during atomistic rupture. To broaden the atomistic energy budget to a macroscale rupture mechanism (i.e., with the size of the fault), we developed a modular multiscale fracture model. Several grain ruptures are simulated in this manner, with each grain containing different crystallographic directions within a polycrystalline olivine matrix. A stochastic simulation scheme was applied to this model to compute multiple grain ruptures and thereby estimate the energy involved in a macroscale rupture. The results obtained were compared to the average moment-scaled functions that were obtained for very deep earthquakes in the Peruvian-Brazilian subduction zone.

Southwest Australia is the most seismically active area in the stable continental region of Australia. The Southwest Australia Seismic Network (SWAN) is a temporary broadband network of 27 stations that has been deployed since October 2020. The SWAN network detected a major earthquake swarm, termed the Arthur River swam, that comprised of 3000+ events total have been located as of December 2022. The swarm appears to be ongoing. Several clusters of other small earthquake swarms are observed within the SWAN array. It is usually assumed that the source of an earthquake swarm is within a brittle fault damage zone, which likely to be very permeable. However, it is not clear that every swarm earthquake is related to fluid motion in a fault damage zone.

We estimate Centroid Moment Tensors of the earthquakes with magnitudes ranging from 4.2 to 5.2 MLv (3.9-4.8 MLa) that occurred during earthquake swarms in order to assess the detailed structure of the focal zone. The centroid moment-tensor is obtained from full waveform modelling through a 4D spatiotemporal grid search allowing for time shifts around the origin time. The inversion generates a set of solutions that constrain the depth, centroid's location and the moment tensor. Our initial analysis for the largest earthquake (MLv 5.2) shows a reverse faulting mechanism at depth of 1 km. We have tested a range of frequency bands and concluded that our local Earth model, developed using earthquakes recorded by SWAN, sufficiently simulates seismic waves up to 0.15 Hz.

Long-term activity change in Very low-frequency earthquakes in the south Ryukyu Trench

DOI: 10.57757/IUGG23-4841 - LINK

Mamoru Nakamura[1]
[1]*University of the Ryukyus, Faculty of Science, Nishihara-cho, Japan*

Very low-frequency earthquakes (VLFEs) occurred regularly along the south Ryukyu Trench. The activity was concentrated at the slab depth of 10-20 km along the trench axis. The VLFEs occurred every two to three months for a few days in a seismic swarm. Long-term variations in VLFE activity reflect temporal changes in the degree of strain accumulation and release in the plate interface. Therefore, I investigated the long-term changes in VLFE activity in the south Ryukyu Trench. First, I analyzed continuous waveforms by NIED F-net and Taiwan BATS broadband seismic stations from 2003 to 2019. Second, I detected the VLFEs using the cross-correlation technique by Asano et al. (2014). As a result, I detected VLFE candidates with similar waveforms to those known as regular earthquakes as template events.

The VLFE activity in south Ryukyu Trench decreased gradually from 2003 to 2009. The degree of VLFEs decrease was greater west of the center of the clusters and more minor to the northeast. In 2002, a series of MJ 7.0 earthquakes (March 26, 2002) and MJ 6.9 (March 31, 2002) interplate earthquakes occurred in the west and south of the VLFE clusters. The afterslip associated with the March 26, 2002 earthquake occurred in the north of western part of the VLFE clusters (Nakamura, 2009). These would have caused stress changes in the plate interface in the central and western parts of the VLFE clusters and would have activated the VLFEs. After then, the VLFE activity would have decreased gradually, accompanying the stress release.

Pseudo-dynamic source modeling is an efficient tool to simulate near-source ground motions and investigate their characteristics. It combines the advantages of both kinematic and dynamic source modeling. In other words, it keeps the computational efficiency of the kinematic source modeling, while the input values of the pseudo-dynamic source models are constrained by analyzing a set of dynamic source models. In this study, we investigated the non-stationary characteristics of the dynamic source models. Although the pre-existing pseudo-dynamic source modeling method assumes the stationarity of source parameters, it is reasonable to expect the non-stationary distributions of kinematic source parameters such as asperities. We carefully analyzed a set of dynamic source parameters, focusing on their non-stationary distributions. Then the non-stationary components (trend part) were extracted by using elliptical Gaussian surfaces. After extracting the trend part, we confirmed that the source statistics of the remaining distribution (fluctuation part) show a reasonable level of stationarity. We further plan to simulate near-source ground motions by using the separated source models into trend and fluctuation parts. Then we investigate the contribution of each source component to the frequency contents of near-source ground motions. We expect to improve the pseudo-dynamic source model significantly by considering the non-stationarity of source parameters and dealing with the trend and fluctuation parts separately.

Full waveform-based moment tensor (MT) inversion allows for studying complex rupturing processes, including volumetric changes. However, small-magnitude earthquakes in swarms or aftershock sequences often have a poor signal-to-noise ratio that hinders full waveform-based MT inversion. We overcome this limitation by exploiting waveform similarity of events that occur close in space and rupture the same fault, as commonly observed for swarms and seismic sequences. By stacking the waveforms of such events, characteristic features are amplified while noise is suppressed. Consequently, full waveform-based MT inversions can be applied to obtain a composite mechanism. In our work, we apply the waveform-based network-similarity clustering toolbox Clusty to identify multiplets within seismic sequences in the SE Alps and N Dinarides between 2016 and 2019. We stack their waveforms and subsequently perform probabilistic MT inversions. The resulting composite mechanisms are interpreted along with MTs of single, larger events and known local faults. We discuss the limits of the method and investigate the required thresholds for waveform similarity and stacking approaches. We provide a comprehensive workflow that links two toolboxes: Clusty for event clustering and Grond for MT inversion. In future works, we aim to extend our approach to remote earthquakes, which are often monitored only by a few distant stations with poor SNR.

A declustered catalogue of 324 focal mechanism solutions has been used to evaluate the stress distribution of the western part of the India-Eurasia collision zone, and its kinematics and seismotectonic implications. In this study, we have obtained stress fields for different tectonic settings identified based on geology, tectonics and focal mechanism availability. The results show NE-SW trending principal stress axis (σ_1) with compression for the Himalayan seismic belt, while the Karakoram-Tibet region exhibits a strike-slip stress regime. Within the Himalaya region, the western region i.e., between 75° and 77° E latitudes shows arc-oblique compression (NE-SW) in contrast to the arc-normal compression (NNE-SSW) in the central Himalaya (beyond 77°); consistent with available GPS vectors. The stress field for the aftershock sequence of the 2005 Kashmir earthquake and its epicentral region (Hazara Syntaxis) is distinct from its adjacent regions (Pamir, Nanga Parbat and Hindukush), but comparable with that of the Central Himalaya, suggesting a Himalayan-type stress field. The Karakoram fault and Kaurik Chango Rift exhibit transpressional (σ_1: NNE-SSW) and transtensional (σ_1: N-S σ_1) motion, respectively. Further, the varying stress ratio (0.07-0.9) suggests the role of the intermediate stress axis (σ_2) in the areas of low-stress ratios and the stress field heterogeneity, hence varying seismic hazard.

Recent seismicity patterns and seismological investigations affirmed that the Donachiwada fault is the main causative fault for earthquakes in the Koyna region. However, the characteristics of this fault zone at depth is not yet well known. In this study we have selected a potential block of this fault zone and estimated the focal mechanism solutions of earthquakes of M_L~2 of this block recorded during 2015 – 2019 on a combined seismic network i.e. short-period borehole and surface broad-band seismic stations. Out of 29 earthquakes from a 4 x 4 km^2 block of the Donachiwada fault, we selected 10 events which resulted in well constrained solutions. Fault plane solutions are dominated by strike-slip faulting, consistent with a stress controlled by a horizontal compression (P-axis) with an EW trending T-axis. One of the fault planes of each best fit mechanisms are well correlating with the trend of the Donachiwada fault which is aligned in NNE-SSW. Most of the events suggest a steep west dipping nature of the Donachiwada fault. An event that occurred on 19 May 2017 earthquake of M_L 2.6 of this block provides the first seismic evidence of thrust faulting in this region. Also, a 3-D local earthquake tomographic inversion on high-quality travel time data shown an increase in P-wave velocity and a high V_P/V_S anomaly beneath this fault trace. The anomalies obtained by the tomography study are well correlating with the steep dipping planes of the fault zone.

The Himalayas which formed as a result of collision between the Indian and Eurasian plates has been a hotspot for great earthquakes. With an aim to understand the origin of seismicity in and around the northeastern state of Sikkim in India, 27 broadband seismic stations were deployed across the Sikkim Himalayas and Himalayan foreland basin (northern part of West Bengal). The continuous operation of the network since April 2019 to present day has enabled the acquisition of quality data with excellent azimuthal coverage. We have used local earthquakes (epicenter < 200km) detected by the network to study the seismotectonic activity of the region. Progressive relocation of these earthquakes using multiple algorithms facilitated in locating the hypocenters with great precision. We then employed full-waveform moment tensor inversion to obtain the fault plane solutions. Earthquakes concentrated in the central part of the study region are located in the upper crust along the dipping surface of the Main Himalayan Thrust. Whereas, earthquakes concentrated diagonally along the Dhubri-Chungthang Fault Zone are located at mid to lower crustal depths. These crustal earthquakes are observed to have a characteristic strike-slip mechanism. Further north of the study region, earthquakes with focal depths > 40km are observed to originate along an extensional plane as evidenced by the observed normal fault plane solutions. We plan to further investigate these spatially varying trends and determine its role in segmentation along the Himalayas. We will also integrate results from various studies to discern the geodynamic evolution of the Sikkim Himalayas.

AdriaArray seismic network – status in June 2023

DOI: 10.57757/IUGG23-1570 - LINK

With the advent of plate tectonics in the last century, our understanding of the geological evolution of the Earth system improved essentially. The internal deformation and evolution of tectonic plates remain however poorly understood. This holds in particular for the Central Mediterranean: The formerly much larger Adriatic plate is recently consumed in tectonically active belts spanning at its western margin from Sicily, over the Apennines to the Alps and at its eastern margin from the Hellenides, Dinarides towards the Alps. It has been shown that data acquired by dense, regional seismic networks like AlpArray provide crucial information on seismically active faults as well as on the structure and deformation of the lithosphere. The Adriatic Plate and in particular its eastern margin have however not been covered by a homogeneous seismic network yet.

Here we report on the status of AdriaArray – a seismic experiment to cover the Adriatic Plate and its actively deforming margins by a dense broad-band seismic network. Within the AdriaArray region, currently about 990 permanent broad-band stations are operated by more than 40 institutions. In addition, 414 temporary stations from 24 mobile pools are deployed in the region achieving a coverage with an average station distance of 50 – 55 km. The experiment is based on intense cooperation between local network operators, mobile pool operators, field teams, and ORFEUS. Altogether, more than 50 institutions are participating in the AdriaArray experiment. We will report on the time schedule, participating institutions, mobile station pools, and maps of temporary station distribution.

A new 3D model of the Ionian slab geometry and of the Central Mediterranean Moho

DOI: 10.57757/IUGG23-4339 - LINK

Simona Bongiovanni[1], Antonino D'Alessandro[2], Raffaele Martorana[1], Attilio Sulli[1]
[1]University of Palermo, Department of Earth and Marine Sciences, Palermo, Italy
[2]Istituto Nazionale di Geofisica e Vulcanologia, Osservatorio Nazionale Terremoti, Roma, Italy

The Central Mediterranean is a geodynamically complex area resulting from the interaction between the European and African plates. This process caused strong lateral variation in lithospheric thickness and thus strong variation in the Moho topography.
In this work we propose a new 3D Moho map for the Central Mediterranean, obtained from the interpolation of different data as: 2D velocity models (Scarascia et al., 1994; Chironi et al., 2000; Nicolich et al., 2000; Cassinis et al., 2005; Dellong et al., 2018; Agius et al., 2022), gravimetric profiles (Chironi et al., 2000; Dellong et al., 2018) and interpreted seismic reflection profile (Finetti et al., 2005; Civile et al., 2008; Catalano et al., 2013; Fedorik et al., 2018; Tugend et al., 2019; Sulli et al., 2021).
In order to optimize the geometry of the Ionian slab, we used the hypocenters of the seismic events extrapolated from different databases. In particular, we collected relocated seismic events from 1981 to the present.
We obtained a new constrained 3D Moho map for the Central Mediterranean that presents a strong lateral variation. Furthermore, the Ionian slab is quite different with respect to the model proposed by DISS (2021) and its geometry has been adapted to the hypocenters of the deepest seismic events (>40 km deep). In particular it was verticalized starting from about 200 km depth and the width was changed depending on new available data.
This model will allow a better understanding of the structure of the upper mantle and of the complex geodynamics of the area.

Surface wave tomography is a powerful tool for resolving crustal and upper mantle structures without the need of local sources. In this study, we present a 3D model of the Southern Italy and Central Mediterranean region based on the joint inversion of ambient noise and earthquake data. The input data consists of 11 900 phase velocity dispersion curves between 2 and 100 seconds obtained from ambient noise cross correlations and 81 000 phase velocity curves between 8 and 250 seconds obtained from averaging earthquake measurements using the two-station method. The two quality controlled datasets are merged using a correction factor that is derived from inter-station paths where both types of measurements are available.

Azimuthally anisotropic Rayleigh wave phase velocity maps are calculated using a regularized least square approach. The phase velocity maps are inverted for a 3D model by applying a stochastic particle swarm optimization algorithm.

The resulting 3D velocity model reveals several important features of the subsurface structure, including the subducted Calabrian and Hellenic slabs as well as a slab tear beneath Sicily. Moreover, the model images for example the transition from the Ionian Lithosphere to the Calabrian Slab, deformation of the Adriatic Lithosphere and aesthenospheric flow beneath the Tyrrhenian Sea. These results provide valuable insights into the evolution of the subduction zones in the Adriatic and Central Mediterranean region.

Surface wave tomography is a powerful tool for resolving crustal and upper mantle structures without the need of local sources. In this study, we present a 3D model of the Southern Italy and Central Mediterranean region based on the joint inversion of ambient noise and earthquake data. The input data consists of 11 900 phase velocity dispersion curves between 2 and 100 seconds obtained from ambient noise cross correlations and 81 000 phase velocity curves between 8 and 250 seconds obtained from averaging earthquake measurements using the two-station method. The two quality controlled datasets are merged using a correction factor that is derived from inter-station paths where both types of measurements are available.

The Aegean Sea and western Anatolian peninsula are allocated at a widely spread active tectonic deformation zone that has primarily been controlled by the African plate subduction beneath the Hellenic Trench and the movement of the North Anatolian Fault Zone (NAFZ). The Mw7.0 2020 Samos earthquake, for instance, is an expression of the N-S directed extensional tectonic regime developed in response to African slab rollback movement in this region. A proper assessment of tectonic deformation process and its potential seismic hazard require a quantitative understanding of the contribution from the Hellenic subduction and the NAFZ to the surface movement. Here, we analyze the published regional GPS data along Greece-Turkey region to separate those contributions. Using a simple elastic-viscoelastic layered earth model, we first estimate the NAFZ contribution to the GPS velocity at each station with a varying slip rate. Then, we invert residual velocities obtained by subtracting the calculated velocity from the observed data, to derive subduction rate along the Hellenic trench. In the calculation, we assume the elastic thickness of 60 km based on the regional seismic tomography results. Our model results suggest 35 mm/yr of optimum slip rate of identifying the NAFZ, and ~40 mm/yr of the average subduction rate for the Hellenic Trench. The synthetic velocities can explain the observed GPS velocity within an average misfit of 2-3 mm/yr. Our results mean that the Hellenic slab rollback and the NAFZ movement are essential for the observed deformation beneath this region.

We present continuous GNSS data (cGNSS) from SE Spain. We use in this work a total of 11 cGNSS stations located in the Murcia and Valencia regions (ALBA, UTIE, AYOR, VCIA, JUMA, ALCO, DENI, MCIA, CARG, SALI, and TORR). From the site position time series we obtained absolute velocity vectors. To discuss the meaning of this vectors in terms of present deformation, we calculated residual velocity field with respect the mean of two of the stations of our network (ALBA and AYOR). Furthermore, we also projected the residual velocity vectors along the N070E and N340E directions, i.e., sub-parallel and sub-perpendicular to the regional maximum shortening direction.

Our results indicate that the southernmost part of SE Spain (Murcia coast) is presently undergoing a shortening rate of 1.23±0.04 mm/yr along the N340W direction (CARG and MCIA stations). Only one major active fault has been defined in this area (Carrascoy Fault). This fault accommodates 0.7±0.2 mm/yr of N340W shortening. Therefore, the rest of our computed shortening (ca. 0.5 mm/yr) must be accommodated out of this structure.

In the northeastern part of SE Spain, the comparison between coastal stations (DEN, VCIA) and inland stations (ALCO and AYOR) indicates 0.90±0.06 mm/yr of NE-SW extension. No major active fault has been previously described in this area.

We present GNSS data from a survey-mode network located in the Central Betic Cordillera. The Betic Cordillera is a collisional orogen, presently undergoing NNW-SSE shortening, as it is located in the convergence limit between Nubia and Eurasia Plates. Our GNSS network includes seven stations along a ca. 170 km long NE-SW striking profile. For these stations we calculated GNSS velocities from position time series. Then we calculated residual velocities with respect to a fixed Eurasia (ITRF2014 plate motion model(Altamimi et al., 2017)'}" id="614029728">). To discuss our data in terms of regional geodynamic implications we projected the velocity vectors along the N060E direction.

The absolute value of the N060E component of the obtained vectors shows a general increase of velocity from NE to SW, pointing to a regional NE-SW extension. This is in good agreement with previously reported data. Our data permit us to quantify an extension rate of 2.0±0.3 mm/yr. Furthermore, we also quantify the strain partitioning within the Central Betic Cordillera, including the Guadix-Baza and the Granada basins areas of high extensional rates, separated by a low-deformed crustal horst.

Therefore, the Central Betic Cordillera is an area undergoing 2.0±0.3 mm/yr of NE-SW extension within a collisional orogen. Furthermore, this area presents the highest topographic relive of the entire cordillera and an overthickenedcrust. We thus postulate that the extension quantified by our GNSS data could partially be the consequence of upper crustal extension related to gravitational instability. This instability would be produced by the overthickened crust.

Deep subduction versus collision cessation: The fate of continental collisional orogens

DOI: 10.57757/IUGG23-1419 - LINK

The contrasting fates of continental collisional orogens, i.e., deep subduction or collision cessation, are widely recognized by petrological, paleomagnetic and geophysical observations. However, the mechanisms of such different collisional modes, especially the dynamics of continental deep subduction, are controversial. In this study, we integrate the phase transition-induced density evolution into a thermo-mechanical numerical model. Combing the systematic petrological-thermo-mechanical models with force balance analyses, we find that the favorable conditions of continental deep subduction include high metamorphic transformation degree, mildly depleted mantle composition of the subcontinental lithosphere, long preceding oceanic slab, as well as the rheologically weak continental crust and asthenospheric mantle. Otherwise, the collision cessation mode is favored. The further calculations of slab negative buoyancy indicate that the phase transition-induced metamorphic densification of the subducted continental crust and mildly to moderately depleted continental lithospheric mantle can provide a great slab pull force to sustain the self-driven continental deep subduction; however, the positive buoyancy of highly depleted Archean lithospheric mantle impedes deep subduction and causes collision cessation. Based on these systematic numerical models, we also evaluate the crustal mass balance or deficit in continental collisional system, which indicates that a large amount of felsic crust can be subducted deeply with the sinking slab in the regime of continental subduction. In contrast, the recycled felsic crust is negligible in the regime of collision cessation. Thus, the different modes of continental collision play a crucial role in the global crustal recycling and related mantle heterogeneities.

Spatial heterogeneities of density, temperature, and composition in the Antarctic lithosphere are crucial for controlling its geodynamic evolution and ice sheet dynamics. Mantle density and temperature can be estimated from seismic tomography models with a given or assumed mantle composition. However, this conversion is non-unique, as the mantle composition cannot be determined from seismic tomography alone.

Here, we used gravity inversion along with a seismic tomography model to constrain the composition of Antarctic lithosphere. We modelled lithospheric density distribution using a 3D finite element gravity inversion approach based on the esys-escript model in python. We derived a correction to an initial density distribution based on a seismic tomography model (ANT-20) with an initial uniform mantle composition. From the resulting density distribution and the initial seismic velocity distribution, we updated mantle temperature and composition and calculated the lithosphere thickness, mantle viscosity, and geothermal heat flow.

Our result highlights the compositional effect is essential to constraining the mantle temperature in East Antarctica, where our model suggests a highly depleted cratonic mantle in central East Antarctica. When compositional variations are considered, modelled mantle temperature increases in depleted regions by up to 150 °C to accommodate lower density and fast seismic velocity. Sensitivity tests suggest anelasticity effects dominate the uncertainty in resolving mantle temperature in slow seismic velocity regions (for example, West Antarctica). Future work requires constraining the seismic anelasticity to reduce the uncertainties in estimating lithosphere properties in West Antarctica.

Use of ocean tide loading deformation to constrain tomographic models of the Earth

DOI: 10.57757/IUGG23-2255 - LINK

Ocean tides periodically load Earth's surface and thereby introduce deformations. Despite being small in amplitude, surface deformations caused by the strongest tidal constituents can be reliably extracted from GPS data. The resulting signals are sensitive to the material properties of the Earth's interior across a broad range of spatial and temporal scales. This makes it a useful and potentially unique source of information about the planet's response at low frequencies and is complementary to models of the Earth inferred from seismic data. Although the latter is commonly used to constrain Earth's interior, short-period seismic waves are generally insensitive to density. In contrast, previous research indicates that the ocean tide load (OTL) surface displacements may be sensitive to both the elastic properties of the interior as well as to the mass distribution in the lithosphere and, perhaps, the upper parts of the mantle. Comparisons between observed OTL surface displacements and corresponding modelled responses for a suite of 1D reference models yields residuals of up to 0.3 mm (Martens et al., 2016). Regional-scale spatial coherency in the residuals suggests sensitivity to relatively long-wavelength deviations from the globally-averaged Earth structure. By resorting to a finite-element method to solve the 3D elastostatic momentum equation, we investigate whether part of these discrepancies can be explained by 3D structure that are in global tomographic models. The validation of current seismic tomographic models against independent geodetic observables (GPS data) represents a first step towards the self-consistent integration of geodetic and seismic data to image Earth’s crust and mantle.

Travel time seismic tomography for the seismic stratigraphic interpretation of the crust at Coca river, Ecuador

DOI: 10.57757/IUGG23-2529 - LINK

Isabel Garcia Lopez[1], *Sebastian Araujo*[1]
[1]*Universidad Regional Amazónica Ikiam, Geociencias, Tena, Ecuador*

The San Rafael waterfall sinkhole on the Coca River in February 2020 caused by soil erosion raises the question of the stability of the knickpoint structure. The main objective of this research is to obtain tomographic images to interpret the seismic stratigraphic profile around the San Rafael knickpoint using seismic tomography. We use data from fourteen seismic stations of the permanent Ecuadorian seismic network in the region. The tomography results for the vertical cross-section P-wave velocity model show the geological formations and their transition to volcanic deposits. It also shows a structure with a high P-wave velocity value directly below the knickpoint. In contrast, the horizontal cross-section shows the structure of the extension of the volcanic deposits. The relative P-wave velocity shows a volumetric structure below the last pyroclastic deposits generated by the Reventador. The dimensions and characteristic velocity of the anomaly allow us to relate it to an igneous intrusion similar to the granodioritic intrusions known to the east of the volcano cone. Therefore, the presence of this pluton should condition the stability of the Coca riverbed, its slopes, and cliffs. The volcanic deposits in direct contact with the intrusion are suspected to be poorly consolidated. The P-wave velocity model shows that these volcanic deposits have an extension of 40 km. Greater stability is expected upstream of the San Rafael pluton. The relocation obtained by tomography also allows for defining the possible magmatic feeding system of the Reventador volcano.

A comprehensive analysis of the character, formation, and exhumation of continental crust is studied using seismic reflection profiling across the Achankovil shear zone, Southern Granulite Terrain, India, one of the constituents of the 2000 km long East African orogen. Seismic imaging reveals a dipping reflection fabric extending from the surface to 60 km depth. We interpret the structure developed during the subduction-accretion-suturing of the Madurai and Trivandrum blocks. The deep-seated reflection fabric suggests a rheologically strong lower crust, as viscosity did not change much downwards due to the presence of mafic minerals and granulites in place of quartz and feldspars. Gravity modeling along seismic profile indicated density (velocity) perturbation in the form of high and low intrusive bodies of varying composition in the upper crust. The subduction zone environment might be responsible for the formation of ultramafic rocks comprising dunite, glimmerrite, and spinellite minerals in the region. Charnockites (granulites), the orthopyroxene (hypersthene) bearing anhydrous rocks of granitic composition that are formed at P-T condition between 5-12 Kbars and 700-1040^0 C are exposed on the surface. The ultra-high temperature metamorphic rocks provided insights into crustal dynamics and crust-mantle interaction. Seismic and gravity results are integrated with LVZ at 120 km depth derived from tomographic study, high mantle heat flow data, and various rocks/minerals such as sapphirine, humite bearing marbles, alkaline rocks, arc-related magmatism to understand the structure, composition, and thermal state of the lithosphere.

3D Travel time tomography of the Gulf of Lion into the Ligurian Sea

DOI: 10.57757/IUGG23-1633 - LINK

Louisa Murray-Bergquist[1], Anke Dannowski[1], Dietrich Lange[1], Eline Le Breton[2], Heidrun Kopp[3]
[1]GEOMAR Helmholtz Center for Ocean Research Kiel, RD4 Dynamics of the Ocean Floor, Kiel, Germany
[2]Freie Universität Berlin, Institute for Geological Sciences Tectonics & Sedimentary Systems, Berlin, Germany
[3]Christian-Albrechts-Universität Kiel, Marine Geodynamics, Kiel, Germany

The Ligurian Sea is located in a complex tectonic area, at the Western Alps – Northern Apennines junction. Little is known about the structure of the basin and the continuation of the Alpine orogen offshore. The Ligurian Sea formed as a back-arc basin related to the retreat of the Apennine subduction zone. During extension, the Corsica-Sardinia block drifted eastwards, rotating counter-clockwise to its current position. The nature of the crust in the basin, whether atypical oceanic crust, thinned continental crust, or even exhumed mantle with thick sediment cover, is still a topic of debate. If oceanic crust was formed, its extent is poorly mapped.

Moreover, seismic and geodetic data show that the basin is now under compression. The area is known to have hosted large, tsunamigenic earthquakes in the past, however, its location boarding France, Monaco, and Italy, and climate mean that the coastline is densely populated despite the risk. Understanding the nature of the tectonics in the basin can therefore help assess the seismic hazard of the area.

In this project we use P-wave travel time tomography to generate a 3D velocity model of a section of the Gulf of Lion into the Ligurian Sea. This project is part of the DFG Priority Program "Mountain Building Processes in Four Dimensions (4DMB)". We use data from the LOBSTER-AlpArray OBS as well as from the 2006 SARDINIA Experiment. With FMTOMO we incorporate reflected and refracted rays as well as water multiples which in some cases improves the ray coverage.

The Ligurian Sea is located in a complex tectonic area, at the Western Alps – Northern Apennines junction. Little is known about the structure of the basin and the continuation of the Alpine orogen offshore. The Ligurian Sea formed as a back-arc basin related to the retreat of the Apennine subduction zone. During extension, the Corsica-Sardinia block drifted eastwards, rotating counter-clockwise to its current position. The nature of the crust in the basin, whether atypical oceanic crust, thinned continental crust, or even exhumed mantle with thick sediment cover, is still a topic of debate. If oceanic crust was formed, its extent is poorly mapped.

Moreover, seismic and geodetic data show that the basin is now under compression. The area is known to have hosted large, tsunamigenic earthquakes in the past, however, its location boarding France, Monaco, and Italy, and climate mean that the coastline is densely populated despite the risk. This study aims to build a 3D stratigraphic database based on the correlation of boreholes with logs and seismic reflection lines calibrated in terms of age, lithology, and environment. The aim of this study is to build a 3D stratigraphic database based on the correlation of logging wells and analysis of seismic reflection lines calibrated in age, lithology, and sedimentation environment from previous borehole wells. The MSBGC basin has been intensively prospected for hydrocarbons since the 1950s, both onshore and offshore. Extensive seismic reflection, gravity, magnetic and well data are available. Since 2014, major discoveries have been made in offshore Senegal, prompting interest in conducting a predictive study from offshore to onshore to identify possible continuities between the environments.

Results from the lithostratigraphic investigations we undertook show a mitigated offshore-onshore correlation. This is probably due to the size of the area, the scattered wells or the geological and tectonic phenomena that have affected the basin.

Petrophysical analyses obtained on some wells show that the Maastrichtian reservoirs are made up of sandstone, sandstone sand, and clayey sand. This is probably due to the major regression that occurred in the Upper Maestrichtian, which is expressed in the overlying sandstone deposits found in most wells. Maestrichtian has excellent reservoir properties with average porosities of at least 28% and high permeabilities with clay volumes below 50%.

The Collaborative Seismic Earth Model: Generation 2

DOI: 10.57757/IUGG23-1818 - LINK

Sebastian Noe[1], *Dirk-Philipp van Herwaarden*[1], *Solvi Thrastarson*[1], *Andreas Fichtner*[1]

We present the second generation of the Collaborative Seismic Earth Model (CSEM), a multi-scale global tomographic Earth model that continuously evolves via successive regional and global-scale refinements. Harvesting the distributed human and computation power across the tomography community, the CSEM framework allows to systematically build on previously accumulated knowledge. This is achieved by providing the current version of the CSEM as a starting model for regional tomographic studies and incorporating these findings into the following version of the CSEM.

The CSEM hosts 21 refinements from full seismic waveform inversion with diverse regional scales ranging from hundreds of km to entire continents. Noticeable changes since the first generation include detailed local updates for the Central Andes, Iran, South-east Asia, and the Western US, and continental scale refinements for Africa and Asia. A global long-period model improves the resolution int areas that have not been covered by other refinements. The current CSEM combines three-component waveform data from 1,637 events and over 700,000 unique source-receiver pairs across all regional updates.

To complete the model, we perform a global full waveform inversion over multiple period bands to a minimum period of 50 s. With this approach we ensure waveform prediction across regional model boundaries and that the resolved Earth structure is part of a single coherent model. We demonstrate seismic waveform prediction of minimum periods of 50 s on the global scale and for 20 s to 30 s in selected areas. Active participation in the project is encouraged.

Mejillones peninsula located in the north of Chile is considered a potential seismic barrier. Two major earthquakes have occurred south and north of it: The M8.1 1995 Antofagasta and the M7.8 2007 Tocopilla earthquakes. Slip and aftershock distribution show the central axis of this peninsula as the limit. We use travel time data of earthquakes recovered by three networks, overlapping in space but not in time, including offshore stations (CINCA network 1995; TaskForce 2007, and MEJIPE 2013-2015). A three-dimensional local tomographic inversion was performed using ~4000 events. The resolution of tomographic images was analysed by the model resolution matrix and numerical tests. Vp velocity and Vp/Vs ratio images are capable of resolving main tectonic units up to 80 km depth. Our work shows the presence of two basal possible underplating structures: The first is located below the peninsula with similar dimensions of it (~60 km) found at depths > 35 km and a second structure of smaller dimensions is located to the north where the Tocopilla earthquake nucleated. This evidence justifies the possible segmentation in the rupture zones of both earthquakes in the north of Chile.

The Himalaya as the type example of continental collisional orogeny has resulted from the convergence between the Indian lithosphere and the Eurasian lithosphere. Recent enhancement in broadband instrumentation in the northwest Himalaya (Jammu and Kashmir or J&K) provides an unprecedented dataset to study the deformation due to the Indo-Eurasia convergence. The main tectonic feature in the J&K Himalaya is the intermontane Kashmir basin. The Kashmir basin occurs in between the rupture zones of two historic earthquakes and hence is referred to as the "Kashmir seismic gap". We determine azimuthal seismic anisotropy using core refracted shear waves (SKS) and interpret the results to develop insight into the prevailing geodynamics of the region. We use data from the J&K Seismological NETwork (JAKSNET), operational between 2013 and 2022, which consisted of 24 broadband seismograph stations. The network extends across the Himalayan arc from the Siwalik (S), Lesser, Greater, and the Tethyan Himalaya (N), and along the arc from Jammu-Kishtwar (E) to the Kashmir Valley (W). Seismic data from 427 earthquakes (Mw>=5.5), within an epicentral distance range of 85°-135°, are selected and provide good azimuthal coverage for most stations. Specifically, we will present individual station measurements of splitting parameters, and the lateral variation of anisotropy and consider whether the anisotropy signatures are likely to have arisen from pre-collision or present day deformation. By correlating anisotropic parameters with geodetic and long-term geologic measurements we aim to understand the relationship between upper crustal deformation and the mantle flow field.

The Himalaya as the type example of continental collisional orogeny has resulted from the convergence between the Indian lithosphere and the Eurasian lithosphere. Mantle anisotropy from shear-wave splitting along the Bohemian Massif-Eastern Alps north-south transect

DOI: 10.57757/IUGG23-1690 - LINK

Ludek Vecsey[1], *Jaroslava Plomerova*[1], *AlpArray Working Groups*[2]
[1]*Institute of Geophysics of the Czech Academy of Sciences, Department of Seismology, Prague, Czech Republic*
[2]*http://www.alparray.ethz.ch, Eth, Zurich, Switzerland*

Splitting of shear waves is considered to be evidence of their propagation through an anisotropic medium. We evaluated splitting parameters of core-mantle refracted shear waves (SKS) along with their particle motions (PM), recorded during the passive seismic experiments AlpArray-EASI (2014-2015) and the AlpArray Seismic Network (2016-2019). The study area covers the western part of the Bohemian Massif and the Eastern Alps in about 200 km broad NS-oriented transect. Careful signal preprocessing includes several steps: automated identification of SKS waveforms, filtering and quality check. Special attention is paid to checking the geographical orientation of seismometers at all stations. Parameters of anisotropy – shear-wave split delay time and direction of the fast split shear waves in the LQT coordinate system are evaluated in 3D by two modified splitting methods, the eigenvalue and the transverse energy methods. To improve the splitting analysis results, we also include so-called null splits, i.e., results for directions where SKS waves do not split or their splitting is close to null. In the case of waveforms with a low signal-to-noise ratio (SNR) we apply a more robust PM method. The modified version of splitting methods (Vecsey et al., 2008) allows us to retrieve the 3D orientation of large-scale anisotropic structures in domains of the mantle lithosphere and to detect abrupt changes of their fabrics as well as present-day deformations within the sub-lithospheric part of the upper mantle.

The North China Craton (NCC) is one of the oldest craton in the world. Since the Cenozoic, the NCC has experienced strong lithospheric thinning, accompanied by extensive tectonic deformation and volcanic activities. To better constrain the geodynamic processes and mechanisms of the lithospheric deformation, we used a linear damped least squares method to inverse simultaneously Rayleigh wave phase velocity and azimuthal anisotropy at periods of 10-80 s with teleseismic data recorded by 388 permanent stations in the NCC and its adjacent areas. The results reveal that the anomalies of Rayleigh wave phase velocity and azimuthal anisotropy are in good agreement with the tectonic domains in the NCC. The whole lithosphere of the Ordos block shows a high-phase velocity and rotated fast axis, which is related to the well-preserved thick lithospheric root and counterclockwise rotation of the Ordos block. The horizontal extension of the upwelling materials within the lower crust under the Datong volcano contributes to the regional rotation pattern of the fast axis direction of Rayleigh wave together with a distinct low-velocity anomaly. A NW-SE trending azimuthal anisotropy and a low-velocity anomaly originated from the Datong volcano at atop of the asthenosphere are revealed to be subparallel to the Zhangbo fault zone. This observation may be caused by the upwelling magma of the Datong volcano flow into the asthenosphere of the eastern NCC, which also provides new insights into the understanding of the lithospheric thinning of the eastern NCC.

Tethyan oceanic subduction, terrane accretion and continental collision of the Indian and Eurasian plates since 50Ma ago lead to the current Himalayan orogen. As imagined from geophysical data, the deep structure and anisotropy of the lithosphere-asthenosphere system provides important clues in understanding the modality of the orogenic convergence and collision. Based on the seismic data from CENC, IRIS and ISC, using surface wave tomography, we calculated the group velocity. Base on Metropolis rule, we improved the simulated annealing algorithm to simultaneously inverse the velocities and thicknesses and identified the Moho depth and the bottom of lithosphere. We computed receiver functions at permanent and portables stations to provide constrains for crustal deformation. A harmonic analysis was employed to investigate the accurate crustal anisotropy. Crustal shortening and thickening should have occurred beneath the study region. Its partial melting might have enhanced the crustal anisotropy and promoted the accumulation and release of strain. The Himalayan block (HM) is covered by a high velocity anomsaly of about 5% indicating a relatively thin asthenosphere with high velocity. The Vs models demonstrate the leading edge of the subducting Indian slab reaches up to Bangong-Nujiang suture belt (BNS). It indicated that the crust with the thickness of about 65 km in HM and the lithosphere (~160 km). The epicenters in HM is relatively deeper than that northern BNS, more deep focus earthquakes are located in the uppermost mantle. The study is supported by the Chinese National Science Foundation (41774069).

Partnerships with Earth Science for Society, the Canadian Risk and Hazards Network, the Assembly of First Nations, the International Association of Emergency Managers, the Canadian Federation of Earth Sciences and others have been critical for reaching the target audience of the Pan Canadian bilingual E3 Survey. Research partners also circulated our 2022 article entitled *A new earthquake warning system will prepare Canada for dangerous shaking* and its key message:

"*About 10 million people live in Canada's earthquake-prone zones. Yet few have practical knowledge of what to do with new early warning system alerts which aim to save lives and protect livelihoods*" .

Importantly, such partnerships also provide the structure for the distribution of the E3 Survey final report.

The primary aim of this presentation is to outline how our partners have helped us to research and report on three questions of national interest:

- What connects Canadian science education, earthquake literacy and time/space specific skills required to succeed in earthquake prone locations ?
- How do Canadians build their earthquake literacy?
- Why does Canada needs earthquake literacy taught in disaster risk management activities and programs?

We showcase how the Knowledge to Action Framework analysis of E3 Survey results reveals multiple aspects of E3 delivery that need to change. We suggest that with evidence based recommendations, our partners can identify resource needs and pinpoint future interventions. Overall, we conclude that investment in future E3 products – via digital delivery - may revolutionize E3 geoliteracy levels and close the E3 Knowledge to Action gap.

The theme of the University of Calgary Natural Resources Canada (NRCan) funded project is: *Addressing misconceptions around magnitude and intensity to inform earthquake early warning (EEW) alerting strategies*

Last year, the Earthquake Early Warning Education (E3) socio cultural research project began. The E3 project has a dual purpose: to promote debate on the issues shaping Canadian earthquake risk management; and, to reflect on the biases in the media that reports on earthquakes. As seismic science - societal risk educators, we represent scholarship from across the spectrum (natural sciences, social sciences, and humanities). The E3 socio cultural project allows us to look ahead. We consider the contemporary and historical processes that shape how Canada will do E3 once the NRCan EEW is implemented in 2024.

This presentation provides a preliminary report on the Pan Canadian bilingual E3 Survey results.

Survey participants responses were needed to reveal the challenges this project faces. As a result, we have been provided with insights into the Canadian seismic science-society interface; and, the challenges this project faces. The E3 survey results will continue to make an impact both in Canadian E3 and in the training of future disaster risk management (DRM) practitioners.

The E3 socio cultural project is an opportunity to talk about how Canada might use existing tools, perspectives, social media, and DRM training sessions to effectively support the NRCan EEW in 2024 and beyond.

Generative adversarial networks as a fast surrogate model for simulations

DOI: 10.57757/IUGG23-4913 - LINK

Stuart Mead[1], *James Hilton*[2]
[1]*Massey University, College of Sciences, Palmerston North, New Zealand*
[2]*CSIRO, Data61, Melbourne, Australia*

The complexity and level of detail in numerical models for geosciences have increased as computational power has become more available and parallelism and new computational techniques have reduced the computational burden of numerical modelling. However simulations still pose a large computational challenge where a large number of simulations are required to adequately sample the input space. One approach to alleviating these limitations is through construction of a surrogate model. A surrogate (or metamodel) is a model of the simulation results within a defined parameter space. Surrogate models typically learn from simulation results to create a fast approximation to the numerical model. We have been using Generative Adversarial Networks (GAN's) as a surrogate model to depth-averaged simulations of debris avalanches at Ruapehu volcano, New Zealand. This GAN appears highly successful, creating inundation outlines of volcanic debris avalanches (VDA) with high precision (>90% similarity to simulations in some cases) and more than 130,000 times faster than VDA simulations. Our trials of GANs so far highlight a few key points: (1) well-trained GAN surrogates have high accuracy in reproducing model footprints, (2) the surrogate GANs show better accuracy when constrained to groups with similar simulation inputs (i.e. it is not generalizable), and (3) different loss functions (mean-square error vs. mean absolute error) affect trainability and accuracy. These results, and our attempts to push the limits of GAN's to problems that consider time-varying inputs, such as bushfire spread, will be highlighted.

The complexity and level of detail in numerical models for geosciences have increased as computational power has become more available and parallelism and new computational techniques have reduced the computational burden of numerical modelling. However simulations still pose a large computational challenge where a large number of simulations are required to adequately sample the input space. One approach to alleviating these limitations is through construction of a surrogate model. A surrogate (or metamodel) is a model of the simulation results within a defined parameter space. Surrogate models typically learn from simulation results to create a fast approximation to the numerical model. The prediction of global sedimentation rates is a critical aspect of comprehending various phenomena, such as carbon sequestration and seafloor stability. With the advent of machine learning, there has been an increasing trend towards utilizing these techniques to predict quantities on the seafloor, including porosity and total organic carbon. Several studies have been conducted to predict sedimentation rates[cm/ka] and mass accumulation rates[Mt/yr] using techniques such as k Nearest Neighbors and neural networks. However, a significant issue with these methods is the observed tendency for the models to over-predict sediment budget, a crucial parameter in evaluating the validity of predictions. This bias may stem from the paucity of low sedimentation rate data points on the continental shelves, where most scientific expeditions concentrate on high sedimentation rate areas. This bias disregards valuable data on low sedimentation rates, which would be useful in developing a comprehensive global map of sedimentation rates. To address this issue, there are several potential methods. The first involves identifying physical parameters, such as porosity, sediment grain size and bottom currents, that correlate with low sedimentation rates and can be utilized to identify these areas. The second involves utilizing few-shot learning, a machine learning technique that allows for training with limited low sedimentation rate labels. The third method involves the use of numerical models in small spatial areas, which can offer further insights into the processes behind low sedimentation rates and provide more data for analysis.

Access to big data in remote sensing, deep learning and machine learning models, along with good computational power has improved the accuracy for flood mapping. However, the reasons for this improved classification performance for such models, still remain largely unexplored. In this study, we explore the use of Sentinel-1 synthetic aperture radar (SAR) data and auxiliary layers for flood detection, with a focus on identifying the most important features for accurate classification. In addition to the pre- and post-event SAR layers, the auxiliary layers used in this study include topography, permanent water, and land-use land cover, along with SAR texture layers for binary flood inundation classification. Random forest model was tested for four completely different flood events characterized by notable differences in land-use, flood magnitude, and elevation patterns. Several scenarios were constructed to evaluate which input features contributed the most to the identification of an appropriate decision boundary for the classification. The contribution of the input features to model performance was explored using permutation feature importance. Our results demonstrate that SAR data, along with the auxiliary layers, can effectively identify flooded areas with high accuracy. Among the auxiliary data selected, the feature importance analysis shows that the topography plays a more important role than permanent water and land-use landcover for flood delineation.

A single triggering event such as strong precipitation, may result in swarms of shallow landslides that cumulatively pose significant risks to population, infrastructure and the environment. There is large scientific and societal interest in hazard maps that display the susceptibility to shallow landslide occurrence while accounting for spatio-temporal variability of triggers and influencing factors. In this study, we implemented a generic and scalable hazard mapping workflow in accordance with the FAIR principles that relies on a Random Forest Classifier. It is a purely data-driven approach which due to its modular implementation allows a flexible adaptation to different areas of interest and integrated data. It's application results in individualized and reproducible hazard maps. The validation of these maps as well as the underlying workflow is considered as well. The workflow facilitates dynamic hazard maps of varying temporal scope. This temporal dynamic is achieved through the integration of highly volatile features such as precipitation events. In this way, hazard maps can be created depending on the weather forecast. Geohazard potential changes dramatically in response to volatile triggering conditions making their inclusion into the mapping process a natural extension to the established static hazard mapping features. First results of enriching data-driven landslide hazard mapping with temporal data are promising. The resulting temporally dynamic hazard maps offer a wide range of opportunities to improve landslide risk management.

Climate change, global warming, and increasing weather extremes, especially in Sub-Arctic and Arctic regions with unusual freeze-thaw cycles, can cause more and more challenges to the infrastructure such as road networks. The maintenance and repair of road network can be time consuming and expensive. Better targeted and proactively planned maintenance could have economical benefits and increase the safeness of the roads. To tackle this, artificial intelligence (AI) and machine learning (ML) techniques with the availability of digitalised diverse historical and real-time data, can be utilised, on one hand, to better understand the causes of the thaw damages and frost heave affecting the roads, and on the other hand, to build more advanced forecasting models for short- and long-term road conditions and thaw damage risks. In this work, as a first step, for building data-driven ML approaches to Arctic road damage forecasting, the possibilities of applying different multi-source are analysed. To this end, we are applying multi-source data sets of historical weather observations, in situ and mobile measurements of road surface and ground, and response variables of thaw damage and road wearing. As a result, we are showing 1) the benefits of different data sources using explanatory analysis, 2) the importance of different observations explaining the road conditions, and 3) the guideline of building explainable AI and ML approaches to combine digitalised information to forecast road conditions such as the thaw damage probability on road network in Northern Finland.

BRDF/Albedo Retrievals using Unsupervised Segmentation in the Arctic in the context of NASA ARCSIX

DOI: 10.57757/IUGG23-2059 - LINK

Vikas Hanasoge Nataraja[1]
[1]*University of Colorado Boulder, Department of Atmospheric and Oceanic Sciences, Boulder, India*

Since the late 1990s, NASA's Earth Observing System constellation of satellites has provided continuous, long-term observations of atmospheric and surface processes on Earth including surface albedo and Bidirectional Reflectance Distribution Function (BRDF) that are generated as an operational product using cloud-cleared, multi-angle surface reflectances over the course of several days. The BRDF is central to imagery-based cloud and aerosol retrievals, while the surface albedo is a fundamental Earth energy budget parameter. Yet, this product is currently unavailable at higher latitudes where (1) the low contrast between clouds and sea ice/snow poses a challenge for cloud clearing, and (2) drifting ice floes are not accounted for, resulting in a significant gap in our understanding of the Arctic radiation budget.

To address this gap, we propose the development of a BRDF/albedo product for moving sea ice floes and snow called the Sea Ice Floe and Snow Albedo Tracker (SIF-SAT). By leveraging multi-overpass, multi-angular satellite data, SIF-SAT will retrieve BRDF and albedo under low contrast and moving surface conditions. We combine existing cloud masks with machine learning (ML) models to produce cloud-cleared scenes in the Arctic. These scenes are then fed to a segmentation algorithm to identify individual sea ice floes and their reflectances are tracked over time to obtain BRDF and albedo. This presentation will primarily focus on the cloud-clearing model which has implications for radiation science in polar regions. SIF-SAT will enhance our capabilities in the Arctic and enable more accurate estimates of the cloud-radiative effect and ice-albedo feedback.
